In contrast to preoccupied adolescents, adolescents with dismissing strategies appear more likely to take on externalizing behaviors, which may serve to distract attention from attachment-related cues (Bakermans-Kranenburg & Van IJzendoorn, 2009; Kobak & Cole, 1994). Dismissing attachment states of mind have been found predictive of increasing delinquency and externalizing behavior over both shorter and longer spans of adolescence (Allen et al., 2002, 2007), although not all studies reveal such an effect (Kobak & Zajac, 2011). In addition, dismissing attachment strategies have been linked to difficulty getting assistance from peers and teachers, as well as to peer-reported social withdrawal during the transition to college (Larose & Bernier, 2001). Consistent with this finding, insecurity that manifests itself primarily as dismissal of attachment in early adolescence has been linked to relative *decreases* in social skills over time (Allen et al., 2002) and to less active coping strategies (Seiffge-Krenke & Beyers, 2005). Cole-Detke and Kobak (1996) also reported that in a college population, individuals with an eating disorder were more likely to use dismissing strategies; the attention given to their eating behaviors was hypothesized to distract from internal states of emotional distress. Unlike preoccupied adolescents, dismissing adolescents do not appear to be particularly sensitive to parental behaviors. For example, a factor such as parental control of adolescent behavior, which is well established as a buffer against delinquency, does not appear to serve this role for dismissing teens (Allen et al., 1998).

Unresolved states of mind have been the subject of far less psychopathology research than dismissing or preoccupied states. Unresolved states have been linked to prior negative experiences including poor early attachments in infancy and the preschool years, problematic middle school teacher-child relationships, and friendship difficulties in early adolescence (Aikins, Howes, & Hamilton, 2009; Madigan, Moran, & Pederson, 2006). Experiences of trauma and childhood sexual abuse have also been linked to an unresolved attachment state of mind in adolescence (Bailey, Moran, & Pederson, 2007; Madigan, Vaillancourt, McKibbin, & Benoit, 2012). In turn, these states

of mind have been significantly related to dissociative thought problems in adolescence (Madigan et al., 2012). Among adolescents requiring residential treatment, a heightened prevalence of insecure-unresolved attachment status has been repeatedly observed (Allen, Hauser, & Borman-Spurrell, 1996; Wallis & Steele, 2001).

Beyond the AAI, insecurity assessed via a number of other attachment measures has been linked to problems in functioning. Using the Childhood Attachment Interview (Target, Fonagy, & Shmueli-Goetz, 2003), patterned after the AAI's approach to assessing states of mind, adolescent insecurity has been linked to oppositional defiant disorder and teacher ratings of behavioral adjustment difficulties at school (Scott, Briskman, Woolgar, Humayun, & O'Connor, 2011). Both effects were observed, over and above those obtained from careful observations of qualities of parenting behavior (Scott et al., 2011). Using the Experiences in Close Relationships measure, Lee and Hankin (2009) found that both anxious and avoidant attachment styles predicted increases in anxiety and depressive symptoms over time.

We also now have evidence of specific parent-adolescent attachment relationship qualities linked to adolescent mental health. Adolescents' perceptions of parents as a secure base are associated with lower parent reports of adolescent internalizing and externalizing symptoms (Woodhouse, Dykas, & Cassidy, 2009). Maternal attachment states of mind have been found to predict sons' military adjustment, even over and above sons' states of mind, suggesting continued potential influence of mother-son attachment processes (Scharf, Maysless, & Kivenson-Baron, 2012). Higher levels of security in adolescents' current attachment styles also predict lower levels of substance abuse, an effect that appears to be mediated by higher levels of maternal monitoring of adolescent behavior (Branstetter, Furman, & Cottrell, 2009).

When long-term predictions to adolescence from earlier periods were examined in the Minnesota Study of Risk and Adaptation, stable patterns (as opposed to occasional instances) of insecurity were the strongest predictors of a variety of problematic functional outcomes (Van Ryzin, Carlson, & Sroufe, 2011). Relatedly, predictions from infancy appear to be mediated partly by problematic peer relationships in the intervening period (Bosquet & Egeland, 2006). Together, these findings suggest that in terms of future predictions, enduring patterns of problematic attachment and

social relationship functioning may be of greater importance than occasional instances of apparent insecurity.

Attachment theory is also beginning to serve as an underpinning for interventions with disturbed adolescents. Pilot work on the Connect Program, an attachment-focused, manualized intervention for parents and teens at risk for aggressive behavior, has found decreases in levels of conduct problems, as well as depression and anxiety over time, among participating teens (Moretti & Obsuth, 2009). Within long-term residential treatment, security has been found to predict adolescents' secure base use with therapists, although this effect was not seen in short-term treatment (Zegers, Schuengel, Van IJzendoorn, & Janssens, 2006). This suggests that only long-term treatment may have been able to create a sufficiently intense relationship between teen and therapist to call attachment states of mind strongly into play.

Lifespan Continuity, Discontinuity, and an Organizational Perspective on Attachment in Adolescence

A fundamental challenge for lifespan theories of attachment is the finding that adolescent attachment processes display only modest continuity with qualities of attachment relationships earlier in the lifespan (Hamilton, 2000; Weinfeld, Whaley, & Egeland, 2004), even though the AAI appears to produce relatively stable classifications across adolescence (Allen et al., 2004; Zimmermann & Becker-Stoll, 2002). Adolescent security assessed with the AAI also displays very modest concurrent correlations with maternal security and none with paternal security (Allen et al., 2004; Scharf et al., 2012). Some concordances have been observed between specific adolescent state-of-mind scales within the AAI and both maternal and paternal state-of-mind scales, although even these are quite modest in size (Scharf et al., 2012). The low absolute magnitude of these continuities is consistent with the notion that as AAI states of mind develop, inputs beyond early caregiver relationship qualities and parents' current states of mind play a prominent role.

Research is now beginning to identify qualities of the ongoing parent-adolescent relationship that may influence adolescent attachment security. For example, when autonomy-undermining, enmeshed behavior between mothers and ado-

lescents is observed at age 16, it predicts relative decreases in security in adolescent states of mind from ages 16 to 18 (Allen et al., 2004). Conversely, the presence of adolescent *secure-base scripts*—adolescents' expectations that attachment relationships will provide a secure base from which to explore the larger environment—has been linked to security in adolescent states of mind (Dykas et al., 2006). Also, parents' self-reported secure attachment styles have now been found to predict adolescents' use of parents as a secure base while discussing a disagreement, with consistent mediation of adolescent security via parents' lack of hostile behavior toward the adolescent (Jones & Cassidy, 2014).

Genetic factors have also been examined as potential sources of continuity and discontinuity in attachment processes across time and generations. With attachment as assessed via a Child Attachment Interview, designed to closely follow the principles of the AAI (Shmueli-Goetz, Target, Fonagy, & Datta, 2008), substantial heritability is found along with significant nonshared environment effects and virtually no shared environmental effects (Fearon, Shmueli-Goetz, Viding, Fonagy, & Plomin, 2014). These authors suggest that as children develop, heritable traits gradually influence their interactions with caregivers in ways that then shape their attachment states of mind, but do so uniquely for each child within a family. Conversely, evidence of strong environmental influences on attachment is found among youth exposed to extremes in poor parenting during early childhood. Among these youth, about half are secure in Child Attachment Interview assessments of their relationships with foster parents, whereas almost all are insecure in relationship to birth parents (Joseph, O'Connor, Briskman, Maughan, & Scott, 2014).

Perhaps the most important explanation for the lack of strong continuity between infant Strange Situation status and adolescent AAI security, however, lies in the fundamental difference in the nature of these two constructs. If we simply examine the origin of the AAI and the validation research that led to its rapid adoption in the field, it is difficult to avoid the conclusion that the AAI is most directly tapping not the *attachment* system of the individual, but the *caregiving* system, although clearly the two are closely connected (Allen & Manning, 2007). Just as with adults, the AAI coding system predicts adolescent parents' success as caregivers in raising a secure infant far more strongly than it predicts any other single out-

come (Ward & Carlson, 1995)—as indeed it was primarily designed to do (Main et al., 1985). This may well explain why the AAI is more strongly related to current peer relationships than to parental relationships: Teens rarely serve as caregivers to parents but may at times meet needs of peers. Observed continuities between infant attachment status and adolescent management of autonomy struggles with parents also make clear that infant attachment status has implications for future adolescent relationship qualities, even if not directly for adolescent states of mind (Grossmann et al., 2005; Zimmermann et al., 2001). Infant security with mothers has even been found to be more predictive of observed qualities of autonomy and relatedness in adolescent–mother interactions than it is of adolescent states of mind regarding attachment (Becker-Stoll et al., 2008). Together, these findings suggest that continuity from infant attachment security to the qualities of an adolescent attachment *relationship* can be observed, even in the absence of continuity from infant security to the adolescent’s later internalized *state of mind* regarding attachment.

Recognition of the multifaceted nature of the attachment system in adolescence can help make sense of these findings. Prior to recent advances, researchers often had only the AAI to rely on in assessing adolescent attachment. The temptation to squeeze myriad constructs (e.g., current relationship security, representations of current and past relationships, attachment styles) under the umbrella of the AAI was understandable, although it made explaining inconsistent continuity findings nearly impossible. Recently, however, the field has advanced to the point that we now have the means to assess directly many facets of the attachment system independently, and to gain greater precision in our terminology and understanding of attachment as an organizational construct.

In understanding what these developments mean for the relation of adolescent attachment to attachment at other stages, a botanical metaphor perhaps best captures the organic and complex nature of the phenomena at hand. We can view the attachment system as analogous to a tree with strong roots in infant–caregiver attachment as seen in the Strange Situation. By adolescence, those roots remain and support the health of the tree, but they have now given rise to a highly complex organism with multiple facets, each distinct, yet each part of the same organic whole: We now can and must attend not only to historical and on-going attachment relationships to caregivers (the

roots and tree trunk) but also to the beginnings of new attachment relationships with close peers and romantic partners (the branches), to patterns of information processing relative to attachment that are affected by and affect each of these (the shape of the tree), and to the emergence of a caregiving system (flowers) that ultimately will affect attachment processes in the next generation (seeds). In addition, *each* of these facets is influenced by environmental factors such as exposure to severe stressors and new peer relationships.

Understanding continuities between the infant Strange Situation and the adolescent AAI remains a worthy endeavor, but this botanical metaphor suggests that this task is in many ways analogous to trying to find the similarities between the roots and the flowers of a tree. There are likely to be not only multiple areas of continuity but also multiple areas of divergence and, indeed, branching among distinct yet related attachment constructs. The search for simple “stability” in attachment from infancy to adolescence becomes logically problematic because measuring stability requires the existence of the same construct at both points. Even the search for exceptionally strong continuities over time between fundamentally different facets of an organic system may well lead to disappointment. Links are likely to exist, but they are likely to be more complex than straightforward, as befits any truly developmental process. To put it most simply, the growing complexity of the adolescent social, emotional, and cognitive world necessitates a growing complexity of our understanding of the role of the attachment system as an organic factor within it.

Acknowledgment

This chapter was completed with the assistance of grants from the National Institute of Child Health and Human Development.

Chapter 20

Pair Bonds as Attachments

Mounting Evidence in Support of Bowlby's Hypothesis

Debra M. Zeifman
Cindy Hazan

When Bowlby (1979) made his often-cited claim that attachment is an integral part of human existence “from the cradle to the grave,” it was more a hypothesis than an empirically established fact. In spite of limited empirical proof, from the time adult romantic relationships were first conceptualized as attachments (Ainsworth, 1989; Hazan & Shaver, 1987), investigations of adult attachment have proliferated, based largely on the assumption that pair-bond relationships are the prototypical adult instantiation of attachment (Ainsworth, 1991). In this chapter, we examine the basis for the assumption that romantic relationships qualify as attachment bonds and therefore constitute the appropriate context for investigating adult attachment phenomena. We review a growing body of evidence that infant–caregiver and adult romantic relationships share unique psychological properties, are subserved by many of the same hormonal and neurophysiological mechanisms, and serve similar functions from an evolutionary standpoint. In doing so, we critically examine a corollary of attachment theory: that attachments confer benefits that are distinct from those associated with other relationships. Throughout the chapter, we present findings from diverse disciplines supporting Bowlby's original hypothesis.

One reason for questioning the assumption that romantic relationships are genuine attach-

ments concerns the presumed function of attachment bonds. In theory, the attachment behavioral system evolved in response to selection pressures in the “environment of evolutionary adaptedness” (EEA) that made it advantageous for infants to maintain proximity to protectors (Bowlby, 1958, 1969/1982). Few would argue with the adaptive benefits of a system that led vulnerable young to seek protection from their more mature and competent guardians, or with the necessity of such a system for human infant survival. It is considerably less apparent that attachment might contribute to *adult* survival (Kirkpatrick, 1998) or why enduring bonds between sexual partners is the norm in our species (Quinlan, 2008). It cannot simply be assumed that adult attachment serves the same function as infant attachment. Attachment to a romantic partner is not necessary for survival; nor is a pair bond necessary for survival of offspring. If, however, having an attachment to a romantic partner enhances individuals' chances of survival and/or the survival of joint offspring, it can be said to serve a similar function in adulthood as it does in infancy.

Do pair-bond partners replace parents in their roles as principal attachment figures, and if so, by what processes does the transition occur? Is there compelling evidence that the attachment system is operative in adult romantic relationships? What

are the unique features of attachment relationships that distinguish them from other kinds of relationships? Are adult attachment relationships the ideal mating context, or are short-term sexual pairings equally advantageous for producing and rearing offspring? Are sexual/romantic partnerships unique in the fitness advantages they confer or can the same benefits be gleaned from friendships? These are some of the questions addressed in this chapter.

In our research, we started by investigating the process by which attachments are transferred from parents to peers. We briefly summarize our findings and review literature that supports the idea that pair bonds are attachments in the technical sense. Throughout the chapter, we address issues related to the function and evolutionary significance of the attachment system in adulthood, paying particular attention to how the attachment system relates to other behavioral systems. Within our broad overview of the literature, we integrate recent evidence suggesting that many of the same brain regions implicated in infant attachment are also involved in forming adult attachments. Finally, we consider alternative evolutionary and sociological theories of relationships, and address contradictions with attachment theory.

From Parental Attachment to Pair Bonds

How Attachment Is Defined

Bowlby (1969/1982) defined the specific socio-emotional bond to which his theory applied, and distinguished it from other kinds of social ties. Attachment bonds have four defining features: *proximity maintenance*, *separation distress*, *safe haven*, and *secure base*. Once an attachment bond has formed, these features are readily observable in the overt behavior of an infant in relation to a primary caregiver (usually the mother). She serves as a secure base from which the infant (hereafter called “he” for convenience) ventures forth and interacts with the social and physical world. He continuously monitors her proximity and availability. If he senses danger or feels anxious for any reason, he retreats to her as a source of comfort and a haven of safety. Because separations from her signal potential danger, he will object to and be distressed by them. As long as she is perceived to be sufficiently near and responsive, he will be motivated to explore his environment.

In theory, this dynamic balance between attachment and exploration is an integral part of behavior throughout the lifespan, and the four essential features of attachment relationships are characteristic of adult attachments as well. Nevertheless, changes as a function of maturation are expected. One predictable change concerns the time and distance from the attachment figure that can be comfortably tolerated. A typical 12-month-old will exhibit greater distress (and more disrupted exploration) as the result of even brief separations from a caregiver than will a 36-month-old (Marvin, Britner, & Russell, Chapter 13, this volume). By late childhood or early adolescence, longer separations are usually negotiated without undue upset, and separation distress is less apparent except in the case of unexpected and/or extended caregiver unavailability. One basis for growth in children’s ability to tolerate separations is cognitive—older children can conjure a mental representation of an attachment figure, comprehend the circumstances of her absence (e.g., “Mommy is at work”), and imagine and await an impending reunion. Adults begin their relationships with a well-developed ability to mentally represent (and fantasize about) others, which leads to important differences between infant and adult attachment dynamics.

Two other changes in attachments across development are their degree of mutuality and the integration of sexuality with other aspects of the emotional bond. The asymmetrical (complementary) attachments of early life—in which infants seek and derive security from caregivers but do not provide security in return—are hypothesized to be replaced by more symmetrical (reciprocal) attachments. And, whereas infants initially seek out caregivers because caregivers tend to basic needs, such as hunger and the need for contact comfort, sexual attraction is often the precipitating force bringing adult partners into intimate contact in adulthood. According to Bowlby and others, the pair-bond relationship—in which sexual partners *mutually* derive and provide security—is the prototype of attachment in adulthood. Thus, in the typical course of relationship development, the sexual mating, caregiving, and attachment systems often become integrated (Fraley & Shaver, 2000; Hazan & Shaver, 1994; Mikulincer & Goodman, 2006; Shaver, Hazan, & Bradshaw, 1988). And although these interrelated behavioral systems can operate independently of one another, especially in the early stages of relationships (Diamond, 2004; Fisher, Aron, Mashek, Li, & Brown, 2002), the

three systems are often integrated in pair-bond relationships that endure (O’Leary, Acevedo, Aron, Huddy, & Mashek, 2012).

The Ontogeny of Infant Attachment

Given the opportunity, all normal human infants become attached to their primary caregivers, typically within the first 8 months of life. Attachment formation proceeds through a series of phases, beginning in the first weeks of life and culminating with the establishment of a “goal-corrected partnership” toward the middle of the third year (Bowlby, 1969/1982). The process begins with close physical proximity, which is initially maintained by intentional actions of the caregiver and reflexive behavior on the part of the infant (e.g., crying, sucking, clinging). In time, the infant learns to associate the caregiver with comfort and alleviation of distress (i.e., with viewing her as a safe haven). Typically, by about 8 months of age, and concurrent with the onset of self-produced locomotion and stranger wariness, the infant begins to protest separations and to use the caregiver as a base of security while exploring. Separation distress is an accepted indicator that an attachment bond is fully formed. Note that the components, which together define attachment, do not emerge simultaneously but rather in sequence, and full-blown attachments take a period of time to develop.

Although multiple attachments are the norm, not all attachment figures are equivalent. An infant shows clear discrimination among caregivers and a consistent preference for the principal caregiver (Colin, 1985, 1987; Cummings, 1980). Even if several caregivers are regularly available, an infant reliably seeks and maintains proximity to one, especially when distressed (Ainsworth, 1967, 1982). The infant also exhibits more intense protest upon being separated from the principal attachment figure compared to others (Schaffer & Emerson, 1964) and in unfamiliar settings is most reassured by this figure’s presence (Ricciuti, 1974; Shill, Solyom, & Biven, 1984). Therefore, the principal attachment figure is not simply one among a coterie of possible protectors, but the individual with whom the infant has a privileged relationship. Bowlby (1958, 1969/1982) referred to this tendency to form one special attachment as “monotropy,” and he considered it a crucial aspect of the survival-enhancing function of attachment (see also Cassidy, Chapter 1, this volume).

Over the course of development, the composition and structure of individuals’ attachment hierarchies change. According to Ainsworth (1989), parental figures tend to be permanent members of the attachment hierarchy, but they eventually assume a position secondary in importance to the pair-bond partner. We explored the timing and processes of the transition from complementary (parental) to reciprocal (peer) attachment in two related studies (see Hazan & Zeifman, 1994).

The Transfer of Attachment from Parents to Peers

Peer relationships during childhood and adolescence are usually characterized as *affiliative*, that is, functionally distinct from parental attachments and presumably regulated by a different behavioral system. Although there is obvious overlap in the behaviors that typify these two kinds of social bonds, affiliative relationships at this age primarily provide stimulation and increase arousal, in contrast to the arousal-moderating and security-enhancing provisions of attachment bonds. Yet *some* components of attachment may be present in peer relationships in childhood.

One aspect of attachment—proximity seeking—seems to be typical of peer relationships by childhood, although such relationships would not qualify as attachments in the full sense of the term. By age 3, children are capable of sustaining complex social interactions with agemates and show a growing interest in doing so (Gottman, 1983; Rubin, 1980). During middle childhood, youngsters develop more intimate relationships with their peers (Buhrmester & Furman, 1987) and increasingly turn to them for comfort. By late adolescence, peers come to be preferred over parents as sources of emotional support (Steinberg & Silverberg, 1986). The confiding and support-seeking aspects of peer relationships appear to be functionally similar to the parent-directed safe-haven behavior of infancy and early childhood.

Based on these developmental shifts in the *target* of attachment behaviors, we reasoned that a key to understanding the transfer of attachment from parents to peers might lie in an analysis of attachment at the component level. We used an interview measure of attachment’s four components and administered it to over 100 children and adolescents ranging in age from 6 to 17. For each of the components, participants were asked to name the single *most preferred* person in several representative situations.

We found that nearly all children and adolescents in the sample were peer-oriented in terms of proximity seeking; they preferred to spend time in the company of peers rather than parents. Regarding the safe-haven component, there was an apparent shift between ages 8 and 14, with peers coming to be preferred over parents as sources of comfort and emotional support. For the majority, however, parents continued to serve as bases of security and as the primary sources of separation distress. Only among the oldest adolescents (the 15- to 17-year-old group) did we find full-blown attachments to peers—relationships containing all four components. Of this minority that considered peers to be their primary attachment figure, the overwhelming majority named a boyfriend or girlfriend (i.e., a *romantic partner*).

In a second study, we explored the time course of adult attachment formation. Research on romantic relationship formation suggests that whether and which attachment features are present may depend on how long a couple has been together. For example, romantic couples typically experience an especially strong desire for physical proximity and contact in the initial stages of a relationship (Berscheid, 1984), whereas the provision of mutual support and care becomes more important in later stages (Reedy, Birren, & Schaie, 1981; Sternberg, 1986). Thus, in adult as well as infant attachments, the presence or absence of attachment components may depend on the stage of relationship development.

We administered the same interview used in our child and adolescent study to a diverse sample of over 100 adults ranging in age from 18 to 82, but this time we grouped subjects by *stage* of relationship development rather than age. Three relationship status groups were identified: “not in a romantic relationship,” “in a romantic relationship for less than 2 years,” and “in a romantic relationship for 2 or more years.” The majority of participant responses to questions about the target of attachment behaviors were captured by the following categories: parent, adult sibling, friend, and romantic partner.

We found that adults were clearly peer-oriented in both proximity-seeking and safe-haven behaviors. Nearly all adult respondents preferred spending time with and seeking emotional support from their friends and/or partners rather than their parents. But findings for the other two components varied as a function of relationship status. Participants in romantic relationships of at least 2 years’ duration overwhelmingly named partners as

the individuals whose absence was most distressing and whose presence served as a base of security. Those in shorter-term romantic relationships and those without partners tended to name parents.

The results of these studies (and a replication by Fraley & Davis, 1997) are consistent with Bowlby’s hypothesis that attachment behavior typically becomes redirected toward a sexual partner in adulthood. Full-blown attachments (with all four components) were observed almost exclusively in two kinds of social relationships—with parents or romantic partners. Furthermore, and just as Bowlby predicted, pair-bond partners did assume the status of principal attachment figures (by being preferred over parents). Finally, it appears that romantic relationships require approximately 2 years to become full-blown attachments. Individuals in shorter-term romantic relationships and those without partners tended to look to parents to satisfy some attachment needs.

Since the time of our original studies, neuroimaging research has strengthened two of our claims: that romantic partners provide emotional support distinct from the variety provided by friends or strangers, and that romantic relationships take a period of time to gel. In one study, volunteers who were deeply in love with their long-term romantic partners viewed photographs of their partners and of a friend with whom they were equally well acquainted. Compared to photographs of friends, photographs of romantic partners evoked a different pattern of neural activity, implicating regions involved in pair bonding and attachment (Bartels & Zeki, 2000). In another study, women who held their spouses’ hands while being subjected to the threat of electrical shock showed less activation of regions indicative of perceived threat than married women who held the hand of an unfamiliar male experimenter. The effect was also dose-dependent: Women who reported the highest levels of marital satisfaction had the greatest reduction in activation associated with perceived threat (Coan, Schaefer, & Davidson, 2006). These results, together with our initial finding that romantic relationships uniquely display the four characteristic features of attachments, suggest that romantic partners may provide emotional security in adulthood that is not typically provided by other relationships.

Neuroimaging studies also strengthen the claim that attachments take a period of time to develop. In the earliest stages of romance, individuals who are “in love” show increased activation in dopamine-rich regions of the brain associated with

reward when viewing the photograph of a romantic partner compared to the photograph of a close friend (Xu et al., 2011). In the more advanced stages of romantic relationships, when viewing photos of their romantic partners, individuals also show activation in opioid-rich regions associated with maternal attachment and pair bonding (Acevedo, Aron, Fisher, & Brown, 2012a, 2012b). These differences in brain activity produced by imagining a short- versus long-term partner are consistent with differences we documented in the targets of attachment behavior depending on the length of a relationship. Romantic partners begin as sources of arousal and positive, often sexual, stimulation; it is only after a period of time that romantic partners become attachment figures capable of providing not only stimulation but also emotional security.

The Nature of the Bond in Pair Bonds

So far, we have presented evidence that pair-bond relationships are characterized by the same features as infant–caregiver attachments and develop according to the same process, at least in terms of the sequence in which various components come into play. If the attachment system is operative in pair bonds, its effects should also be conspicuous in other aspects of relationship functioning. In fact, the congruencies are far-reaching. They include the nature of physical contact that typifies and distinguishes attachment bonds, the factors that influence the selection of attachment figures, reactions to attachment disruption and loss, and the centrality of attachment to physical health and psychological well-being. We discuss each of these in turn.

Physical Contact

Freud was among the first to write about the striking similarities in the physical intimacy that typifies lovers and mother–infant pairs. Like caregivers and their infants, adult sexual partners (at least initially) spend much time engaged in mutual gazing, cuddling, nuzzling, sucking, and kissing in the context of prolonged face-to-face, skin-to-skin, belly-to-belly contact, and the touching of body parts otherwise considered “private.” It is noteworthy that these most intimate of human interpersonal exchanges are, in virtually every

culture, limited to parent–infant and pair-bond relationships (Eibl-Eibesfeldt, 1975). Although some forms of intimate contact may occur in isolation within other social relationships (e.g., kissing among friends), their collective occurrence is more restricted. When friends violate these social norms by engaging in intimate physical contact, they label themselves “friends with benefits” to denote the provision of benefits not usually associated with mere friendship (Carey, 2007).

Nearly universal prohibitions against physical intimacy outside recognized pair bonds (at least for females) has generally been attributed to the fact that copulations outside such bonds reduce confidence in paternity. Such restrictions may also reflect an implicit understanding that close physical contact with another could lead to a subsidiary emotional bond that would jeopardize the principal one. In subcultures where extrapair sexual contact is permitted, efforts to avoid emotional involvement are common. For example, prostitutes commonly refuse to engage in kissing and other forms of intimate face-to-face contact with their clients (Nass & Fisher, 1988). If an emotional bond is not desired in the context of a physically intimate relationship, special steps must be taken to protect against its formation. Research on “friends with benefits” indicates that these relationships often become strained when one party becomes more attached than the other (Carey, 2007).

There is evidence that the chemical basis for the effects of close physical contact may be the same for lovers and mother–infant pairs. Oxytocin, a peptide released during suckling/nursing interactions and thought to induce infant attachment and maternal bonding, is also released at sexual climax and has been implicated in the cuddling that often follows sexual intercourse (i.e., “afterplay”; Carter, 1992, 2003).

Esch and Stefano (2007) have noted a similarity in the contexts in which physical contact between attachment partners typically takes place. In the case of infants, emotional distress (in the form of crying) typically precipitates caregiver interventions that involve intimate physical contact, such as breast feeding. In the case of adults, sexual desire or need, which can be described as stressful (Marazziti & Canale, 2004), precedes physical contact, and, typically, sexual intercourse. In both cases, an uncomfortable state of arousal leads an individual to seek social contact with another person who is a source of comfort and relief. Repeated sequences in which physical contact with a poten-

tial attachment figure serves to relieve overarousal are likely to recruit the hypothalamic–pituitary–adrenal (HPA) axis and other physiological means of coping with stress. The HPA axis, in turn, may trigger the release of opioids and neuropeptides, such as oxytocin, known to induce feelings of well-being and contentment (Esch & Stefano, 2007). It is through intimate physical contact, therefore, that an attachment figure becomes not only a source of pleasure and stimulation but also a source of calm and contentment.

Similarities in the nature and context of physical contact that typify pair-bond and infant–caregiver relationships differentiate them from other classes of social relationships.

Although it is the sexual system that motivates intimate contact in the initial stages of adult romantic relationships, and the attachment system that motivates contact in infant–caregiver relationships, repeated intimate physical contact fosters the development of an attachment.

Selection Criteria

If pair–bond relationships involve the attachment system, one might expect some overlap between infants and adult romantic partners in terms of the criteria on which selections are based. However, the qualities that make one a good mother or father are not necessarily the same qualities that make one appealing as a sexual partner. There is the additional complication of well-documented sex differences in mate selection criteria, attributed to differences in parental investment that are present and influential even before conception.

Differential parental investment theory (Trivers, 1972) holds that sexual encounters may have vastly different consequences for males and females, resulting in different optimal mating strategies and different mate selection criteria. Males have an abundant supply of small sperm cells that is constantly replenished, whereas females have a far more limited supply of large egg cells, produced at a rate of about one per month. Added to this are the female burdens of gestation and lactation, requiring years of investment. Because the male contribution to offspring can be so limited, the most effective reproductive strategy for males may be to take advantage of all mating opportunities with fertile partners. Females, for whom every sexual encounter is potentially quite costly, might benefit from being choosier and limiting sexual encounters to males who possess and appear willing to share valuable resources. Research confirms

that females are in fact “choosier” than males, though they employ different strategies depending on the phase of their menstrual cycle—selecting men with “good genes” in the most fertile phase, and men with “good character,” or a tendency to invest in offspring, during the less fertile phase of the cycle (Gangestad, Garver-Apgar, Simpson, & Cousins, 2007).

Numerous studies have found sex differences in mate selection criteria consistent with male–female differences in parental investment. For example, in a survey of 37 cultures, Buss (1989) found that males generally assign greater importance than females to the physical appearance of potential mates, preferring partners who look youthful and healthy—both of which may have at one time been reasonably good indices of fertility (Buss, 1989; Symons, 1979). In contrast, females typically care more than males about the social status and earning power of potential partners; this is a sensible mate selection strategy for ensuring that offspring are themselves well provided for and reproductively fit.

Sex differences are negligible, however, when it comes to evaluating potential partners for long- versus short-term relationships (Kenrick, Groth, Trost, & Sadalla, 1993). Given that humans tend to reproduce in the context of long-term relationships, it is this context that is most relevant to understanding mate selection in our species. Moreover, although sex differences in the relative importance of traits such as physical appearance and social status are reliable, *neither* trait is assigned highest priority by *either* sex. For both men and women, the most highly valued qualities in a potential mate are “kind/understanding” and “intelligent” (Buss, 1989). In choosing among potential reproductive partners, males *and* females prefer those who are responsive and competent, and these traits matter more to them than wealth or beauty.

Men and women also tend to prefer partners who are similar to themselves on numerous dimensions, including socioeconomic status and physical attractiveness (Berscheid, 1984; Hinz, 1989). This may reflect the more general tendency to prefer what is familiar. In the case of mating, preexisting similarities draw potential partners into the same activities and social circles, thereby increasing familiarity. The English word *familiar* comes from the Latin *familia*, which connotes “family” or “household.” Others who are similar can seem like family, and may be especially appealing partners for romantic relationships.

It is noteworthy that the factors found to exert the greatest influence on the selection of pair-bond partners are similar to those used by infants in “choosing” among potential attachment figures. In the case of infants, “preference” is given to individuals who are kind, responsive, competent, and familiar—especially in the context of distress alleviation. The one who most consistently and most competently reduces discomfort and provides a safe haven (i.e., the *principal* caregiver) is the one to whom an infant is most likely to become attached (Bowlby, 1958, 1969/1982). Adults are sensitive to these same cues and care more about these qualities than about cues of fertility or resources, suggesting that reproductive partners are evaluated as potential attachment figures. Because pair-bond relationships are relatively enduring, attachment-relevant criteria are taken into account when mates are selected.

Prototypical pair bonds involve the integration of three social-behavioral systems: sexual mating, caregiving, and attachment. Attachment-relevant qualities consistently top the list of mate-selection criteria for both genders across cultures (Shackelford, Schmitt, & Buss, 2005). These qualities are relevant to mating because we humans need to select reproductive partners who will also be good companions and parents.

Reactions to Separation and Loss

Additional evidence that attachment is integral to pair-bond relationships comes from research on bereavement and routine marital separation. The original inspiration for Bowlby’s theory came from his observations of infants and children separated from their principal caregivers. He found it remarkable (and indeed in conflict with prevailing secondary drive theories) that the separations were so distressing, given that nutritional and hygienic needs were being met by surrogates. Even more striking were the similarities across children in how they responded. Bowlby identified what appeared to be a universal pattern of reactions, which he labeled the “protest–despair–detachment” sequence. The initial reaction is characterized by agitation, hyperactivity, crying, resistance to others’ offers of comfort, and extreme anxiety, often to the point of panic. Eventually, this active protest subsides, only to be replaced by a period of lethargy, inactivity, and disrupted sleeping and eating behavior. In time, a degree of emotional detachment from the lost attachment figure fa-

cilitates the resumption of normal, pre-separation activities and functioning.

If the attachment system is operative in pair bonds, adult reactions to the loss of a partner should be similar to those of infants separated from their caregivers. Several studies have documented essentially the same sequence in adults grieving for the loss of a spouse: initial anxiety and panic, followed by lethargy and depression, and eventually recovery through emotional detachment (Hazan & Shaver, 1992; Parkes & Weiss, 1983; Weiss, 1975) or reorganization (Fraley & Shaver, 1999; Chapter 3, this volume). Even brief, routine separations are enough to trigger this pattern of response in some married individuals (Vormbrock, 1993).

The protest–despair–detachment (or reorganization) sequence is observed almost exclusively in two social-relational contexts: infant– and child–caregiver relationships and pair bonds. The death of a relative or the decision of a friend to move away may cause sadness, but such events do not normally evoke panic. The profound separation reactions of infants and adult lovers may reflect the mutual reliance of attachment partners on one another to regulate internal physiological states (Hofer, 1994). It makes good adaptive sense to react with anxiety and protest to even the temporary “loss” of an individual who serves as a primary source of emotional and/or physical security. The fact that this reaction is the norm among adults separated from their long-term partners, and *not* the normal reaction to the loss of other kinds of social ties, is another indication that the attachment system is active in pair bonds.

Physical and Psychological Health Effects

The notion that attachment meets a very real biological need, at least early in life, was established in studies of infants reared in orphanages and other institutional settings (Robertson, 1953; Spitz, 1946). Although adults are clearly less dependent on social bonds for basic survival, there is ample evidence that they incur health benefits from having one, and suffer health decrements as a consequence of the absence or loss of such bonds. Relationship disruption (especially divorce) makes one more susceptible to a wide range of physical and psychological ills, including disease, impaired immune functioning, accidents, substance abuse, suicide, and various other forms of psychopathology (e.g., Bloom, Asher, & White, 1978; Goodwin, Hurt, Key, & Sarret, 1987; Lynch, 1977; Uchino,

Cacioppo, & Kiecolt-Glaser, 1996; and several chapters in Part V of this volume).

Among the most common life stressors, attachment-related losses cause the most subjective distress. Death of a spouse is the leading stressful event on the Social Readjustment Rating Scale, followed by divorce and marital separation (Holmes & Rahe, 1967). Weiss (1973) found that loneliness takes at least two distinct forms, depending on whether social deprivation is due to the absence of an intimate companion (which he labeled “emotional loneliness”) or a lack of friends (“social loneliness”). Consistent with Weiss’s theory, a national survey indicated that the loss or absence of a pair-bond relationship was associated with feelings of “desperation” and anxiety, whereas lack of friendships was associated with feelings of “restless boredom” (Rubenstein & Shaver, 1982). Social support in the form of friendship does not help alleviate the distress of losing or being separated from a spouse (Stroebe, Stroebe, Abakoumkin, & Schut, 1996). Vormbrock’s (1993) review of the literature on war- and job-related routine marital separations led to a similar conclusion: The social provisions of pair bonds are sufficiently distinctive that most social relationships cannot compensate for their loss. Interestingly, Vormbrock found that renewing relationships with parental *attachment* figures was helpful in moderating the anxiety caused by spousal absence.

If attachment bonds have exceptional effects on physical and psychological functioning, such effects should be absent not only in other types of relationships but also in the kinds of relationships that typically develop into attachments but have yet to achieve that status. In fact, early maternal deprivation is associated with long-term developmental consequences *only* if it occurs *after* an attachment bond between infant and mother has been established (Bowlby, 1958). Separations prior to 8 months of age do not increase the probability of poor developmental outcomes. Similarly, Weiss (1988) found that widows and widowers married for less than 2 years did not show the same (protest–despair–detachment/reorganization) sequence of reactions as those grieving for the loss of longer-term bonds.

In summary, the results of a number of studies indicate that bonds between adult partners and infant–caregiver pairs are similarly and uniquely powerful in their impact on physical and psychological well-being. Other kinds of interpersonal relationships offer valuable social provisions, but emotional security does not appear to be one of

them. Otherwise, disruptions would give rise to acute anxiety, which they do not. If separation distress is a marker of attachment, bonds between long-term adult partners clearly qualify.

The Function of Attachment in Adult Life

Bowlby (1969/1982) argued that the attachment system is a species-typical characteristic that evolved to serve a protective, survival-enhancing function. Infants who became attached to and then stayed close to protectors had significantly better chances of living to reproductive age than infants who failed to develop such bonds. The survival value and evolutionary origins of adult attachment are less obvious and therefore are subject to debate.

Some theorists (e.g., Kirkpatrick, 1998) reject the notion that the attachment system is integral to pair bonds on the grounds that reflexive proximity seeking in the face of danger would be maladaptive for adults. According to this line of reasoning, a propensity to seek protection from a mate, rather than aiding in the fight against some external threat, would be more likely to jeopardize adult survival than enhance it. Because females are, on average, smaller and weaker than their male counterparts, it is particularly doubtful that men could gain a survival advantage by turning to their female partners for assistance. Furthermore, given the unlikelihood that an entire system would be retained yet undergo a qualitative change in its function, pair bonds cannot involve the attachment system. There are several flaws in this line of reasoning, however.

One major shortcoming of this argument is its limited conceptualization of the protective function of attachment. Although the risk of predation in the EEA was undoubtedly reduced for infants who became attached to their caregivers, the benefits of the bond would have extended far beyond physical protection, even in infancy. Attachments also ensure that infants receive adequate care in the form of food, warmth, shelter, guidance, and monitoring—all of which enhance survival. By relying on a narrow definition of *protection*, the argument fails to take into account normative developmental changes in the behavioral manifestations of attachment. As children mature and become more competent, primitive forms of attachment behavior, such as reflexive proximity

seeking, decline. Older children and adolescents, however, continue to depend on parents for many aspects of care, and continue to benefit from having someone who is deeply invested in their welfare and reliably available to help if needed. The fact that a behavior is transformed across development is insufficient proof of divergent function (Tinbergen, 1963). Feeding behavior also changes dramatically from infancy to adulthood, but the basic function—procuring nutrition—remains essentially the same.

To evaluate whether attachment serves the same protective function in adulthood as in infancy requires that *protection* be defined in a manner that encompasses its full meaning and acknowledges normative developmental change. Furthermore, to address the question of function, it must be established that such protection affords adaptive advantage by translating reliably into enhanced survival and reproductive success in the EEA. Hence, a key to understanding the function of attachment in adulthood lies in an examination of the circumstances in which pair bonding evolved.

The Evolution of Pair Bonds

If human reproductive success required nothing more than conception, reproductive partners could part ways as soon as a viable pregnancy was achieved. In actuality, however, the vast majority of human males and females opt to remain with the same partner for a more extended period of time (Eibl-Eibesfeldt, 1989; Mellen, 1981). This trend is thought to have followed a birthing crisis in which the infant's large head, housing a more fully developed brain, could not easily pass through the birth canal of our bipedal female ancestors (Trevathan, 1987). Infants who were born prematurely, with less developed brains and smaller heads, were more likely to survive (as were their mothers). Immaturity at birth also offered the added advantage of a longer period of learning during a time of heightened neural plasticity. This would have been a distinct advantage in a species with complex social organization as our own. The benefits of premature birth, however, brought new risks and challenges. The effort required to care adequately for exceedingly dependent offspring during a protracted period of immaturity, along with the major tasks of socialization, made paternal investment an advantage, if not a necessity. Exceptionally helpless and vulnerable offspring would have had poor chances of surviving to re-

productive age or developing the necessary skills for mating and parenting without a strong force to keep fathers around and involved.

Many unique features of human sexuality appear to have evolved for the purpose of fostering an enduring bond between reproductive partners. Most mammals mate only during the short estrus periods of the female, but human sexual desire and activity are not so restricted. Women can be sexually receptive during any phase of their menstrual cycle, despite the fact that conception is possible only during a small fraction of it. This physiological adaptation enables a couple to maintain a continuous tie on the basis of sexual reward (Eibl-Eibesfeldt, 1975). Concealed ovulation may also increase the costs of straying. Males of many diverse species guard their mates during periods of sexual receptivity so as to ensure paternity. If ovulation is hidden, as it is in humans, it is difficult for the male to determine when fertilization is possible, and the optimal male strategy may shift toward guarding and remaining with the same sexual partner for longer periods of time (Alcock, 1989).

When the adaptive problem of immature offspring and the corresponding need for paternal investment arose in the course of human evolution, our species—by virtue of its altricial nature—already had available a well-designed, specialized, flexible, but reliable mechanism for ensuring that two individuals would be highly motivated to stay together and vigorously resist being separated. The mechanism was attachment. In light of the generally conservative tendencies of evolution and natural selection, it is highly probable that this preexisting mechanism would have been exploited for the purpose of keeping reproductive partners together. Pair bonds are primarily reproductive relationships, but sex serves more than a reproductive function in our species. The unique features of human reproductive physiology and anatomy help to ensure that partners will engage in the kinds of intimate exchanges known to foster attachment formation.

Reproductive Advantages of Pair Bonds

In our species, reproductive success requires negotiation of at least three adaptive challenges: surviving to reproductive age, mating, and providing adequate care to offspring so that they too will survive to reproduce. We have argued that the relative immaturity of human newborns created

a situation in the EEA in which survival depended on not only infants forming a strong bond to protectors but also a mechanism that would hold reproductive partners together for an extended period of time. The attachment system, which had evolved to ensure an enduring bond between infants and caregivers, was exploited for this additional purpose. But the advantages of pair bonding extend beyond its role in offspring survival. Benefits include enhanced survival and reproductive fitness for mates, as well as the intergenerational transmission of reproductive strategies that confer further advantage to offspring (see Simpson & Belsky, Chapter 5, this volume).

There is mounting evidence that offspring mating strategies may depend critically on the pair-bond status of parents, especially mothers. Adolescents from father-absent homes show precocious sexual interest, earlier sexual maturation, more negative attitudes toward potential mates, and less interest in long-term relationships than do their counterparts reared in father-present homes (Belsky, 1999; Draper & Belsky, 1990; Draper & Harpending, 1982; Ellis, McFayden-Ketchum, Dodge, Pettit, & Bates, 1999; Surbey, 1990). Girls in father-absent homes are at increased risk for early sexual activity and teenage pregnancy (Ellis et al., 2003). In other words, if parents choose not to remain together, their children are more likely to adopt approaches to mating that emphasize quantity over quality. Parental divorce has also been found to affect offspring mating strategies and behavior (Barber, 1998). Female children of divorce tend to fear closeness and abandonment, whereas male children show a lack of achievement orientation and a greater likelihood of abandoning relationships (Henry & Holmes, 1998; Wallerstein, 1994). Thus, the failure of reproductive partners to maintain long-term bonds may have a negative effect on the mating success of their offspring.

Whether opportunistic, short-term mating strategies are less advantageous than stable, long-term strategies is the source of an ongoing debate (e.g., Belsky, 1999; Buss, 1997; Schmitt, 2005). According to life history theory (Stearns, 1992), organisms possess finite resources that must be allocated to various challenges, including survival, growth, mating, and parenting. Local circumstances determine the balance of time and energy an individual devotes to each. Adolescents from unstable families may benefit from adopting a strategy of mating early and often so as to ensure the survival of at least some offspring in an unpredictable envi-

ronment. Both long- and short-term strategies can be viewed as reasonable and comparably adaptive responses to different ecologies, and these strategies can shift within an individual's lifetime in response to changing life circumstances.

We have argued that although it is clearly advantageous for humans to be capable of facultative mating adaptations that take account of varying ecological conditions (Buss & Schmitt, 1993; Gangestad & Simpson, 2000), the correlates of short- and long-term mating strategies are not supportive of the view that they are different but equal (for alternative viewpoints, see Belsky, 1999; Simpson & Belsky, Chapter 5, this volume). The ability to adjust behavior to nonoptimal circumstances is clearly important, but such adjustments are unlikely to produce optimal results. In many cultures, infant mortality rates are higher among children without an investing father (Hill & Hurtado, 1995). Infants raised by both parents are weaned at a later age than those who are raised by single mothers, suggesting one avenue through which infant health and parental fitness may be enhanced by the presence of strong pair bonds (Quinlan & Quinlan, 2008). In the currency of evolution, a superior strategy is one that enhances reproductive success. Pair bonds not only contribute to the survival of offspring but also leave offspring better equipped to attract and retain mates of their own, which in turn improves overall reproductive fitness.

In addition to the direct and indirect benefits that accrue to the progeny of stable pair bonds, there are advantages for the mates themselves. Women ovulate more regularly if they are in a stable sexual relationship (e.g., Cutler, Garcia, Huggins, & Preti, 1986; Veith, Buck, Getzlaf, Van Dalfsen, & Slade, 1983), and they reach menopause significantly later if sexual activity is consistent (Kaczmarek, 2007). The quality of attachments also influences reproductive success. Women suffering from infertility of unknown etiology tend to have an avoidant attachment style (Justo, Maia, Ferreira-Diniz, Santos, & Moreira, 1997). Earlier we cited evidence that partners in long-term relationships enjoy more robust physical and mental health. More fit individuals would be better able to protect and provide for themselves and loved ones. As for the protective aspects of attachment, adults, too, need someone to look out for them—someone to search for them if they fail to show up at the expected time, take care of them when they are sick, help defend them against external threats, and reassure them.

One reason pair bonds may enhance fitness is that sexual partners are equally and uniquely genetically related to their joint offspring and are therefore highly motivated to work together to ensure their survival. Although it is widely acknowledged that mates share genetic interests in offspring, it is generally assumed that this shared genetic investment is not as binding as the shared genetic interests of blood relatives because sexual loyalties can be easily reversed as in the case of infidelity (Daly & Wilson, 1996). This assumption, however, may underestimate the degree of relatedness of sexual partners. In fact, with the exception of first-degree relatives, a high degree of inbreeding has been the norm in our species (Thornhill, 1991). The low incidence of interracial marriage and the prevalence of look-alike partners (Hinsz, 1989) indicate that individuals tend to select mates from their own genetic pool. Although mates will not typically be first-degree relatives, they are still more likely to be “related” than two randomly selected individuals from the population at large.

The symmetry in degree of genetic relatedness of parents to their joint offspring may explain fathers’ unique motivation to provide adequately when a mother is engaged in the energetically costly practice of breast feeding. In a survey of diverse traditional societies, stable pair bonds were strongly associated with later infant weaning ages (Quinlan & Quinlan, 2008). The presence of adult relatives other than the child’s father in the household, in contrast, had the opposite effect on the duration of breast feeding, hastening weaning. One reason fathers may be uniquely positioned to support lactation is that a father and mother are the only two adults who share 50% of their genes with their child. Even in an extended-kin household, other relatives share at most only 25% of their genes with the offspring of a single mother, as in the case of a grandmother living with her daughter and grandchild. Although mothers may benefit from the contributions of relatives other than the child’s father, they may also feel obligated to wean offspring sooner, so that they can contribute to a household in ways that benefit the whole family. Some authors have therefore suggested that pair bonds evolved in order to support lactation (Quinlan & Quinlan, 2008), or that lactation is a “critical period” for paternal investment (Marlowe, 2003).

Sexual partners share an interest in having their offspring survive and thrive. Although there are multiple pathways to reproductive success, and

optimal reproductive strategies depend on local ecologies, there is substantial evidence that the survival and fitness of humans is enhanced by the presence of both strong pair bonds and investing fathers. On the basis of the evidence, we would argue that the attachment system serves to cement an enduring emotional bond between sexual partners that translates today, as it did in the EEA, into differential survival of offspring and reproductive success under many environmental conditions.

A Model of Adult Attachment Formation

Bowlby (1969/1982) identified four phases in the development of infant–caregiver attachments: preattachment, attachment in the making, clear-cut attachment, and goal-corrected partnership (see Marvin, Britner, & Russell, Chapter 13, this volume). We have proposed a corresponding four-phase model of adult attachment using Bowlby’s model as a provisional guide (Hazan, Gur-Yaish, & Campa, 2004; Zeifman & Hazan, 1997). We have likened the adult counterpart of the infant preattachment phase to what Eibl-Eibesfeldt (1989) called the “proceptive program.” Males and females of reproductive age are inherently interested in social interaction with potential mates and display flirtatious signals somewhat indiscriminately. It is likely that these playful, sexually charged exchanges continue when partners first become involved and that they are more characteristic of partners’ interactions than attachment behaviors *per se*.

In contrast, as described earlier, the behaviors of partners in the throes of romantic infatuation show many resemblances to infant–caregiver interactions (Shaver et al., 1988), including prolonged mutual gazing, cuddling, nuzzling, and “baby talk.” We have suggested that these types of exchanges may be indicative of the second phase, “attachment in the making.” This is consistent with Bowlby’s (1979) view that “in terms of subjective experience, the formation of a bond is described as falling in love” (p. 69). In infancy, the onset of the third phase, “clear-cut attachment,” is indicated by the emergence of new attachment behaviors—and, specifically, by their organization around a single caregiver who has become the reliably preferred target of proximity maintenance and safe-haven behaviors, and elicitor of secure-base and separation-distress behaviors.

The childhood indicators of the fourth phase, “goal-corrected partnership,” primarily reflect cognitive-developmental changes over the first 3 years of life. We have hypothesized that there nevertheless may be a comparable final phase in adult attachment formation, characterized by a decline in overt displays of attachment behavior and a re-direction of attention to other aspects of life (e.g., work, hobbies, and friendships). In a goal-corrected partnership, a romantic partner has achieved the status of an attachment figure and serves as a secure base, emboldening the individual to explore his or her environment with a greater sense of security (Feeney & Thrush, 2010).

The concept of stages in establishing an adult attachment has gained support empirically. As noted earlier, it is now clear that individuals display different patterns of neural activity in response to viewing photos of their romantic partners depending on how long they have been in a relationship (e.g., Xu et al., 2011). Fisher and her colleagues (2002; Fisher, Aron, & Brown, 2005) have proposed three stages of romantic relationship development that correspond to the behavioral systems recruited sequentially, and that serve somewhat independent functions. In the first stage, lust, driven by sex hormones, triggers interest in *any* potential partner. This nonspecific sexual interest is replaced by romantic attraction to a *specific* person, a stage Fisher and colleagues associate with the mating system and hypothesize is undergirded by neurotransmitters, such as dopamine, that are central to reward and arousal. The ultimate value of the mating system is that focusing attention on one specific individual conserves mating effort and reproductive energy. Finally, the attachment system is recruited in relationships that progress to the next stage in order to ensure that couples stay together long enough to provide and care for offspring. Although Fisher and colleagues (2002) do not explicitly propose a time frame, this three-stage framework might be seen as corresponding to the preattachment, attachment in the making, and clear-cut attachment phases that we have proposed.

Attachment versus Other Perspectives on Mating

The attachment theory (AT) perspective on human mating has at times been misunderstood. For example, AT is mischaracterized as claim-

ing that there is only one adaptive mating strategy, monogamous pair bonding (e.g., Schmitt, 2005). In this section, we address some of these misconceptions and explain areas of difference and complementarity among various evolutionary perspectives on human mating. In particular, we address two prominent theories: sexual strategies theory (SST; Buss & Schmitt, 1993), which emphasizes between-gender differences in preference for long-term versus short-term mating strategies; and strategic pluralism theory (SPT; Gangestad & Simpson, 2000), which emphasizes within-gender variability in the adoption of short- versus long-term mating strategies as a function of ecological factors.

AT posits that attachment is one of three interrelated behavioral systems operating in a pair bond, alongside the sexual/mating and caregiving systems. We have reviewed evidence that these three systems are distinct in their neurobiological underpinnings, behavioral manifestations, and psychological dynamics (Fisher, 2000; Fisher et al., 2002). It is understood that relationships can engage these systems somewhat independently (e.g., sexual behavior in the absence of attachment; Diamond, 2004). In the typical pair bond, however, the three systems become integrated. In adults, sexual attraction motivates the kind of physical interactions that over time tend to foster mutual attachment and caregiving. If a pair bond results in the birth of a child, then caregiving is extended to offspring (Hazan & Zeifman, 1994).

AT, SST, and SPT differ in which or how many of the various behavioral systems they address. SST focuses almost exclusively on the sexual/mating system, in which there are well-documented sex differences. For example, compared to females, college-age males report greater desire for short-term matings (Buss & Schmitt, 1993). AT, in contrast, is not concerned with hypothetical mating behavior or short-term matings; attachments are, by definition, *enduring* emotional bonds. SPT, like SST, focuses on the sexual/mating system but also indirectly on the caregiving system, in the form of parental investment, and especially on tradeoffs in the effort afforded to each. The balance of effort allocated to mating versus caregiving is hypothesized to vary within gender as a function of various ecological factors. For example, in highly unstable environments, both males and females show increased interest in short-term strategies (Gangestad & Simpson, 2000). SPT acknowledges that long-term mating is the behavioral norm, but it does not address the nature of

the bond that develops between long-term mates. AT is unique in that it focuses on the dynamics of a pair bond as an integration of the sexual mating, caregiving, and attachment systems.

Another common misconception regarding AT is that an enduring bond or an attachment implies sexual monogamy (Schmitt, 2005). We adopt the view common among animal researchers that *monogamy* refers to a broader constellation of social behaviors between sexual partners, such as nonsexual proximity maintenance, joint territory, prolonged association, and shared parenting (Dewsbury, 1987; Moller, 2003). Although human mating could not be described as monogamous if monogamy were synonymous with sexual fidelity, most human mating systems qualify for less constrained definitions of monogamy (Dewsbury, 1987). Indeed, many animals that are viewed as monogamous because they show a reliable preference for a specific mate engage in copulations outside pair bonds, as evidenced by genetic investigations of paternity (Carter et al., 1997; Mendoza & Mason, 1997). And, across the animal kingdom, one of the characteristics that best predicts monogamy is having immature young in need of extensive parental care for a protracted maturation period, as humans do (Dewsbury, 1987; Moller, 2003).

We have argued here and elsewhere that long-term pair bonds confer reproductive benefits relative to other mating strategies. This does not mean that other reproductive strategies are not also adaptive. It is important to distinguish between optimal adaptations and optimal outcomes. Ainsworth, Blehar, Waters, and Wall (1978) described three attachment styles among infants: secure, insecure-avoidant, and insecure-ambivalent. Whereas the secure attachment style is considered optimal as both an adaptation and an outcome, the two insecure attachment styles are also considered optimal adaptations to particular caregiving environments—a rejecting caregiver in the case of an avoidant infant, and an inconsistent one in the case of an ambivalent one (Ainsworth et al., 1978)—but not optimal outcomes. Similarly, short-term mating strategies may be adaptive in that they optimize existing resources, particularly when resources are scarce and environments are unpredictable (Belsky, Steinberg, & Draper, 1991; Gangestad & Simpson, 2000); at the same time, they may be nonoptimal in terms of outcome when compared to the long-term strategies typically adopted in more stable environments.

Another source of confusion is the relation between attachment style and mating strategy.

Whereas *attachment style* concerns an individual's expectations regarding the availability and responsiveness of mates, *mating strategy* concerns how mates are obtained, whether for the long or the short term. Avoidant individuals have low expectations regarding the availability and responsiveness of partners (Hazan & Shaver, 1994; Mikulincer & Shaver, 2007), and are more apt than secure individuals to adopt a short-term mating strategy (Schachner & Shaver, 2004; Simpson & Gangestad, 1991). However, in spite of negative expectations, many avoidant individuals marry (a long-term strategy), as evidenced by the significant proportion of individuals in studies of attachment style and marriage who are classified as avoidant (e.g., Feeney, Noller, & Callan, 1994; Fuller & Fincham, 1995; Kobak & Hazan, 1991). Having a particular attachment style may predispose one toward a particular mating strategy, but it is by no means determinative.

One reason attachment style and mating strategy do not necessarily follow a single developmental trajectory (e.g., from secure attachment to monogamous, long-term mating strategy) is that each is responsive to environmental conditions at different points in development. AT locates the critical “decision point” shaping attachment style in childhood (in response to the local caregiving environment), whereas SPT locates the “decision point” for mating strategy in adulthood (in response to the local mating environment). However, neither attachment styles nor mating strategies are static entities; both accommodate ongoing events and existing resources and can change across the lifespan (Bowlby, 1980; Fuller & Fincham, 1995).

Schmitt (2005) has criticized the AT view that long-term pair bonds are adaptive, on the grounds that self-reported preferences for short-term mating strategies are associated in a college-age population with such adaptive personality traits as self-esteem, extraversion, and emotional stability. If, for the sake of argument, we accept the premise that an adaptive mating strategy is one that is associated with other adaptive personality traits, we have to consider whether the sexual behaviors of college students qualify as mating or reproductive strategies in the evolutionary sense. Insofar as mating strategies in evolutionary terms are strategies for producing and rearing offspring, sexual behavior that is intentionally uncoupled from that goal might not qualify as a mating strategy at all. In our current culture, birth control and the loosening of restrictions on premarital sex

allow college-age adults to make conscious decisions about engaging in a period of sexual experimentation. This freedom from the potential consequences of sexual behavior was impossible in our EEA or in previous generations, and it may represent a behavioral *neophenotype*—a new pattern of behavior that was not commonly observed or that did not exist before in nature (Kuo, 1967).

Given modern means of avoiding pregnancy, preferring a short-term mate or an uncommitted sexual relationship during college or early adulthood may be distinct from adopting a similar mating strategy in the postcollege years, when decisions about long-term mates and children are often made in our culture. In fact, among men who are slightly older than college age and married, short-term mating strategies are not related to positive personality traits (Schmitt, 2005). This suggests that conclusions about mating strategies based on college-age samples may generalize poorly to marital and familial relationships—the typical contexts in which reproduction occurs.

In addition to the problem of basing conclusions about mating strategies on college-age samples, one of the weaknesses of SST is that the preponderance of SST research is based on expressed preferences or hypothetical behavior rather than actual behavior (e.g., Buss, 1989). For example, typical short-term mating measures ask respondents to indicate the number of sexual partners desired across various time frames and/or the likelihood of engaging in sexual intercourse with desirable partners after knowing them for various time intervals (Buss & Schmitt, 1993; Schmitt, Shackelford, Duntley, Tooke, & Buss, 2001). Although such preferences may tell us about the motivational systems underlying behavior, they do not tell the complete story of the behavior itself or of its effect on outcomes. For example, although humans evolved a preference for foods high in sugar and fat content when food was scarce, this preference in our current environment contributes to obesity, disease, and premature morbidity. Similarly, a robust libido and sexual imagination in and of themselves may be associated with positive outcomes because social, cultural, religious, and demographic constraints limit the expression of sexual behavior in most societies. The impact of restricted versus unrestricted sexual practices on various outcomes is, on the other hand, somewhat independent of the impact of restricted and unrestricted sexual desire.

When studies examine the personality profiles of those who actually engage in behavior that

is typical of short-term strategies, rather than those who merely express a preference for doing so, the results paint a less sanguine portrait of short-term strategists. In fact, Paul, McManus, and Hayes (2000) found that individuals who reported experiencing “hookups” (i.e., casual sexual encounters with relative strangers), especially hookups involving sexual intercourse, had lower self-esteem than those who did not. The emphasis of SST on the correlates of expressed preferences rather than actual practices also downplays the negative mental health consequences of short-term strategies, which are apparent from an extensive clinical literature on the harmful effects of emotional loneliness, breakups, divorce, and sexual infidelity (Hall & Fincham, 2006; Weber, 1998; Weiss, 1975). These damaging effects of relationship disruption and dissolution, coupled with growing evidence of therapeutic effects of relationship endurance, suggest that although diverse reproductive strategies exist, long-term strategies are likely to continue to be the norm.

Are Attachment Relationships Truly Unique?

One premise of attachment theory that has been challenged in recent years is the notion that attachment relationships confer unique benefits that are not readily available in other close relationships such as sibling relationships or friendships (DePaulo & Morris, 2005). DePaulo has coined the term *singlism* to refer to the fact that public policy discriminates against singles, and that singles are often subjected to harsh judgment and negative stereotypes simply by virtue of remaining uncoupled in a society that values pair bonds and marriage. Included in her case for the stigmatization of singles are psychologists’ claims that marriage promotes health and well-being and that singlehood is detrimental to health and well-being (Seligman, 2002). In their critique of AT and of our work in particular, DePaulo and Morris (2005, p. 75) fault us for failing to consider that non-sexual relationships might count as attachments, and having a “dreamy” or idealized view of sexual unions that fails to take quality into account. In the next section, we clarify our position in relation to three of DePaulo and Morris’s assertions.

First, the debate over who qualifies as a principal attachment figure in a modern culture like our own, in which many individuals elect to remain

single well into adulthood, in some ways mirrors earlier challenges to Bowlby's claim that mothers are typically at the apex of the attachment hierarchy in childhood even in extended-kin homes or in the era of day care. In our view, DePaulo and Morris (2005) are right to call into question exactly which relationships ought to be viewed as full-blown or principal attachments in adulthood. In fact, that question was at the heart of our original study of the transfer of attachment from parents to peers, and bears on the larger question of how attachment hierarchies change over time in the normal course of development and maturation. Although we do not preclude the possibility of adults being principally attached to siblings, other relatives, or close friends, we have found, as have others, that this is not the case for the majority of adults. Typically, although some types of attachment behaviors may be preferentially directed toward friends and relatives, the majority of adults view a romantic partner as their *principal* attachment figure (Pitman & Scharfe, 2010; Trinke & Bartholomew, 1997). We would contend that just as most infants form a principal attachment to a mother-like figure, most adults form a principal attachment to a sexual or romantic partner.

Second, DePaulo and Morris (2005) question the assumption that the health benefits of being pair bonded are restricted to those who are married or cohabitating with a sexual partner. There again, our position is based on empirical evidence and stresses the ultimate outcome that interests evolutionarily minded psychologists most: reproductive fitness. Married people do enjoy better physical and mental health than do singles or even cohabitating adults (Horwitz, White, & Howell-White, 1996), although the reasons for this effect are far from clear and continue to be the subject of intense debate (Musick & Bumpass, 2012). More importantly for reproductive fitness, children reared in homes of married mothers enjoy enriched environments, better health, more stable finances, and greater emotional security than their counterparts reared in the homes of single or cohabitating mothers (Bzostek & Beck, 2011; Rosenkrantz Aronson, & Huston, 2004). One study published in an obstetrics journal concludes that marriage protects pregnancy and is associated with lower rates of numerous adverse birth outcomes, including prematurity and low birthweight. The authors note that in their examination of birth records from the 1990s in a Finnish teaching hospital, this marital-context advantage persisted even after cohabitation and single parenthood had become

less stigmatized (Raatikainen, Heiskanen, & Heinen, 2005). Indeed, from our own evolutionary standpoint, it is surprising that cohabitation does not confer benefits on par with marriage, and may reflect the instability of cohabitation relative to marriage (Lichter, Qian, & Mellott, 2006) or a lower level of commitment from the outset among those who cohabit rather than marry.

Third, DePaulo and Morris (2005) and others have argued that psychologists' claims regarding the benefits of marriage often fail to take into account the quality of marriage, and are based largely on comparisons between happily married couples and singles rather than singles and all marrieds, happy and otherwise. Indeed, it is clear that research comparing the health and well-being of both adults and children in conflict-ridden marriages to those in stable, happy marriages strongly support the contention that marriage is not a panacea and can be detrimental to one's health (Bzostek & Beck, 2011; Musick & Bumpass, 2012). We agree with DePaulo and Morris's assertion that relationship quality must be taken into account in any study of the health benefits or costs of being coupled. We would argue, however, that AT has, if anything, emphasized the impact of individual differences in relationship quality (i.e., attachment style) on relationship dynamics and outcomes, sometimes to the neglect of normative processes.

Conclusions

The evidence reviewed in this chapter indicates that pair bonds are similar in many respects to the one type of interpersonal tie that most researchers agree does involve the attachment system—infant-caregiver bonds. Furthermore, the similarities extend far beyond the superficial to include fundamental features, functions, dynamics, and processes. From this extensive evidence, we conclude that attachment is indeed integral to pair bonds and that, conversely, pair bonds are the prototypical (if not the only) instantiation of attachment in adulthood.

As for the functions of attachment in adult life, we have argued that there is significant overlap with those of attachment in infancy. The attachment system helps to ensure the development of an enduring bond that enhances survival and reproductive fitness in direct, as well as indirect, ways. Pair bonds are not simply mutually beneficial alliances based on the principles of reciprocal al-

truism. Instead, they involve such a profound psychological and physiological interdependence that the absence or loss of one partner can be literally life threatening for the other.

Bowlby's original hypotheses concerning pair-bond attachment were based on little more than his formidable powers of observation and deep insights into human affectional behavior. In the time since their formulation, a substantial body of empirical data on relationships has been amassed—one that, on the whole, supports his initial speculations. The evidence indicates that attachment needs persist from the cradle to the grave. And, just as Bowlby surmised, in adulthood, such needs are typically satisfied by pair bonds.

Chapter 21

Adult Romantic Attachment

Developments in the Study of Couple Relationships

Judith A. Feeney

My partner is extremely affectionate, which suits me down to the ground. I've always, always craved affection all my life, mainly through parental—bad parental—relationships. So, I don't know, but I put it down to that. And she's the only person I've ever gone out with that's actually given me the affection I've wanted.

—RESEARCH PARTICIPANT

It is not unusual for people, in describing their couple relationships, to emphasize the impact of early experiences with caregivers; such an emphasis is reflected in this brief quotation from a research participant. This focus on the legacy of early social experiences is consistent with Bowlby's (1969/1982, 1973, 1980) theory of attachment, which recognizes the vital role of attachment behavior throughout the life cycle, and the enormous importance for later relationships of the bonds formed between children and their caregivers. This chapter examines the proposition that romantic love can be conceptualized as an attachment process, influenced in part by experiences with caregivers. The aim is to present the original theoretical and empirical work on which this proposition is based, to outline the considerable advances that have since occurred in this research area, and to explore some unresolved issues and likely future directions.

The First Studies of Romantic Love as Attachment

Although Bowlby's attachment theory dealt primarily with the bonds that form between infants and their caregivers, theoretical work dating from the early 1980s argued for the relevance of attachment principles to adults' close relationships as well. These arguments centered on the functions of attachment bonds. Specifically, infant attachment bonds involve "proximity maintenance" and "separation protest" (seeking proximity to an attachment figure and resisting separation; see Cassidy, Chapter 1, this volume), and establishment of a "secure base" (using the attachment figure as a base from which to explore the environment) and a "safe haven" (turning to the attachment figure for comfort in times of threat). According to Weiss (1982, 1991), these attachment functions apply to most committed

couple relationships: Adults derive comfort and security from their partners, want to be with them (especially in times of stress), and protest when partners' availability is threatened. Similarly, Ainsworth (1989) described sexual pair bonds as the prime example of adult attachments.

Attachment theory also suggests a link between the *quality* of infant attachment relationships and subsequent adult attachment relationships. Bowlby proposed that during the years of "immaturity" (infancy to adolescence), individuals gradually develop expectations of attachment figures, based on experiences with these individuals. Expectations about the availability and responsiveness of attachment figures are incorporated into "internal working models," which guide perceptions and behavior in later relationships (see Bretherton & Munholland, Chapter 4, this volume, for an extensive discussion of working models).

Despite claims of continuity between childhood and adult relationships, the attachment perspective on romantic relationships did not become an active topic of research until Hazan and Shaver reported their seminal studies (Hazan & Shaver, 1987; Shaver & Hazan, 1988; Shaver, Hazan, & Bradshaw, 1988). In these papers, Hazan and Shaver proposed that romantic love could be conceptualized as an attachment process. Furthermore, because variations in early social experience produce relatively lasting differences in relationship styles, the three major attachment styles described in the infant literature (Ainsworth, Blehar, Waters, & Wall, 1978) should be manifested in romantic love. (Following Hazan and Shaver's terminology, I use the terms *secure*, *avoidant*, and *anxious-ambivalent* to refer to these styles in adults.)

In support of these arguments, Hazan and Shaver presented theoretical analyses of love and attachment, integrated with new empirical data. Their theoretical analyses (Shaver & Hazan, 1988) addressed several issues, including the conceptualization of adult love as an integration of behavioral systems (attachment, caregiving, and sex), and compared the attachment perspective with previous theories of love. These issues are briefly discussed later in this chapter.

The empirical studies (Hazan & Shaver, 1987) assessed the link between attachment style and aspects of childhood and adult relationships. Hazan and Shaver developed a forced-choice, self-report measure of adult attachment consisting of three paragraphs, designed to capture the main

features of the three infant attachment patterns described by Ainsworth and colleagues (1978). Participants were asked to choose the paragraph most descriptive of their feelings in close relationships. This measure was used with a large sample of respondents to a questionnaire printed in a local newspaper, and in a separate study with an undergraduate sample. Participants completed questions assessing general attitudes toward close relationships, together with experiences specific to their "most important romance." Results showed that the frequencies of the three styles were similar to those observed among American infants from middle-class families: Just over half the adults described themselves as "secure," and of the remainder, slightly more classified themselves as "avoidant" than as "anxious-ambivalent." In line with predictions based on attachment theory, the three attachment groups differed in their reports of early family relationships, working models of attachment, and love experiences.

In reporting their results, Hazan and Shaver (1987) noted the limitations of their initial studies. Because of constraints on data collection, the measures were brief and simple, and focused on participants' experience of a single romantic relationship. Although this focus might seem to imply a trait approach, the authors recognized that relationship qualities are influenced by "factors unique to particular partners and circumstances" (Hazan & Shaver, 1987, p. 521). This important point is addressed again later in this chapter.

Early Studies of Romantic Attachment: Replications and Extensions

Despite the limitations of their initial research, Hazan and Shaver succeeded in providing both a *normative* account of romantic love (i.e., an account of the typical processes of romantic attachment) and an understanding of *individual differences* in adult relationship styles. Providing a bridge between infant attachment theory and theories of romantic love, their work generated intense interest among relationship researchers, who soon set out to replicate and extend the initial findings. Two questions addressed by these early studies were the conceptual links between love and attachment, and the salience of attachment issues to individuals in romantic relationships. (Some early studies also assessed attachment-related differenc-

es in affect regulation; see Mikulincer & Shaver, 2015; Chapter 24, this volume.)

Conceptualizing Love and Attachment

The first two studies discussed here addressed the conceptualization of love and attachment. Shaver and Hazan (1988) proposed that previous theories of love (theories of “love styles”; of “anxious” love; and of separate components of love) could be integrated within the attachment perspective. To test this proposition, Levy and Davis (1988) assessed the links between attachment style and measures of the love styles described by Lee (1973, 1988) and the components of love discussed by Sternberg (1986; for further discussion of these theories, see Sternberg & Weis, 2006.)

The love styles described by Lee are *eros* (passionate love), *ludus* (game-playing love), *storge* (friendship love), *mania* (possessive, dependent love), *pragma* (logical, “shopping-list” love), and *agape* (selfless love). Shaver and Hazan (1988) argued that this typology could be reduced to the three attachment styles: Their formulation linked secure attachment to a combination of *eros* and *agape*, avoidant attachment to *ludus*, and anxious-ambivalent attachment to *mania* (*storge* and *pragma* were not seen as forms of romantic love). Levy and Davis’s (1988) results, based on ratings of each attachment and love style, largely supported this formulation. Furthermore, all three components of Sternberg’s (1986) model of love (intimacy, passion, commitment) were related positively to secure attachment and negatively to avoidant and anxious-ambivalent attachment, highlighting the

link between secure attachment and better relationship functioning.

Like Levy and Davis (1988), we (J. A. Feeney & Noller, 1990) were interested in the interrelations among theories of love (Table 21.1 summarizes the findings of these two studies). In particular, we queried the assertion that theories of “anxious love” are unidimensional, and equivalent to anxious-ambivalent attachment (Shaver & Hazan, 1988). Using factor analysis, we assessed the structure of a broad set of measures: self-esteem, loving, love styles, and anxious love (e.g., “limerence”; Tennov, 1979). Of particular interest was the fact that measures of anxious love were multidimensional. The limerence measure, for example, yielded four factors: “obsessive preoccupation,” “self-conscious anxiety with partners,” “emotional dependence,” and “idealization.” Four higher-order factors emerged from the set of measures: “neurotic love” (preoccupation, dependence, and idealization); “circumspect love” (friendship, pragma); “self-confidence” (self-esteem, lack of self-conscious anxiety); and “avoidance of intimacy” (high scores on *ludus*; low scores on loving, *eros*, and *agape*). All four factors strongly differentiated the attachment groups. Secure participants’ experience of love was self-confident and neither neurotic nor intimacy-avoiding. Both insecure groups lacked self-confidence, but whereas avoidant participants reported avoiding intimacy, anxious-ambivalent individuals reported a desperate, impetuous approach to love. Although these results generally supported Shaver and Hazan’s formulation, it seems that one aspect of anxious love (“self-conscious anxiety”) characterizes both insecure groups, rather than being specific to anxious-ambivalence.

TABLE 21.1. Measures of Love Associated with the Three Major Attachment Styles as of 1990

Measure	Secure	Avoidant	Anxious-ambivalent
Love styles	<i>Eros</i> (passionate love), <i>agape</i> (selfless love)	<i>Ludus</i> (game-playing love)	<i>Mania</i> (possessive love)
Components of love	High on intimacy, passion, and commitment	Low on intimacy, passion, and commitment	Low on intimacy, passion, and commitment
Higher-order factors	High on self-confidence (high on self-esteem and low on self-conscious anxiety with partners); low on avoidance of intimacy; low on neurotic love	High on avoidance of intimacy (high on <i>ludus</i> and low on <i>eros</i> , <i>agape</i> , and loving); low on self-confidence; low on neurotic love	High on neurotic love (high on preoccupation, dependence, and idealization); low on circumspect love (friendship, pragma); low on self-confidence; low on avoidance of intimacy

Note. Data from J. A. Feeney and Noller (1990) and Levy and Davis (1988).

Salience of Attachment Issues to Perceptions of Romantic Relationships

The studies reported so far point to meaningful relations between romantic attachment style and love experiences. However, these studies relied on closed-ended, self-report measures. Because such structured measures may lead to response sets such as experimenter demand and social desirability, we (J. A. Feeney & Noller, 1991) argued that these studies had not established the *salience* of attachment issues to individuals' evaluations of their romantic relationships; that is, attachment issues may not be very important to individuals, except when they are introduced by measurement procedures.

To address this problem, we asked participants in dating relationships to provide open-ended verbal descriptions of their relationships, and later, to complete Hazan and Shaver's (1987) measure of attachment style. Using content analysis, we examined whether participants spontaneously referred to issues that are central to working models of attachment: openness, closeness, dependence, commitment, and affection. Supporting the salience of attachment themes, we found that 89% of the sample referred to at least one of these issues; on average, one-fifth of the content of the transcripts was devoted to these issues. The three attachment groups also differed markedly in the content of their reports, as illustrated by the ex-

tracts in Table 21.2. Secure participants described mutual support but advocated a balance between intimacy and autonomy. Both secure and avoidant participants described their relationships as friendship-based; unlike secure participants, however, avoidant individuals preferred clear limits to closeness, dependence, commitment, and displays of affection. Anxious-ambivalent participants, in contrast, preferred unqualified closeness, commitment and affection, and tended to idealize their partners. These results fit with findings based on structured measures of relationship experiences.

Advances in Conceptualization and Measurement

Understanding recent studies of romantic attachment requires us to consider the advances in conceptualization and measurement on which they are based. In terms of measurement, Hazan and Shaver's (1987) forced-choice item had clear limitations (as they themselves noted). Reliance on a single item required assumptions about the number of attachment styles and raised concerns about reliability of measurement. Given these problems, researchers soon sought more refined measures. Before these refinements are discussed, however, two points should be noted.

First, the three-group measure continues to be used by some researchers, and offers both ease of

TABLE 21.2. Extracts from Open-Ended Reports of Romantic Relationships Supplied by Participants from Three Attachment Groups

Secure: "We're really good friends, and we sort of knew each other for a long time before we started going out—and we like the same sort of things. Another thing which I like a lot is that he gets on well with all my close friends. We can always talk things over. Like if we're having any fights, we usually resolve them by talking it over—he's a very reasonable person. I can just be my own person, so it's good, because it's not a possessive relationship. I think that we trust each other a lot."

Avoidant: "My partner is my best friend, and that's the way I think of him. He's as special to me as any of my other friends. His expectations in life don't include marriage, or any long-term commitment to any female, which is fine with me, because that's not what my expectations are as well. I find that he doesn't want to be overly intimate, and he doesn't expect too much commitment—which is good. . . . Sometimes it's a worry that a person can be that close to you, and be in such control of your life."

Anxious-ambivalent: "So I went in there . . . and he was sitting on the bench, and I took one look, and I actually melted. He was the best-looking thing I'd ever seen, and that was the first thing that struck me about him. So we went out and we had lunch in the park. . . . So we just sort of sat there—and in silence—but it wasn't awkward . . . like, you know, when you meet strangers and you can't think of anything to say, it's usually awkward. It wasn't like that. We just sat there, and it was incredible—like we'd known each other for a real long time, and we'd only met for about 10 seconds, so that was—straightaway my first feelings for him started coming out."

Note. Data from J. A. Feeney and Noller (1991).

administration and a strong conceptual link with infant attachment theory. Furthermore, it has shown consistent links with relationship variables. Thus, the question is not whether that measure produces meaningful and valid results, but rather, how it might be improved psychometrically.

Second, it should be noted that Hazan and Shaver were not the first researchers to measure adult attachment. The Adult Attachment Interview (AAI; George, Kaplan, & Main, 1984) taps memories of childhood relationships with parents, and respondents' evaluations of the effects of these experiences on their adult personality. Interview transcripts can be used to identify three attachment patterns ("secure," "dismissing," and "preoccupied"), based on the content and coherence of the accounts. The validity of this measure is supported by links between parents' attachment classification, assessed by the AAI, and their children's attachment classification, assessed by observers (Main & Goldwyn, 1984; Main, Goldwyn, & Hesse, 2003). AAI classifications have also been related to couple relationship quality, as noted later in this chapter. Most of the measures discussed in this chapter differ from the AAI in two key respects: They focus on adult romantic attachment (as opposed to current state of mind regarding childhood attachment), and they require less in-depth training to administer and score. (For more details concerning the AAI, see Crowell, Fraley, & Roisman, Chapter 27, and Hesse, Chapter 26, this volume.)

Typologies of Attachment: Three or Four Styles?

Hazan and Shaver's (1987) original measure described three styles, based on extrapolation from studies of the major infant attachment styles. Bartholomew (1990; Bartholomew & Horowitz, 1991) subsequently proposed a four-group model of adult attachment, based on Bowlby's claim that attachment patterns reflect working models of self and others. Bartholomew argued that models of self can be dichotomized as positive or negative (the self is seen as worthy of love and attention, or as unworthy). Similarly, models of others can be positive or negative (others are seen as available and caring, or as unreliable or rejecting). Working models of self and others jointly define four attachment styles, including two avoidant styles (see Figure 21.1). "Dismissing-avoidant" individuals emphasize achievement and self-reliance, maintaining a sense of self-worth at the expense of intimacy. "Fearful-avoidant" individuals desire intimacy but distrust others, avoiding close involvements that may entail loss or rejection.

Self-report prototypes of the four attachment styles were developed (similar in form to Hazan and Shaver's three descriptions), together with interview schedules that yield ratings on the four prototypes (Bartholomew & Horowitz, 1991). Substantial convergence has been established between Bartholomew's interview and self-report measures, and between classifications from Bar-

MODEL OF SELF (Dependence)

		Positive (Low)	Negative (High)
MODEL OF OTHER (Avoidance)	Positive (Low)	<p>SECURE Comfortable with intimacy and autonomy</p>	<p>PREOCCUPIED Preoccupied (Main) Ambivalent (Hazan) Overly dependent</p>
	Negative (High)	<p>DISMISSING Denial of attachment Dismissing (Main) Counterdependent</p>	<p>FEARFUL Fear of attachment Avoidant (Hazan) Socially avoidant</p>

FIGURE 21.1. The four adult attachment styles defined by Bartholomew in terms of working models of self and others. From Bartholomew (1990). Copyright 1990 by Sage Publications, Inc. Reprinted by permission.

tholomew's interview schedule and those based on the AAI (Bartholomew & Shaver, 1998), although this continues to be disputed (see Crowell et al., Chapter 27, this volume). The three-group and four-group measures also show meaningful relations with each other (Brennan, Shaver, & Tobey, 1991). Participants who choose the secure category of Bartholomew's measure also tend to choose the secure category of the other, and those choosing the preoccupied category tend to choose the original anxious-ambivalent category. Most fearful-avoidant individuals endorse Hazan and Shaver's description of avoidance (which emphasizes discomfort with closeness), but dismissing-avoidant individuals are drawn from both secure and avoidant groups.

The four-group model is validated by empirical support for two distinct types of avoidance. For example, the interpersonal problems of fearful-avoidant individuals involve social insecurity and lack of assertiveness, whereas those of dismissing-avoidant individuals involve excessive coldness (Bartholomew & Horowitz, 1991; J. A. Feeney, Noller, & Hanrahan, 1994). As a result, researchers have increasingly adopted the four-group model of adult attachment. This model is consistent with reports of a fourth infant attachment style, marked by characteristics of both avoidance and anxious ambivalence (e.g., Crittenden, 1985; Main & Solomon, 1990), in that fearful-avoidant adults tend to endorse both avoidant and anxious-ambivalent prototypes (Brennan et al., 1991).

From Categorical to Dimensional Measures

Questions have been raised not only about the number of adult attachment styles, but also about the appropriate form of measurement. Categorical measures have several limitations: They fail to capture individual differences within a particular attachment style; they seem to imply that attachment styles are mutually exclusive; and they assume that the themes within each attachment description form a consistent whole. To address these issues, researchers began breaking each description into its component statements and using factor-analytic methods to investigate the structure. Although item content varied slightly across studies, findings generally suggested two major dimensions, "avoidance" (discomfort with closeness) and "attachment anxiety" (J. A. Feeney, Noller, & Callan, 1994; J. A. Feeney, Noller, & Hanrahan, 1994; Simpson, Rholes, & Nelligan, 1992).

Avoidance contrasts elements of the original secure and avoidant descriptions (e.g., "I find it easy to trust others" vs. "I am nervous when anyone gets too close"). Attachment anxiety taps themes central to anxious-ambivalent attachment, such as fear of rejection and desire for extreme closeness (e.g., "I often worry that my partner doesn't really love me," "I find that others are reluctant to get as close as I would like").

Similarly, a comprehensive study of all available self-report items (Brennan, Clark, & Shaver, 1998) yielded two higher-order factors: "anxiety" (about relationship issues) and "avoidance" (discomfort with closeness and interdependence). These dimensions are related to the four groups of Bartholomew's model: Dismissing and fearful groups report more avoidance of intimacy than secure and preoccupied groups, suggesting that avoidance is linked to working models of others; preoccupied and fearful groups report more anxiety about rejection and unlovability than secure and dismissing groups, suggesting that anxiety is linked to working models of self (J. A. Feeney, 1995). The Experiences in Close Relationships Scale (ECR), developed by Brennan and colleagues (1998), has been widely used, and many studies have supported its validity. Short forms of the measure have also been proposed, using either the first half of the full item set (Mikulincer, Shaver, Gillath, & Nitzberg, 2005) or a subset of items selected on the basis of item response theory (e.g., Lafontaine, Brassard, Lussier, Valois, Shaver, & Johnson, 2015). One full-length version, the revised ECR (ECR-R; Fraley, Waller, & Brennan, 2000) was designed to yield better discrimination at the "secure" ends of each scale (anxiety and avoidance).

Griffin and Bartholomew (1994) advocated a "prototype" approach to the assessment of adult attachment: This regards the four types as important predictors of relationship outcomes (adding to the predictive power of the two dimensions) but recognizes that the boundaries between them are "fuzzy." However, Fraley and Waller (1998) rejected this conclusion, noting that the question of whether individual differences should be viewed in terms of categories (latent types) or dimensions cannot be resolved by cluster analysis, by examining the distributions of attachment variables, or by considerations of convenience. Taxometric techniques, designed specifically to evaluate evidence of "groups" versus "dimensions," suggest that differences in adult attachment are best understood in terms of dimensions (Fraley & Waller, 1998).

Although considerable consensus exists concerning the utility and structure of dimensional self-report measures of romantic attachment, reducing this complex construct to two dimensions inevitably loses some information. In a study employing the Attachment Style Questionnaire (ASQ; J. A. Feeney, Noller, & Hanrahan, 1994) with Italian clinical and nonclinical samples (Fossati et al., 2003), use of the minimum partial statistic to estimate the correct number of factors confirmed the five factors proposed earlier (J. A. Feeney, Noller, & Hanrahan, 1994): “confidence in self and others,” “need for approval,” “preoccupation with relationships,” “discomfort with closeness,” and “relationships as secondary” (to achievement). Furthermore, discomfort with closeness was related to sample (clinical, non-clinical), but relationships as secondary was not; yet when only two factors are extracted from the ASQ, items from both these scales load on the same primary dimension (avoidance). Similarly, in later research (Fossati et al., 2009), impulsive aggression was predicted by preoccupation with relationships but not by need for approval; yet items from both these scales define the primary dimension of anxiety. Hence, in some contexts, measures with more complex structures may offer important advantages.

Working Models and Romantic Attachment

Theoretical and empirical work on the structure and function of working models highlights their importance to relationship experiences. With regard to structure, Collins and Read (1994) argued that individuals develop a hierarchy of working models, with a set of generalized models lying at the top, models for particular classes of relationships (e.g., family members, peers) at an intermediate level, and models for particular relationships (e.g., father, spouse) at the lowest level. Research suggests that models higher in the hierarchy apply to a wide range of others but are less predictive for any specific situation (Fraleigh, Heffernan, Vicary, & Brumbaugh, 2011; Overall, Fletcher, & Friesen, 2003.) Furthermore, there is evidence that the effects of general working models may be moderated by relationship-specific models, as assessed by perceptions of partner responsiveness and supportiveness (Collins, Guichard, Ford, & Feeney, 2004).

Collins and colleagues (2004; Collins & Read, 1994) further suggested that working models include four components: memories of attachment-related experiences; beliefs, attitudes, and expectations of self and others in relation to attachment; attachment-related goals and needs; and strategies and plans for achieving these goals. These components vary across attachment groups, as summarized in Table 21.3 (the three-group model is used here because many experimental studies of affect regulation are based on it).

With regard to memory, for example, secure individuals tend to remember their parents as warm and affectionate; avoidant individuals remember their mothers as cold and rejecting; and anxious-ambivalent individuals remember their fathers as unfair (e.g., J. A. Feeney & Noller, 1990; Priel & Besser, 2000; Rothbard & Shaver, 1994). These findings from retrospective reports fit with attachment theory (although not with the link in AAI research between dismissing avoidance and idealization of parents), but we cannot be sure to what extent the memories are affected by more recent experiences. Attachment avoidance and anxiety are also linked to faster associative responses between exposure to the name of mother or romantic partner and negative personal attributes, implying the existence of negative representations of close others in an associative memory network (Zayas & Shoda, 2005). Furthermore, recent studies (e.g., Selcuk, Zayas, Gunaydin, Hazan, & Kross, 2012) suggest that although the negative affect elicited by upsetting memories can be reduced by activating mental representations of attachment figures, these benefits are weaker for insecure adults (especially those high in avoidance).

In terms of functions, working models shape our cognitive, emotional, and behavioral responses to others (Collins & Read, 1994; Collins et al., 2004; Mikulincer & Shaver, 2015, Chapters 6 and 7). Working models affect cognitive responses by directing us to pay attention to certain aspects of social stimuli (particularly goal-related stimuli), by creating biases in memory encoding and retrieval, and by affecting explanation processes. For example, secure adults show faster recognition of positive-outcome words set in an interpersonal context, whereas avoidant adults show faster recognition of negative-outcome words (Baldwin, Fehr, Keedian, Siedel, & Thomson, 1993). Furthermore, secure adults' explanations of relationship events reflect their stronger sense of security and confidence in partners' availability (Collins, 1996; Gallo & Smith, 2001), and their appraisals of rela-

TABLE 21.3. Attachment Group Differences in Working Models

Secure	Avoidant	Anxious-ambivalent
<u>Memories</u>		
Parents warm and affectionate	Mothers cold and rejecting	Fathers unfair
<u>Attachment-related beliefs, attitudes</u>		
Few self-doubts; high in self-worth and self-efficacy	Suspicious of human motives	Others complex and difficult to understand
Generally liked by others	Others intrusive; not trustworthy or dependable	People have little control over own lives
Thinks others are generally well-intentioned and good-hearted	Doubts honesty and integrity of parents and others	Relational ambivalence
Thinks others are generally trustworthy, dependable, and altruistic	Lacks confidence in social situations; expects relationship failure	Unrealistic expectations of partners and relationships
Interpersonally oriented	Not interpersonally oriented	Hungry for love and support
<u>Attachment-related goals and needs</u>		
Desires intimate relationships and interdependence	Desires to maintain physical and emotional distance	Desires extreme intimacy and validation from partners
Seeks balance of closeness and autonomy in relationships	Limits intimacy to satisfy needs for autonomy; averse to commitment	Seeks lower levels of autonomy
Mutual care and support	Places greater weight on goals such as impersonal achievement	Fears rejection and abandonment
<u>Plans and strategies</u>		
Acknowledges distress	Manages distress by cutting off negative affect	Heightened displays of distress and anger
Modulates negative affect in constructive way	Minimizes distress-related emotional displays; denies vulnerability	Solicitous and compliant at times; also demanding and coercive
Invests in relationship development and maintenance	Compulsive self-reliance; withholds intimate disclosure	Focuses on own emotional needs

relationship partners are more stable over time (Alfasi, Gramzow, & Carnelley, 2010), and less contingent on recent partner behavior (J. A. Feeney, 2002; Pietromonaco & Feldman Barrett, 2006).

With regard to emotional responses, working models affect both primary and secondary appraisals of relational events (Collins et al., 2004). *Primary appraisal* refers to the immediate emotional reaction to a situation. In *secondary appraisal*, cognitive processing may maintain, amplify, or lessen the initial emotional response, depending on how the individual interprets the experience. For example, individuals who are anxious about attachment feel more immediate distress in the face of hurtful partner behavior; furthermore, they often

interpret this behavior as intentional and undeserved, which tends to amplify the distress (J. A. Feeney, 2004, 2005). Many studies have linked attachment anxiety and avoidance with difficulties in emotion regulation, and research also points to differences in brain responses to stressful events (see Shaver & Mikulincer, 2013, for a review).

Working models affect behavioral responses through the activation of stored plans and strategies, and the construction of new plans and strategies (Collins & Read, 1994). An example of a stored strategy that may have developed in childhood is an individual “running to Mother” whenever conflict with the spouse arises. In the absence of an available existing strategy, new

strategies may be devised for current situations. Hence, working models may affect decisions about whether to avoid conflict issues or discuss them openly with one's spouse (J. A. Feeney, 2003). Research has linked attachment insecurity to a range of maladaptive relational behaviors, including unselective responses during speed dating (McClure, Lydon, Baccus, & Baldwin, 2010), less synchronization with partners' behavior (Gabriel, Kawakami, Bartak, Kang, & Mann, 2010), and less honesty and authenticity (Gillath, Sesko, Shaver, & Chun, 2010).

Stability, Change and the Conceptualization of Attachment

Although studies have shown reasonable stability of attachment patterns across the early childhood years, the extent of stability remains an issue both for developmental researchers and for investigators of romantic attachment. Attachment theory supports both the tendency toward stability and the possibility of change. Several factors promote the stability of working models (Bowlby, 1980). First, individuals tend to select environments that fit their beliefs about self and others. Second, the information-processing biases outlined earlier lead people to perceive social events in ways that support existing models. Third, working models may be self-perpetuating; for example, someone who believes that others are untrustworthy may approach them defensively, eliciting further rejection.

Despite these forces promoting stability, change in working models is clearly possible. For example, becoming involved in a stable, satisfying relationship may disconfirm negative expectations based on earlier experiences. The high percentage of secure respondents generally found in samples of stable couples supports this effect (J. A. Feeney, Noller, & Callan, 1994; Senchak & Leonard, 1992), as does the following comment made by a research participant:

I had a real problem trusting anyone at the start of any relationship. A couple of things happened to me when I was young, which I had some emotional difficulties getting over. At the start of our relationship, if P. had been separated from me, I would have been constantly thinking: "What was he doing?"; "Was he with another girl?"; "Was he cheating on me?"; all that would have been running through my head. Over a 3-year period of going out, you look at it in a different light; you learn to trust him.

Similarly, a secure person who is involved in a particularly negative relationship may become insecure as a result, as suggested by another research participant:

Before I started seeing T., I was in another long relationship with another fellow . . . and the last couple of months were really bad. I was always really confident about myself and secure about myself, but he made me feel in 2 months—just seemed to ruin everything I'd ever felt good about myself, and I felt bad about everything I did, and he made me feel bad. And so I've got this constant thing in the back of my head that maybe that might happen again.

Quantitative research has assessed the stability of adult romantic attachment over intervals ranging from 1 week to 27 years. Given the large number of studies addressing this topic, a consideration of the individual findings is beyond the scope of this chapter; however, broad conclusions can be drawn (Mikulincer & Shaver, 2015). With forced-choice (three- or four-group) measures, approximately one-fourth of participants show a change in attachment type across assessments (Baldwin & Fehr, 1995). This figure varies little with the time lag between assessments. Ratings of attachment prototypes are moderately stable, as are multiple-item scales (e.g., J. A. Feeney, Noller, & Callan, 1994; J. A. Feeney, Passmore, & Peterson, 2007); when the limited reliability of multiple-item scales is considered, their stability is quite high. And interview measures (whether forced-choice or ratings) tend to be even more stable than self-reports or peer reports (Scharfe & Bartholomew, 1994).

Given that adult attachment measures are not perfectly stable (even accounting for unreliability), researchers have considered the meaning of "change over time" (Davila & Cobb, 2004). Some have posited individual differences in the stability of attachment, whereby adverse early experiences render certain individuals more prone to change (Davila, Burge, & Hammen, 1997), but longitudinal studies provide mixed support for this claim (J. A. Feeney et al., 2007; Scharfe & Cole, 2006). Others have debated whether attachment style should be conceptualized as an enduring, trait-like characteristic, or as reflecting recent experiences in particular relationships. Stability data (outlined earlier) support both positions. Stability estimates are moderately high; indeed, some data suggest that attachment style is more stable than relationship status (Kirkpatrick & Hazan, 1994).

However, other studies highlight the role of recent experiences, linking change in attachment to the formation and dissolution of couple bonds (e.g., Kirkpatrick & Hazan, 1994; Scharfe & Cole, 2006) and to first-time parenthood (J. A. Feeney, Alexander, Noller, & Hohaus, 2003).

Importantly, “traits” and “relationships” are intertwined rather than mutually exclusive (Fraley & Brumbaugh, 2004). For example, by choosing particular partners, individuals may find themselves in situations that confirm their relational expectations. Supporting this claim, studies of romantic attachment reveal a degree of “partner matching.” Although the form of this matching remains contentious (are we attracted to secure partners, or to those with a similar or a complementary style?), most studies of hypothetical partners and of real couples find links between partners’ attachment characteristics (Holmes & Johnson, 2009; Strauss, Morry, & Kito, 2012). In particular, there is substantial evidence that secure individuals tend to be paired with secure, responsive partners—a situation that should confirm positive working models. Hence, attachment is both trait-like and somewhat contextually fluid.

A related controversy regarding change in attachment contrasts the role of major relational events versus the role of short-term fluctuations. According to the first perspective, change is most likely in the face of significant relationship experiences. As noted earlier, several studies have supported this position; however, others have failed to do so (see Mikulincer & Shaver, 2015, for a review). The second perspective proposes that adults have multiple attachment orientations, derived from their varied relational experiences; at any given time, attachment measures reflect the orientation elicited by situational factors. This perspective is supported by evidence that priming adults to think about a particular kind of relationship influences perceptions of partners (Baldwin, Keelan, Fehr, Enns, & Koh-Rangarajoo, 1996). Furthermore, relatively simple manipulations involving exposure to security-priming words or to mental representations of responsive attachment figures influence working models and associated responses: Positive effects of priming extend to affect (Selcuk et al., 2012), perceptions of romantic partners (Carnelley & Rowe, 2007), forgiveness of partner transgressions (Karremans & Aarts, 2007), and responses to partners’ hurtful behavior (Casidy, Shaver, Mikulincer, & Lavy, 2009).

Fraley and Brumbaugh (2004) have advanced the debate over stability and change by clarifying

issues related to attachment organization. These researchers argued that once a developmental pathway becomes established, it is less likely to change: Social environments are usually relatively stable, and intraindividual processes (e.g., assimilation of new information) operate to maintain expectations. Nevertheless, external events exert a nontrivial influence. Fraley and Brumbaugh further noted that simply studying the stability of attachment across two time points tells us little about attachment organization. Data regarding *patterns* of stability (rather than just the *degree* of stability) are needed to evaluate two contrasting positions: the *prototype perspective* (which assumes that although attachment patterns can change, a stable factor underlies them and promotes continuity), and the *contextual or revisionist perspective* (which views working models as fluid structures, sensitive to changes in social environments). Two intensive longitudinal studies of attachment, assessing the magnitude and patterns of correlations over time, supported the prototype model (Fraley, Vicary, Brumbaugh, & Roisman, 2011). As the researchers noted, this support for a latent, enduring factor raises important questions about the persistence of changes induced by security priming; perhaps enduring change in attachment also requires other major change, such as change in the attachment network.

On a related note, Xu and Shrouf (2013) discussed the suitability of measures of adult attachment for capturing the dynamics of attachment change. They argued that researchers need to consider the within-person reliability of different measures (as well as the traditional between-person reliability). In particular, within-person change is important in evaluating whether attachment has been influenced by priming manipulations over a limited period of time, before the new experiences are likely to have been integrated into working models.

Romantic Attachment Security and Relationship Quality

A huge body of research attests to the link between romantic attachment security (whether assessed in terms of styles or dimensions) and the quality of couple relationships (see Mikulincer & Shaver, 2015, Chapter 10). Again, a complete presentation of individual findings is beyond the scope of this chapter; however, the following sections pro-

vide an overview of the major issues, together with illustrative findings.

Early studies of dating relationships (Levy & Davis, 1988; Simpson, 1990) linked secure attachment with high levels of trust, commitment, satisfaction, and interdependence. By contrast (and consistent with attachment theory), avoidant and anxious-ambivalent attachment were negatively related to trust and satisfaction, and avoidant attachment was also related to low levels of interdependence and commitment.

Since then, many studies (increasingly employing longitudinal designs and multiple assessment methods) have confirmed the link between attachment security and the quality of dating relationships. For example, a recent prospective study (Holland, Fraley, & Roisman, 2012; Holland & Roisman, 2010) assessed attachment using both the ECR and the AAI, scoring the latter along two dimensions: security versus insecurity and deactivation (dismissing) versus hyperactivation (preoccupation). Using the ECR, anxiety (but not avoidance) predicted poor relationship quality, both self-reported and observer-rated, a year later. The AAI measure of deactivation–hyperactivation yielded few results, but higher security prospectively predicted perceived and observed relationship quality, even when researchers controlled for prior levels of interpersonal functioning.

Attachment measures also predict the quality of marital relationships. In an early study of attachment and marriage (Kobak & Hazan, 1991), spouses completed measures of working models and marital satisfaction, and engaged in interaction tasks that involved confiding and problem solving. Accuracy of working models (extent of agreement with the spouse about one's own working models) was related to marital satisfaction and to observers' ratings of marital interaction. Furthermore, secure working models were related to higher marital satisfaction and to ratings of less rejection and more supportiveness during problem solving.

Again, subsequent research has confirmed the link between attachment security and marital quality (e.g., Banse, 2004; J. A. Feeney, 2002; Meyers & Landsberger, 2002). In an innovative approach to this topic, Roberts and Greenberg (2002) developed an interaction task that required spouses to discuss times when they had experienced positive feelings toward one another. Coding of the interactions revealed that all spouses in highly satisfying marriages shared feelings related to at least one of the attachment functions de-

scribed earlier (proximity seeking, separation protest, secure base, and safe haven). Most referred to three or four of these functions, supporting the importance of "felt security" and of the specific themes outlined by attachment theory.

More recent longitudinal research (Clark, Lemay, Graham, Pataki, & Finkel, 2010) has also linked attachment security to endorsement of a communal norm in marriage, reflecting concern for the partner's welfare. Specifically, attachment anxiety premarriage was linked concurrently to lower adherence to a communal norm and lower perceptions of partners' adherence to a communal norm; attachment avoidance showed both concurrent and prospective links with adherence to an exchange (reciprocity-based) norm. These results are important given that couples generally reported valuing and striving toward the communal norm.

Collectively, these studies of dating and marital relationships highlight robust links between individuals' own insecurity and poor relationship functioning (dyadic effects are addressed shortly). It is worth noting that some early studies of dating couples suggested that the implications of attachment dimensions for relationship quality might be gender-specific; that is, women's attachment anxiety was a strong correlate of their negative relationship evaluations, whereas for men, comfort with closeness was the crucial attachment dimension (Collins & Read, 1990; Kirkpatrick & Davis, 1994). However, subsequent research has generally failed to replicate these gender differences; rather, both avoidance and anxiety predict reduced relationship satisfaction for both genders (Mikulincer & Shaver, 2015). Further, these findings extend to men's and women's same-sex relationships (Mohr, Selterman, & Fassinger, 2013).

Recent meta-analyses of studies of dating and marriage have confirmed adult attachment as an important predictor of multiple dimensions of relationship quality. A major contribution of one meta-analysis (Li & Chan, 2012) was to highlight the differential correlates of avoidance and anxiety. Specifically, avoidance is more strongly related to low levels of connectedness, support and general relationship satisfaction, whereas anxiety is more strongly related to conflict. These findings fit with attachment theory: Avoidance involves deactivation of the attachment system, marked by physical and emotional distancing, whereas anxiety involves hyperactivation, manifested in needy and demanding behavior (Mikulincer & Shaver, 2015). This meta-analysis also established

that gender has little effect on these associations. In another meta-analysis, Hadden, Smith, and Webster (2014) suggest that the negative associations of anxiety and avoidance with relationship functioning are stronger in longer than in shorter relationships, within cross-sectional samples. This finding raises intriguing alternative explanations that require further investigation; for example, the negative effects of insecurity may accumulate over time, or they may become unmasked as the initial novelty of new relationships fades, or may become stronger as expectations of intimacy increase (Hadden et al., 2014).

Attachment and Relationship Quality: The Role of Communication

In evaluating the implications of attachment security for relationship quality, it is important to consider the role of communication. Communication is the main avenue through which attachment relationships are maintained (Bretherton, 1990; Kobak & Duemmler, 1994), and conflict-centered communication in particular involves attachment-related processes such as affect regulation (Pietromonaco, Greenwood, & Barrett, 2004). As I discuss next, many researchers have studied attachment and couple communication, using a range of research methods.

In one of the first studies of this topic, Pistole (1989) investigated attachment and conflict resolution styles, using a questionnaire methodology, in a sample of students involved in love relationships. Secure individuals were more likely to use an integrating (problem solving) strategy than those who were insecure, and also compromised more than anxious-ambivalent individuals. Anxious-ambivalent participants were more likely to oblige their partners than were avoidant participants. Subsequently, O'Connell Corcoran and Mallinckrodt (2000) related conflict resolution styles to the ASQ (J. A. Feeney, Noller, & Hanrahan, 1994). Confidence in self and others was related positively to integrating and compromising, and negatively to avoiding; discomfort with closeness showed the reverse pattern of associations. These findings suggest that secure persons' use of more constructive conflict strategies reflects their concern both for supporting their own interests and for enhancing their relationships.

In another study of conflict-centered communication, Gaines, Work, Johnson, Youn, and Lai (2000) examined reported responses to "accommodative dilemmas"—that is, situations in which

an intimate partner behaves negatively. Secure attachment was inversely related to the destructive responses of neglect (passively allowing the situation to deteriorate) and exit (actively harming the relationship). Similarly, studies by Creasey and colleagues (Creasey & Hesson-McInness, 2001; Creasey, Kershaw, & Boston, 1999) linked attachment anxiety and avoidance to questionnaire reports of negative escalation, poorer conflict management skills, and fewer positive conflict tactics. (The link between attachment and responses to severe conflict is addressed later; see "Attachment and Couple Relationships under Stress.")

Recent research (Baptist, Thompson, Norton, Hardy, & Link, 2012) also supports the role of attachment in the intergenerational transmission of relationship difficulties. This study examined avoidance and anxiety as moderators of the association between emotional disengagement in the family of origin and young adults' conflict styles (assessed by responses to scenarios depicting validating, volatile, hostile and conflict-avoiding behaviors). Reports of family disengagement interacted with attachment to predict conflict styles: Anxiety exacerbated the effects of family disengagement on hostile responses, whereas low avoidance buffered its effects on volatile responses.

Patterns of self-disclosure (another key aspect of communication) have also been linked with attachment style (Keelan, Dion, & Dion, 1998; Mikulincer & Nachshon, 1991). In general, secure and anxious-ambivalent individuals report more self-disclosure than avoidant individuals. Security is also associated with greater ability to elicit disclosure from relationship partners, with *topical reciprocity* (discussing the particular topics raised by partners), and with *flexibility* (adapting the extent of self-disclosure to the target and the situation). Similarly, secure individuals report more open expression of feelings (both positive and negative) to their romantic partners (Caldwell & Shaver, 2012; J. A. Feeney, 1995, 1999a).

Research continues to clarify the nature of attachment-related effects on disclosure. Observing dating and married couples as they conversed about routine aspects of their daily life, Tan, Overall, and Taylor (2012) found that the negative link between disclosure and insecurity (both avoidance and anxiety) was specific to the disclosure of thoughts and feelings about the couple relationship. Highlighting the importance of this finding, relationship-focused disclosure was positively associated with relationship quality over time. Furthermore, in a student sample, Garrison, Kahn, Sauer, and Florczak (2012) measured both gener-

alized disclosure tendencies and daily diary reports of “emotional disclosure” regarding unpleasant events. Avoidance was negatively linked to both measures of disclosure. Overall, anxiety showed only weak associations with disclosure measures; however, highly anxious individuals engaged in more emotional disclosure when the emotional intensity of events was high, consistent with their vulnerability to stress and their reliance on others to help regulate affect.

In a comprehensive study of couple communication, we (J. A. Feeney, Noller, & Callan, 1994) followed newlywed couples for 2 years, assessing attachment (comfort with closeness, attachment anxiety) and three aspects of communication: the quality of daily interactions (via diary reports), nonverbal accuracy (via the standard content paradigm), and conflict style (via questionnaires). In daily interactions, husbands’ comfort with closeness predicted their greater involvement, disclosure, and satisfaction, whereas wives’ attachment anxiety predicted their ratings of domination, conflict, and dissatisfaction. Furthermore, husbands low in attachment anxiety and wives high in comfort showed more nonverbal accuracy. The key correlate of conflict style was attachment anxiety; highly anxious spouses rated their conflicts as coercive and distressing. Longitudinal analyses showed bidirectional relations between attachment and communication, supporting the claim that working models and relationship experiences influence one another. Consistent with these widespread links between attachment and communication variables, subsequent research has linked avoidance and anxiety to less *communication competence* (a composite measure of assertiveness, interpersonal sensitivity, and self-disclosure; Anders & Tucker, 2000).

Relationship Quality and Communication: Dyadic Effects

Many of the studies reported to this point have employed both members of couples, allowing researchers to assess whether perceptions of relationship quality are related to the attachment characteristics of the partner, as well as those of the reporter. As noted earlier, Hazan and Shaver (1987) argued that relationship quality is shaped by both partners; recognition of the dyadic nature of attachment effects has been a hallmark of recent research.

Early work on this topic used one of two methods, either comparing “couple types” or cor-

relating the attachment scores of one partner with the relationship functioning of the other. Using the former approach, Senchak and Leonard (1992) compared three types: “secure” (in which both spouses chose the secure description of the three-group attachment measure), “insecure” (in which both spouses chose insecure descriptions), and “mixed” (in which one spouse chose the secure description and the other endorsed an insecure description). They found that secure couples reported better marital adjustment (e.g., more intimacy, positive responses to conflict) than mixed and insecure couples did. Cohn, Silver, Cowan, Cowan, and Pearson (1992) linked observers’ ratings of marital quality to couple types assessed with the AAI. In contrast to Senchak and Leonard’s (1992) findings, mixed couples in this study were rated as similar to secure couples, and as functioning better than insecure couples. Given these conflicting findings regarding the adjustment of mixed couples, it remains unclear whether (or when) a secure partner can buffer the negative effects of insecurity on relationship quality.

Using the correlational approach, early studies of dating relationships (Collins & Read, 1990; Simpson, 1990) suggested that evaluations of dating relationships were linked to partners’ attachment ratings, in ways that paralleled the effects of individuals’ own attachment ratings: Negative evaluations were made by the partners of men who were uncomfortable with closeness and women who were anxious about relationships. Early studies of attachment and marriage also reported partner effects. Kobak and Hazan (1991) found that wives of less secure husbands were more rejecting and less supportive than other wives, and that husbands of secure wives listened more effectively during problem solving. Similarly, we (J. A. Feeney, Noller, & Callan, 1994) found that communication patterns and marital satisfaction in newlyweds were related to both partners’ attachment dimensions. Furthermore, for couples sampled across the life cycle of marriage, marital satisfaction was again related to the comfort and anxiety levels of both partners (J. A. Feeney, 1994).

Given that relationship quality is linked to both partners’ attachment characteristics, a further question arises: Do attachment styles of individuals and their partners *interact* to predict relationship quality? This idea is implied by studies of couple types: For example, a secure person may behave differently, depending on the security of the partner. However, comparing three couple types gives limited information because it fails to distinguish between different forms of insecurity.

As outlined next, interactive effects have been addressed more fully by studies using dimensional attachment measures.

In one of the first studies to explore this issue (J. A. Feeney, 1994), couples sampled across the marital life cycle completed measures of attachment and marital satisfaction. As noted earlier, satisfaction was related to both partners' attachment dimensions (main effects). In addition, moderated regression analyses revealed interaction effects for couples married for 10 years or less. Specifically, wives' anxiety was linked with dissatisfaction for both spouses, only if husbands were low in comfort with closeness; by contrast, husbands' anxiety was linked with dissatisfaction, regardless of wives' comfort (see Figure 21.2). It seems that in more recent marriages, anxious husbands' dependent behavior is destructive, perhaps because it violates the male sex role stereotype. Anxious wives' dependent (and stereotype-confirming) behavior may be less harmful except when husbands struggle with intimacy, and hence provide insufficient support.

Using a similar method, reanalyses of data from the study of newlyweds cited earlier (J. A. Feeney, Noller, & Callan, 1994) revealed that husbands' and wives' anxiety levels interacted to

predict women's reports of conflict behaviors, both concurrently and longitudinally (J. A. Feeney, 2003). Interestingly, this effect varied in form. For example, wives reported most conflict avoidance when both spouses were anxious, suggesting that their avoidance was driven by both partners' insecurities. However, anxious wives with nonanxious husbands reported *more* coercion than those with anxious husbands; if anxious wives perceive non-anxious husbands as failing to understand their concerns, power struggles may result. Other studies confirm the gender-specific nature of some dyadic attachment effects. For example, Gallo and Smith (2001) found that husbands reported low levels of marital support when they themselves were avoidant but their partners were not. Furthermore, in a study incorporating ratings of the four attachment styles delineated by Bartholomew (1990), the positive effects of security and the negative effects of insecurity were either amplified or attenuated in specific dyadic configurations (Banse, 2004). The most consistent finding concerned husbands' dismissing attachment, which attenuated the effects of wives' preoccupied and dismissing tendencies.

Recent studies of dyadic attachment have used more sophisticated statistical techniques.

FIGURE 21.2. Relationships between couples' attachment styles on the one hand, and husband's satisfaction (a) and wives' satisfaction (b) on the other. H, husband; W, wife.

In particular, the actor–partner interdependence model (APIM; Kashy & Kenny, 2000) recognizes that in couple relationships, partners' scores on the variables of interest are likely to be correlated. The model tests for *actor effects* (e.g., the effect of an individual's anxiety on his or her coercion), *partner effects* (e.g., the effect of an individual's anxiety on the partner's coercion), and interactions between these effects. In a study of disclosure patterns in dating couples (Bradford, Feeney, & Campbell, 2002), this approach yielded actor and partner effects but no interactions. For example, actors' avoidance predicted their questionnaire reports of low levels of disclosure; diary records of daily interactions showed consistent negative effects of anxiety (especially partner effects). In another APIM study, Campbell, Simpson, Kashy, and Rholes (2001) reported that both actor and partner avoidance interacted with level of relationship dependence to predict responses to a stressful situation. For instance, avoidant participants who showed little dependence on their relationships were especially prone to displaying negative behavior, and to eliciting such behavior from their partners.

The APIM model (or multilevel modeling more generally) is now widely used in attachment research and continues to yield important findings. Lavy, Mikulincer, and Shaver (2013) conducted a 14-day diary study showing that own anxiety and partner's avoidance were robust predictors of self-reported intrusive behaviors (e.g., invading the partner's privacy). These findings presumably reflect anxious individuals' needs for control, and avoidant individuals' distancing tendencies, which may prompt partners to resort to intrusiveness in order to achieve closeness. Other dyadic studies highlight the utility of multimethod research. For example, a recent study of marital conflict identified several interaction effects of spouses' attachment dimensions, noting that the combination of an avoidant and an anxious spouse generally predicted more physiological reactivity and less effective caregiving. However, some findings were specific to self-reports or to observed behavior (Beck, Pietromonaco, DeBuse, Powers, & Sayer, 2013). Furthermore, Seedall and Wampler (2012) examined the impact of attachment avoidance on *emotional incongruence*, defined as the difference between physiological arousal and self-reports of in-the-moment feelings toward the partner during conflict discussions. Own avoidance and in-the-moment-feelings interacted to predict arousal: More positive feelings for the partner were linked to less physiological arousal

at low levels of avoidance but to *more* physiological arousal (i.e., incongruence) at high levels of avoidance. These results suggest that avoidant people respond to intense arousal by distracting themselves or repressing negative affect, tendencies that may jeopardize long-term satisfaction (Seedall & Wampler, 2012).

Dyadic studies are also important in highlighting attachment-related differences in partners' perceptions of their interactions. In one recent experiment, Beck, Pietromonaco, DeVito, Powers, and Boyle (2014) videotaped newlywed couples during a conflict-resolution discussion, then asked them to rate their own and their partners' responsiveness during the conflict. Observers also coded both partners' responsive behaviors during the conflict. As compared to observers' ratings, more avoidant participants underestimated both their own and their partner's responsiveness. In another study, Overall, Fletcher, Simpson, and Fillo (2015) assessed participants' perceptions of partners' emotions and partners' actual emotions during couple conflict discussions and during daily interactions over a 3-week period. Using partners' reports of their own emotions as the accuracy benchmark, they found that more avoidant participants overestimated the intensity of their partner's negative emotion. Moreover, they exhibited more hostile and defensive responses to the partner's expression of emotions during the recorded interactions.

In summary, research has linked insecurity in self and partner to negative relationship evaluations; anxious attachment in an individual seems particularly likely to erode the partner's satisfaction, irrespective of gender (Mikulincer & Shaver, 2015). Some studies also point to interactive effects, further indicating that attachment can be fully understood only at the level of the dyad. Dyadic attachment effects are varied and complex, however, and sometimes specific to one gender or one research method (Barry & Lawrence, 2013; Beck et al., 2013).

Mediating Variables: Exploring the Mechanisms Linking Security to Relationship Quality

The robust link between attachment security and relationship quality raises questions about the *mechanisms* involved in this association. That is, what do secure people do differently that enhances relationship quality? This question has clear implications for interventions; distressed couples may

be helped not only by interventions that target working models directly but also by approaches that address intervening (mediating) variables.

One of the first studies to address this issue was our study of newlyweds (J. A. Feeney, Noller, & Callan, 1994). Given that attachment security predicted both communication and marital satisfaction, we suggested that communication patterns (e.g., conflict style, nonverbal accuracy) might mediate the link between attachment security and satisfaction. Our results did not support this hypothesis; rather, in these early marriages, attachment and communication exerted independent effects on satisfaction. However, different findings emerged from the study of attachment and conflict across the marital life cycle (J. A. Feeney, 1994). In this study, the links between attachment dimensions and marital satisfaction were mediated by mutual negotiation of conflict, although for husbands, the mediation was only partial.

In the following decade, studies revealed other mediators of the association between security and relationship quality. Specifically, full or partial mediation was reported for variables such as emotional expressiveness (J. A. Feeney, 1999a), self-disclosure (Keelan et al., 1998), overall communication competence (Anders & Tucker, 2000), benign (relationship-maintaining) attributions for negative partner behavior (Gallo & Smith, 2001; Pearce & Halford, 2008; Sumer & Cozzarelli, 2004), tendency to forgive transgressions (Kachadourian, Fincham, & Davila, 2004), low levels of psychological distress (Meyers & Landsberger, 2002), and perceptions of available support from family and friends (Meyers & Landsberger, 2002).

Mediation models have been another major focus of recent research. In a dating sample, making sacrifices for the partner based on avoidance motives (e.g., fearing partner disapproval) mediated between attachment anxiety and relationship dissatisfaction (Mattingly & Clark, 2012). In a study of married couples in Portugal, the negative links of attachment avoidance with relationship functioning were mediated, for women, by less investment in family rituals (Crespo, Davide, Costa, & Fletcher, 2008). Furthermore, among expectant first-time parents, lack of relationship regulation (behaviors designed to enhance the relationship) mediated between own avoidance and anxiety and relationship dissatisfaction, and between males' avoidance and anxiety and females' dissatisfaction (Pepping & Halford, 2012). Importantly, in an empirical test of *double mediation* effects grounded

in attachment theory, Karantzas, Feeney, Goncalves and McCabe (2014) found substantial support for the hypothesized model, in which anxiety and avoidance predicted low levels of partner support and trust, which in turn were linked with poor conflict management and lack of intimacy, and hence, with relationship dissatisfaction.

In short, studies suggest that secure individuals display a more open and positive interpersonal style, as indicated by a range of affective, cognitive, and behavioral variables; these variables promote positive relationship outcomes (Table 21.4 summarizes these findings). However, mediation effects have often been specific to one gender, to relationship type (dating or married), and to attachment dimension (avoidance or anxiety), again highlighting the complexity of attachment-related dynamics.

Relationship Quality: Integrating Attachment, Caregiving, and Sexuality

Shaver and colleagues (1988) argued that sexuality and caregiving are independent behavioral systems that are integrated with the attachment system in romantic love. Furthermore, because the attachment system appears very early in the course of development and shapes relational expectations, it plays a pivotal role in influencing the expression of caregiving and sexuality (Hazan & Shaver, 1994). What support exists for these propositions? Empirical studies clearly support the separate importance of each of the proposed components of love (see reviews by Shaver & Mikulincer, 2006, and the volume on romantic love edited by Mikulincer & Goodman, 2006). I have already discussed the robust link between attachment and relationship quality. Support is also emerging for the influence of attachment on caregiving and sexuality, which I discuss next.

Attachment and Caregiving

In a study of romantic couples, Carnelley, Pietromonaco, and Jaffe (1996) assessed the link between attachment and caregiving, and the implications of these variables for relationship satisfaction. Individuals' attachment security was linked to the provision of more "beneficial" (engaged and reciprocal) care to romantic partners. Moreover, individuals' and partners' attachment security, and partners' provision of beneficial care, all contributed to relationship satisfaction.

TABLE 21.4. Key Aspects of Relationship Quality Associated with Attachment Dimensions

Avoidance (discomfort with closeness)	Relationship anxiety
Relationship dissatisfaction	Relationship dissatisfaction
Distrust of partners	Distrust of partners
Low commitment	Jealousy
Low closeness, interdependence, and connection	High levels of conflict
Low supportiveness	Distress and hurt in the face of conflict
+Low emotional expressiveness	+Coercive and dominating conflict tactics
+Low levels of self-disclosure, including flexibility and reciprocity of disclosure	+Maladaptive (distress-maintaining) attributions for negative partner behavior
+Low tendency to forgive	+Low tendency to forgive
+Low interpersonal competence	+Low interpersonal competence
+Low investment in family rituals	+Avoidance motives for sacrificing
+Low relationship regulation	+Low relationship regulation

Note. + indicates there is evidence that this variable mediates the association between security and better relationship functioning.

Additional support for the link between attachment and caregiving comes from the work of Kunce and Shaver (1994), who developed self-report scales assessing the quality of caregiving in intimate dyads: Proximity, Sensitivity, Cooperation, and Compulsive Caregiving. In a student sample, these scales showed theoretically meaningful links with attachment style. For example, secure persons reported more proximity and sensitivity than dismissing persons; consistent with their need for approval, preoccupied and fearful individuals reported more compulsive (but less sensitive) caregiving. In a study using these scales with a sample of married couples (J. A. Feeney, 1996), secure attachment was linked to beneficial caregiving to the spouse. Specifically, comfort with closeness and low attachment anxiety were related to more Responsive Caregiving (a composite scale assessing proximity, sensitivity, and cooperation) and to less compulsive caregiving. In addition, marital satisfaction was higher for secure spouses, and for those whose partners reported more responsive caregiving.

The importance of both partners' attachment characteristics is highlighted by a two-part study of spousal caregiving (J. A. Feeney & Hohaus, 2001). Each spouse first provided a semistructured account of the time when he or she had most needed to give the other spouse extra care and support. Next, spouses completed questionnaires assessing attachment dimensions, caregiving style, attachment strength (reliance on the spouse for attach-

ment needs), anticipated caregiving burden, and willingness to provide ongoing spousal care in the future. Content analysis of the semistructured accounts linked attachment dimensions to perceptions of the caregiving process. For example, as caregivers, anxious wives used less problem-focused coping and more escape/avoidance, and husbands high in discomfort used less support seeking. In addition, insecurity in either partner was linked to caregivers' tendency to belittle their spouses' needs ("tedious," "tragedy queen"). In the second part of the study, spouses' willingness to provide ongoing care was related negatively to their own and their partners' discomfort and anxiety; these effects involved relatively complex paths through caregiving style, attachment strength, and anticipated burden.

In an ongoing research program, B. C. Feeney and Collins (2004) have broadened the conceptualization of caregiving by distinguishing between two caregiving processes relevant to couples (see Collins, Guichard, Ford, & Feeney, 2006, for a review). *Safe-haven caregiving* involves responding to the partner's distress, and was the focus of most research until recently. In contrast, *secure-base caregiving* involves supporting the partner's personal growth and exploration activities. From Bowlby's (1988) work on attachment and exploration, B. C. Feeney and Collins (2004) developed an integrated model of these processes that recognizes the complementary roles of caregiver and care receiver. Subsequently, this research program

has yielded important findings. For example, attachment dimensions are linked to the motivations for providing (or not providing) secure-base support (B. C. Feeney, Collins, van Vleet, & Tomlinson, 2013): Attachment anxiety is linked to motives reflecting perceived obligation and desire for connection; avoidance is negatively linked to the desire to make the spouse feel good; and both dimensions are linked to perceiving the spouse as needy. Furthermore, these motives predict secure-base behavior; for instance, perceiving the spouse as needy is related to observers' ratings of less effective support.

Consistent with the increasing focus on "positive caregiving," Gosnell and Gable (2013) examined reports of situations in which one partner had shared a success or other positive experience with the other. Avoidant individuals reported feeling embarrassed by partners' support, whereas anxious individuals reported feeling misunderstood. Multilevel modeling also showed that insecure adults tended to react more negatively to perceived partner responsiveness (e.g., with less increase in thankfulness and less reduction in sadness), suggesting a failure to capitalize on positive events.

Attachment and Sexuality

Support has also emerged for the link between attachment style and sexual attitudes and behaviors. In an early but comprehensive study of this topic, Hazan, Zeifman, and Middleton (1994) asked adults to complete measures of attachment style and the frequency and enjoyment of various sexual behaviors. Three distinct sexual styles were identified, consistent with the three major attachment styles. Secure individuals were less likely to be involved in one-night stands or extradyadic sex, and more likely to report mutual initiation and enjoyment of sex. Avoidant individuals tended to report activities reflecting low psychological intimacy (one-night stands, casual sex), as well as less enjoyment of physical contact. Anxious-ambivalent females reported involvement in exhibitionism, voyeurism, and bondage, whereas anxious-ambivalent males were more sexually reticent. For both sexes, anxious-ambivalence was related to enjoyment of holding and caressing, but not of more clearly sexual behaviors.

Although relatively few studies have focused on long-term couple relationships, research continues to support the link between specific forms of insecurity and the expression of sexuality, and

has paid increasing attention to sexual goals and motivations (see Shaver & Mikulincer, 2012, for a review). Gentzler and Kerns (2004) found that avoidance was related to attitudinal and behavioral measures of *unrestricted sexuality*—that is, feeling comfortable in short-term sexual relationships involving little commitment or emotional closeness. Similarly, avoidant individuals have more accepting attitudes toward casual sex than other attachment groups (Brennan & Shaver, 1995; J. A. Feeney, Noller, & Patty, 1993). Avoidance has also been linked to young people rating their sexual encounters as having relatively little importance (Tracy, Shaver, Cooper, & Albino, 2003) and reporting that they engage in sex in order to impress their peers (Schachner & Shaver, 2004). A study of dating couples (Impett, Gordon, & Strachman, 2008) established both actor and partner effects of avoidance on sexual goals: Avoidant individuals were less focused on enhancing intimacy, expressing love, or pleasing the partner, and more focused on avoiding conflict. The strongest partner effect linked avoidance to partners' reports of focusing on one's own pleasure. Recent research has also clarified the motives behind the robust link between attachment avoidance and extradyadic sex (Beaulieu-Pelletier, Philippe, Lecours, & Couture, 2011): Avoidance predicted concerns about partners' desire for engagement, and these concerns in turn predicted involvement in extradyadic sex; thus, this behavior seems to reflect avoidant individuals' desire to distance themselves in the face of partner demands.

Attachment anxiety also shows a unique set of sexuality correlates, particularly for women. Women's anxiety has been linked to sexual promiscuity, extradyadic sex, and number of sexual partners (Bogaert & Sadava, 2002; Gangestad & Thornhill, 1997). These high rates of sexual activity may reflect anxious women's desire for intense closeness and fears that failure to oblige partners may drive them away (Schachner & Shaver, 2004; Tracy et al., 2003). For both sexes, anxious attachment has also been linked to difficulty in negotiating sexual encounters (J. A. Feeney, Peterson, Gallois, & Terry, 2000) and to unsafe sexual practices (J. A. Feeney, Kelly, Gallois, Peterson, & Terry, 1999): Given their fear of rejection, anxious individuals may be reluctant to risk alienating partners by discussing sexual practices or resisting pressure for unprotected sex (J. A. Feeney & Noller, 2004). Indeed, in the study by Impett and colleagues (2008), anxiety was related to engaging in sex to

please the partner, as well as to enhance intimacy and express love.

Integrating Attachment, Caregiving, and Sexuality

Little empirical work has assessed all three components of romantic bonds, despite the theoretical appeal of such integrative work. One exception is a study of the transition to parenthood (J. A. Feeney, Hohaus, Noller, & Alexander, 2001), which followed couples through pregnancy and the first 6 months of parenthood, and included a comparison sample of couples who were not planning to have children in the near future. Couples were interviewed and completed questionnaires assessing attachment (comfort, anxiety), caregiving (responsive and compulsive care), and sexuality (sexual desire, satisfaction with sexual communication). Results supported the influence of attachment on caregiving and sexuality, for both transition and comparison couples: Security predicted later reports of better sexual functioning and more adaptive caregiving (although only the “anxiety” dimension predicted compulsive care and low sexual desire). Additional analyses identified two trajectories of marital satisfaction among new parents: One group of couples showed stable levels of satisfaction, whereas the other reported declines. These two groups were similar in terms of initial psychological adjustment and coping resources but differed in terms of husbands’ attachment and caregiving patterns. The strongest finding was that husbands in couples with declining satisfaction reported more attachment anxiety at the start of the study; these husbands also provided less responsive care to their wives. These findings support the pivotal role of the attachment system and suggest that husbands who enter parenthood with unresolved relationship anxieties put pressure on both partners, perhaps by becoming overly dependent and by responding negatively to conflict.

More recently, Peloquin, Brassard, Delisle, and Bedard (2013) tested an integrative model in which attachment dimensions and caregiving style predicted motives for engaging in sexual intercourse, which in turn predicted sexual satisfaction. Data from a sample of individuals in committed relationships provided substantial support for the model. For example, attachment anxiety was linked to controlling care, which predicted using sex to increase one’s own power. In addition, both anxiety and avoidance predicted less sensi-

tive care, leading to less focus on sex as a way of valuing the partner, and hence to less relationship satisfaction. Again, this study reflects the increasing emphasis on integrating attachment-related motives and behaviors.

At the same time, the caution raised by Mikulincer and Shaver (2015) regarding our understanding of the three behavioral systems is warranted; namely, that the available evidence of interrelations among these systems does little to clarify key theoretical issues: Is the attachment system primary? To what extent do the interrelations reflect the common influence of temperament or personality? And do caregiving and sex have recursive influences on attachment security?

Attachment and Couple Relationships under Stress

Although much of the early research on couple attachment assessed global relationship functioning and suggested pervasive differences between attachment styles, there are compelling reasons for focusing on stressful situations. In infancy, the attachment system regulates the balance between proximity-seeking and exploratory behavior. When attachment figures are nearby and the setting is familiar, infants tend to engage in exploratory activity, but in the face of threat (environmental stressors; conditions in the attachment relationship, such as caregivers’ absence; and internal conditions, such as pain), attachment behavior is likely to be evident (Bowlby, 1969/1982). By analogy, similar situations should activate adults’ attachment behavior, making attachment-style differences more pronounced (Simpson & Rholes, 1994). Because conditions that threaten attachment relationships are directly relevant to couple functioning, the research I discuss next focuses on these conditions: specifically, partner absence (separation and reunion behavior) and severe instances of relationship conflict.

Partner Absence

Attachment-related differences in separation and reunion dynamics have been studied in various ways. Mikulincer, Florian, Birnbaum, and Malishkevich (2002) studied responses to “separation reminders” by asking participants to imagine being separated from a relationship partner. For individuals high in attachment anxiety, this manipulation led to heightened accessibility of

death-related thoughts, especially when long-term or final separations were imagined. This finding suggests that anxious individuals experience separation as catastrophic, and adopt a hypervigilant attitude to preventing such an outcome (Mikulincer et al., 2002).

Researchers have also studied romantic partners' responses to actual separation episodes. For instance, Cafferty, Davis, Medway, O'Hearn, and Chappell (1994) studied reunion dynamics among couples in which the husbands were deployed overseas during the 1990–1991 Gulf War. Four months after reunion, the men and their wives completed questionnaires assessing attachment style, marital satisfaction, conflict, and affect during reunion. For both deployed men and their wives, secure attachment was related to higher marital satisfaction and less postreunion conflict; preoccupied individuals showed particularly low satisfaction and high conflict. Links between attachment style and affect during reunion were confined to men, perhaps because of the more stressful nature of their separation experience.

Fraley and Shaver (1998) conducted an innovative study of airport separations, finding that women who were anxious about attachment reported greater separation distress. In addition, observers' ratings indicated that when separation was imminent, highly avoidant women were less supportive and more distant, and highly anxious men were less likely to maintain contact with their partners. These associations differed from those among nonseparating couples, supporting the assertion that stressful conditions amplify the negative effects of insecurity.

Another study (J. A. Feeney, 1998) investigated three aspects of partner absence and distancing. The first aspect (physical separation) is considered here, and the others (discouraging of proximity, closeness–distance struggles) are considered in the next section. In one part of the study, participants provided open-ended reports of their experiences of being physically separated from their current dating partners. Content analyses linked attachment security with less separation distress, with more constructive coping, and with perceptions that the experience had strengthened the couple bond. Avoidance was strongly predictive of males' separation behavior, being related to less support seeking and more emotion-focused coping (including substance use); anxiety was associated, for both genders, with less diverse coping strategies, and, for women, with reports of failing to discuss relationship issues on reunion.

More recently, Diamond, Hicks and Otter-Henderson (2008) assessed affect, physiology, and behavior linked to travel-related separations among cohabiting and married couples. Both members of the couples showed significant changes from preseparation to separation, and from separation to reunion, in the quality of daily interactions, positive and negative affect, sleeping problems, and cortisol levels. These changes were not moderated by relationship length or satisfaction, but they were greater for those high in attachment anxiety. Furthermore, upon reunion, declines in subjective stress were less pronounced for those high in avoidance, suggesting that they may find reunions quite stressful, given their preference for interpersonal distance.

Severe Relationship Conflict

Like long-term or unexpected separations, severe conflict may threaten the couple bond. A laboratory study of dating couples (Simpson, Rholes, & Phillips, 1996) addressed this issue by randomly assigning couples to discuss either a minor or a major relationship conflict. Anxious participants reported feeling greater distress and hostility during the discussions; observers rated them as showing more anxiety, and also rated avoidant men as engaging in lower-quality interactions. These effects were stronger for couples discussing *major* problems, highlighting the impact of relational stress. Anxious participants who discussed major problems also perceived their relationships more negatively after the discussion than before (when researchers controlled for interaction quality). Interestingly, however, diary reports of everyday interactions (Pietromonaco & Barrett, 1997) suggest that preoccupied individuals perceive high-conflict interactions as more satisfying than do other individuals, presumably because these interactions often involve high levels of partner attention and mutual disclosure.

In the second part of the J. A. Feeney (1998) study, couples engaged in three conflict-centered interactions. One interaction involved conflict over a specific issue (use of leisure time); the other two were designed to elicit attachment-related anxiety by having one partner rebuff the other's attempts to maintain closeness (the role of the distant partner was adopted by the male in one interaction, and by the female in the other). Secure attachment was positively related to self-reported expectations and satisfaction for all three interac-

tions. However, secure attachment was unrelated to observers' ratings of responses to issue-based conflict but predicted less negative affect, less withdrawal, and more constructive conversation in response to partners' distancing. These results integrate two key findings: Attachment exerts pervasive effects on *global perceptions* of relationships but is most evident in *observable behavior* in challenging situations.

Attachment is also relevant to closeness–distance struggles. Closeness–distance (or autonomy–connection) is a core relational dilemma: Intimate partners must forgo some autonomy in order to forge a connection, but too much connection stifles their individual identities. Proximity seeking is a key function of attachment behavior; hence, conflict about closeness and distance is likely to activate the attachment system, and may prove intractable if partners have different attachment goals (Byng-Hall, 1999; Pistole, 1994). The final part of the J. A. Feeney (1998) study addressed this issue. Participants discussed their current relationships, and the transcripts were coded for content relevant to closeness–distance (J. A. Feeney, 1999b). Almost all participants (92%) referred to the closeness–distance theme, but ongoing struggles over this issue were more common when the male was avoidant or the female was anxious. Some couples with two insecure partners reported highly distressing cycles of pursuing–distancing, attesting to the difficult emotional climate of these relationships. Similarly, Bartholomew and Allison (2006) suggested that pursuing–distancing cycles often reflect incompatible attachment needs (usually involving one anxious and one avoidant partner), whereas pursuer–pursuer struggles may arise when both partners are high in attachment anxiety. With both these patterns, failure to achieve distance regulation may result in escalating conflict and couple violence.

The role of attachment processes in couple aggression is supported by a dyadic study of empathy and psychological aggression (Peloquin, Lafontaine, & Brassard, 2011). Psychological aggression was linked to actors' anxiety (for both genders), actors' avoidance (for women), and male partners' anxiety. Lack of empathy was also generally related to attachment insecurity, although there was an unexpected positive link between men's anxiety and empathy. Furthermore, women's lack of empathy mediated the association between their insecurity and psychological aggression.

The relevance of attachment issues to the course of couple conflict is further evidenced by

studies of hurt feelings. Content analysis of victims' retrospective reports of hurtful events, together with ratings by expert judges, support the proposition that hurt feelings are elicited by relational transgressions that threaten positive working models (J. A. Feeney, 2005); that is, the sense of personal injury that is a distinctive feature of hurt feelings reflects damage to core beliefs about self-worth and/or partners' dependability. In addition, individual differences in attachment security predict the long-term outcomes of hurtful events (J. A. Feeney, 2004). As already noted, individuals who are highly anxious respond to hurtful partner behavior with more distress and self-blame, which exacerbates their fears and self-doubts. Moreover, avoidant individuals tend to perceive their partners as lacking remorse for hurtful behavior, which fuels further conflict.

In a recent study, Overall, Girme, Lemay, and Hammond (2014) focused on a specific strategy—guilt induction—that anxiously attached people may use in response to relational transgressions, to express frustration and hurt while at the same time retaining closeness to the transgressive partner. Findings indicated that in situations that create relational tension (e.g., criticism and conflict), attachment anxiety was related to exaggerated expressions of hurt feelings and more guilt-inducing verbal and nonverbal responses (as coded by independent observers). Importantly, partners of more anxious participants reported higher levels of guilt, and more anxious individuals appraised their partner and relationship more positively when their partner felt more guilt. However, partners of anxious participants also reported more relationship dissatisfaction. These results suggest that the manipulative stance adopted by anxiously attached people in response to relational tension may foster intimacy and commitment in the short term (due to partners' compensatory efforts to reduce guilt feelings) but can erode partners' satisfaction in the long term.

Additional support for the role of attachment processes in psychological hurt comes from evidence that security-priming manipulations affect recall of hurtful events. Specifically, priming weakens the associations of attachment anxiety with negative affect, feelings of rejection, and destructive behavioral reactions. Conversely, priming strengthens the associations of attachment avoidance with feelings of rejection and weakens associations with defensive reactions, suggesting increased openness to the painful experience (Shaver, Mikulincer, Lavy, & Cassidy,

2009). In addition, an intervention study involving a couples' workshop, focused on principles of attachment and forgiveness, produced increased relationship satisfaction at 6-month follow-up for females in insecure dyads, in contrast to females in secure dyads or control dyads (J. A. Feeney & Fitzgerald, 2012).

Attachment and Relationship Quality: Further Comments

It is important to note that although attachment measures seem to tap relatively enduring individual differences, attachment style is *not* redundant with basic dimensions of personality. Relations between measures of attachment and personality tend to be modest in size (J. A. Feeney, Noller, & Hanrahan, 1994; Fraley et al., 2011; Nofle & Shaver, 2006; Shaver & Brennan, 1992). In addition, relationship outcomes such as satisfaction and commitment are better predicted by attachment measures than by personality measures (Nofle & Shaver, 2006; Shaver & Brennan, 1992).

Furthermore, although some studies of romantic attachment have simply correlated various self-report measures, this is by no means the only methodology that has been used. Many studies have related attachment measures to independent ratings of behavior (e.g., Barry & Lawrence, 2013; Simpson et al., 1996) or to interview and diary-based reports of relationship functioning (e.g., Bradford et al., 2002; Lavy et al., 2013). Others have gathered corroborative reports from friends (Bartholomew & Horowitz, 1991) or romantic partners (Kobak & Hazan, 1991), or have demonstrated the ability of attachment measures to predict relationship outcomes prospectively (e.g., J. A. Feeney et al., 2001; Holland et al., 2012). Further attesting to the validity of self-reports of romantic attachment, these measures have been linked to indices of unconscious processes, including cognitive processing of relational information (Mikulincer, Gillath, & Shaver, 2002; see Mikulincer & Shaver, Chapter 24, this volume) and physiological processes related to arousal and affect regulation (e.g., Diamond & Hicks, 2005; Diamond et al., 2008; Fraley & Shaver, 1997). Finally, studies have supported specific predictions concerning the relative strength of association between attachment measures and particular behaviors—for example, responses to major versus minor conflicts (Simpson et al., 1996) and to relationship-based versus issue-based conflicts (J.

A. Feeney, 1998). These studies are sufficient in number and diversity to indicate that measures of romantic attachment do not simply tap a generalized tendency to perceive or report events more or less favorably.

Summary and Future Directions

The proposition that couple relationships can be understood in terms of attachment principles has generated immense interest, and by late 2013, approximately 2,700 authors had cited Hazan and Shaver's (1987) groundbreaking studies. The attachment perspective has important strengths, as noted by Shaver and Hazan (1988) and others (e.g., Clark & Reis, 1988). Attachment theory addresses a range of relationship issues, including anxiety, loneliness, and grief; it explains healthy and unhealthy forms of love in terms of the same principles; and it is developmental in focus (the concept of working models can account both for the continuity of early relational patterns, and for the possibility of change).

Attachment theory seems to be especially useful in addressing certain key issues in the study of couple relationships, such as conflict. This theory helps to explain both the sources of relationship conflict and individual differences in conflict behavior. Research suggests that attachment anxiety is of particular importance here. Highly anxious individuals report more relationship conflict, which suggests that much of this conflict is driven by basic insecurities about love and loss. Those who are highly anxious also respond with coercion and negative escalation, which tend to alienate partners.

The studies discussed in this chapter illustrate major advances in adult attachment research, including the move to dimensional measures that provide more complete description of attachment patterns, the development of analytic strategies for testing dyadic effects, and the identification of mediated pathways from security to relationship functioning. There has also been an increased focus on positive relationship processes and outcomes, such as empathy and forgiveness. Together, these studies shed light on the complex ways in which security and insecurity are played out in couple relationships, and have vital implications for enhancing relationships.

Despite these advances, important issues remain unresolved. One issue raised in this chapter

concerns the need to clarify patterns of stability and change in attachment organization, including the intraindividual and relational processes that shape these patterns. This issue may be clarified by longitudinal studies that follow individuals as their first romantic relationships develop—and, equally important, that track individuals who move from relationship to relationship. We are also some way from understanding the interrelations among the behavioral systems of attachment, caregiving and sexuality. In addition, it is important for researchers to integrate findings emerging from studies of couple relationships and from studies of the “individual mind” (see Mikulincer & Shaver, Chapter 24, this volume). Initiatives such as these will broaden the contribution made by the attachment perspective on couple relationships.

Chapter 22

Attachment and Sexual Mating

The Joint Operation of Separate Motivational Systems

Gurit E. Birnbaum

Sex is a fundamental aspect of many adult attachment relationships. Sexual urges and emotional attachments, however, are not necessarily connected. For example, sexual acts often occur outside the context of romantic relationships (e.g., one-night stands, short-term extradyadic copulations) and, as such, they may be devoid of affectional bonding and be used for relationship-irrelevant reasons (e.g., physical gratification, self-enhancement, stress relief). Moreover, affectional bonding between adults does not always entail sexual desire or sexual acts, as in the case of long-term partners who have lost sexual desire for each other and ceased having sex but are still deeply attached to each other. These examples align with the view that sexual mating and attachment are governed by separate motivational systems; that is, the processes underlying sexual desire and affectional bonding are functionally distinct (motivating reproductive acts, maintaining proximity to a caregiver, respectively; Bowlby, 1982; Diamond, 2003; Fisher, 1998; Fisher, Aron, Mashek, Li, & Brown, 2002).

Nevertheless, joint involvement of the sexual and attachment systems is typical of ongoing romantic relationships in which intimates function as both attachment figures and sexual partners (Birnbaum, 2010; Hazan & Zeifman, 1994). Thus, within the context of romantic rela-

tionships, these two behavioral systems mutually influence each other and operate together to affect relationship quality and longevity (Birnbaum, 2010, 2014). In this chapter, I review published evidence that points to a reciprocal relationship between these two systems. I first provide an overview of the contribution of attachment orientations to the appraisal of sexual interactions in adolescence and adulthood, and to our understanding the sex–relationship link. In doing so, I discuss the subordination of the sexual system to attachment processes under relationship-threatening circumstances. I then consider the reverse causal direction, focusing on the role of sex as a promoter of emotional bonds. I conclude by presenting the relationship stage model of sexual desire and suggesting directions for future research on the dual potential of sexual desire for both relationship promotion and deterioration.

The Contribution of Attachment Orientations to the Appraisal of Sexual Interactions

The attachment system, which is the earliest developing social-behavioral system in humans, evolved because it increased infants' survival

chances and future reproductive success by maintaining proximity to supportive figures (Bowlby, 1969/1982, 1973). Over the course of development, the quality of repeated interactions with these attachment figures gradually shapes chronic patterns of relational cognitions and goals. Interactions with attachment figures who are responsive to one's bids for proximity facilitate optimal functioning of the attachment system, promote a sense of attachment security (i.e., confidence that one is lovable and that significant others are supportive when needed), and lead to consolidation of interpersonal goals aimed at forming nurturing intimate relationships. In contrast, recurrent failure to attain the primary goal of "felt security" results in the adoption of alternative regulatory strategies for dealing with the ensuing insecurity: hyperactivation of the attachment system, which characterizes anxious attachment, and deactivation of the attachment system, which characterizes avoidant attachment.

Each of these two defensive attachment strategies is associated with particular constellations of interpersonal goals and mental representations of self and others. Attachment anxiety is associated with extreme abandonment fears, wishes for merger, negative models of the self as needy and helpless, and positive expectations of others as affectionate and warmhearted (Bartholomew & Horowitz, 1991; Mikulincer & Shaver, 2007a). Avoidant attachment, by comparison, is associated with wishes for distance and self-reliance in close relationships, negative models of others as unsupportive, and positive models of self as powerful and controlling (Bartholomew & Horowitz, 1991; Mikulincer & Shaver, 2007a). These early-developing attachment strategies guide interpersonal interactions over the lifespan by affecting desired levels of intimacy and interdependence with adult romantic partners. Accordingly, they are likely to influence the regulatory functioning of the sexual system, which matures later in life (Shaver, Hazan, & Bradshaw, 1988). This theorizing has been widely supported by research showing that attachment orientations help explain variations in the way in which adolescents and adults construe their sexual interactions (see Birnbaum, 2010; Mikulincer & Shaver, 2007b).

Attachment and Sex in Adolescence

The contribution of attachment processes to the construal and experience of sexual encounters can

first be discerned in late adolescence (e.g., Cooper et al., 2006), when attachment needs are increasingly met through intimates, and sexual and romantic explorations become key developmental tasks (see reviews by Collins, Welsh, & Furman, 2009; Tolman & McClelland, 2011; also see Zeifman & Hazan, Chapter 20, this volume). An in-depth look at the sexual dynamics during this period may therefore be particularly informative about how early interpersonal experiences determine the development of sexuality in a relationship context, including the kinds of desires adolescents wish to satisfy, the types of relationships they seek, and what they perceive to be sexually desirable in potential and current partners.

Research has generally indicated that smooth functioning of the attachment system facilitates relaxed engagement in sexual activities and encourages the channelling of sexual desires into a committed intimate relationship, even as early as adolescence. In contrast, negative attachment experiences in childhood and the consolidation of insecure patterns of attachment are likely to impair the functioning of the sexual system in close relationships during this period and later on. Indeed, if a person feels chronically insecure about being loved, whether this is reflected in relational worries or in being uncomfortable with intimacy, it is unlikely that this person's sexual system will function without interference. The nature of interference, however, is different between anxious and avoidant adolescents (Birnbaum, 2010; Mikulincer & Shaver, 2007b).

A more detailed examination of the dynamics of attachment in the sexual realm reveals that, consistent with the idea that attachment security furthers a confident approach to sexuality (Mikulincer & Shaver, 2007b), secure adolescents report lower levels of erotophobia than their less secure peers (i.e., they experience fewer negative affective-evaluative responses to sexual cues). This relaxed approach seems to serve the developmental needs characterizing late adolescence. Indeed, secure adolescents neither tend to delay the onset of intercourse, as avoidant adolescents do, nor engage in sexual intercourse rarely, as anxious adolescent men and avoidant adolescent women do (Cooper, Shaver, & Collins, 1998; Feeney, Noller, & Patty, 1993; Feeney, Peterson, Gallois, & Terry, 2000). Rather, secure adolescents are more likely than insecure adolescents to be involved in long-term romantic relationships, explore their sexual aspects, and enjoy them (Tracy, Shaver, Albino, & Cooper, 2003).

More specifically, secure adolescents differ from their less secure peers in the reasons for engaging in sex and in the circumstances in which they choose to have sex (Cooper et al., 2006). They prefer sexual relationships that involve affection (Potard, Courtois, Réveillère, Bréchon, & Courtois, in press) and, accordingly, are more likely to have sex to promote emotional bonding (e.g., to express love for their partner; Tracy et al., 2003). Secure adolescents are also less likely to have sex because of abandonment fears, and are therefore less likely to defer to their partners' desires and to engage in risky behavior during sex (e.g., having intercourse without birth control or while being intoxicated) or in sexual acts that are otherwise unwanted (Feeney et al., 2000; Paulk & Zayac, 2013; Tracy et al., 2003). This, together with their intimacy goals, may explain why they are less accepting of casual sex and are less likely to engage in it (Feeney et al., 1993; Tracy et al., 2003). Overall, secure adolescents' sexual behavior is one way in which they express their growing commitment to a relationship, promoting the establishment of a satisfying intimate bond with a romantic partner.

Whereas a secure state of mind enables constructive exploration of the sexual realm, attachment insecurities may lead to self-defeating behavior patterns. Attachment-anxious adolescents engage in sex to meet their intense needs for security and love. Tragically, however, their chronic insecurity encourages dysfunctional behavior that confirms their worst fears. In particular, they are more likely than their less anxious agemates to have sex to avoid a partner's rejection (Tracy et al., 2003). Because they wish to avoid partner disapproval and tend to hold onto a partner through sexual acquiescence (Tracy et al., 2003), they find themselves engaging in sexual acts with which they are not comfortable and in which they otherwise would not engage (e.g., Szielasko, Symons, & Price, 2013). Some of these activities (e.g., lack of contraceptive use, alcohol and drug consumption; Feeney et al., 2000; Paulk & Zayac, 2013) expose them to risky situations and result in unwelcome consequences (e.g., sexually transmitted disease; unplanned pregnancies; Cooper et al., 1998, 2006). Their insecurity may also lead them to impose sexual contact on their partners as a way of gaining reassurance or reestablishing connectedness (Szielasko et al., 2013). Such destructive tendencies, which are not satisfying alternatives to genuine intimacy, decrease the likelihood of sustaining mutually gratifying relationships.

Avoidant adolescents, compared to their secure and anxious peers, have a significantly lower preference for sexual relationships that involve affection (Potard et al., in press), probably because they devalue the importance of emotional ties, at least consciously (Fraley & Shaver, 1997), and are threatened by the closeness implied by sex (Birnbaum, 2010). This discomfort with the intimate aspects of sex has many manifestations. Avoidant virgin adolescents report higher levels of erotophobia and fewer noncoital sexual behaviors (e.g., making out, petting) than their less avoidant virgin counterparts (Tracy et al., 2003). When avoidant adolescents do start having sexual intercourse, they do so at an older age (e.g., Bogaert & Sadava, 2002; Gentzler & Kerns, 2004), with lower frequency, and for reasons of self-enhancement and prestige (e.g., being relieved or happy to have lost their virginity) rather than intimacy-promoting ones (e.g., expressing love for their partner; Tracy et al., 2003).

Avoidant adolescents are less likely to enjoy sexual experience and tend to drink or use drugs prior to engaging in sex (Tracy et al., 2003). At the same time, their willingness to forgo intimacy may have health-promoting benefits, leading them to be more likely to use condoms (Feeney et al., 2000). Interestingly, the same motive, intimacy aversion, that leads avoidant adolescents to date rarely and to avoid intimate sexual experience during adolescence takes another form when they move into young adulthood. In particular, they tend to engage in a short-term mating strategy that involves emotionless, uncommitted sexual activities (Cooper et al., 2006; Del Giudice, 2009; Jackson & Kirkpatrick, 2007).

Attachment and Sex in Adulthood

The patterns of regulating intimacy and emotions and of relating to others that were established in infancy and continued through adolescence seem to affect the functioning of the sexual system in adult romantic and marital relationships (e.g., Cooper et al., 2006). Secure individuals pursue committed intimate relationships, and their sense of sexual confidence, comfort with sexual intimacy, and enjoyment of mutually rewarding sexual interactions contribute to maintaining satisfying romantic relationships (Birnbaum, 2010; Mikulincer & Shaver, 2007a). In particular, secure people are motivated by relationship-promoting goals (Mikulincer & Shaver, 2007b) and are therefore less likely than insecure people to engage in ca-

sual sex. Instead, they tend to seek fulfilment of their sexual needs and desires within committed intimate relationships (e.g., Brennan & Shaver, 1995; Paul, McManus, & Hayes, 2000; Stephan & Bachman, 1999).

Their secure state of mind is reflected not only in comfort with intimacy but also in positive sexual self-schemas (e.g., viewing the sexual self as passionate, powerful, and open; Cyranowski & Andersen, 1998). This self-assured approach to sexuality allows secure individuals to experience positive emotions during sexual activity (e.g., Birnbaum, Reis, Mikulincer, Gillath, & Orpaz, 2006) and to respond to their partner's sexual needs without compromising their own preferences. Being free of attachment concerns and sexual performance anxieties also contributes to a "letting go" state of mind that enables them to enjoy exploratory sexual activities with their long-term partner, thereby fostering mutual sexual and relational satisfaction (Mikulincer & Shaver, 2007b; Shaver et al., 1988).

In contrast, preoccupation with attachment concerns keeps interfering with comfortable sexuality for attachment-anxious adults (Bartholomew & Horowitz, 1991; Mikulincer & Shaver, 2007a). Specifically, they use sex to try to achieve attachment goals (e.g., Davis, Shaver, & Vernon, 2003, 2004). For example, they tend to sexualize their desire for affection and are likely to have sex for reasons such as gaining a partner's reassurance and manipulating him or her to reduce the possibility of abandonment (Birnbaum, Mikulincer, & Austerlitz, 2013; Cooper et al., 2006; Davis et al., 2004; Impett, Gordon, & Strachman, 2008; Schachner & Shaver, 2004). They tend to prefer the affectionate aspects of sex (e.g., holding, cuddling, kissing) rather than sex per se (Hazan, Zeifman, & Middleton, 1994). This sexualization of attachment needs is reflected in anxious individuals' "sexting" behavior: They are more likely than less anxious individuals to send texts that solicit sexual activity, possibly in the hope that it will seduce a partner into a more reliable relationship (Weisskirch & Delevi, 2011).

Attachment anxious people are inclined to be attracted to partners who seem willing to provide the sense of reassurance they covet (Birnbaum & Reis, 2012; Holmes & Johnson, 2009; Wei, Mallinckrodt, Larson, & Zakalik, 2005). They fantasize about giving and receiving affection during sexual activity and desire emotional involvement, warmth, and attention from their partners during sexual intercourse (Birnbaum,

Mikulincer, & Gillath, 2011; Birnbaum et al., 2006). Their sexual fantasies also involve submission themes that serve their desire to be irresistibly desired. At the same time, such themes may temporarily satisfy their need to feel that their partner is a stronger, wiser caregiver (Birnbaum, 2007b; Birnbaum, Mikulincer et al., 2011). Unfortunately, attachment-anxious individuals channel not only their relational hopes into the sexual domain but also excessive performance anxieties and relational worries (Birnbaum, Mikulincer, Szepsenwol, Shaver, & Mizrahi, 2014; Birnbaum et al., 2006). In particular, they are threatened by sexual performance failure and the possibility of disappointing their partner (Birnbaum et al., 2014). As a result, they tend to try to please their partners during sexual intercourse, while inhibiting the expression of their own sexual desires (e.g., Davis et al., 2006), often succumbing to unwanted sexual advances (Gentzler & Kerns, 2004; Impett & Peplau, 2002).

Overall, the most conspicuous feature of highly anxious people's construal of sexuality is its ambivalent nature. On the one hand, their erotophilic tendencies (Bogaert & Sadava, 2002) seem to intensify the pleasurable aspects of sex (Birnbaum et al., 2006). On the other hand, doubts about being loved generate negative emotions during sexual intercourse (Birnbaum, 2007a; Birnbaum et al., 2006). Such intruding thoughts and aversive feelings apparently impair anxiously attached people's ability to enjoy sexual interactions freely and frustrate their unrealistic expectations for the ultimate physical and emotional merger. It is therefore hardly surprising that anxiously attached people are prone to suffer from not only relational disillusionment (Mikulincer & Shaver, 2007b) but also sexual disappointment and difficulties (Birnbaum, 2007a; Birnbaum et al., 2006; Burri, Schweitzer, & O'Brien, 2014; Stefanou & McCabe, 2012). In fact, because they rely so heavily on the sexual features of their relationship when appraising their partner's regard for them, their sexual difficulties are likely to be misinterpreted as a sign of rejection and have further negative implications for their relationship (Birnbaum, 2007a; Birnbaum et al., 2006).

Ironically, avoidant individuals use sex, which can be one of the most intimate human interactions, to avoid emotional intimacy. This aversion to emotional intimacy is manifested in approaching sex in a variety of distancing ways. Avoidant people typically dismiss sexual motives that are associated with the promotion of emotion-

al closeness (e.g., expressing affection for a partner; Davis et al., 2004; Impett et al., 2008; Schachner & Shaver, 2004). Instead, they pursue opportunistic, self-serving goals, such as having sex to affirm self-worth, to cope with negative emotions, and to impress peers (Cooper et al., 2006; Schachner & Shaver, 2004). Such self-enhancing motives may account for avoidant people's tendency to engage in one-night stands and short-term extradyadic copulations (Cooper et al., 2006).

Indeed, avoidant people tend to be promiscuous and nonexclusive in intimate relationships. They hold permissive attitudes about casual sex (Brennan & Shaver, 1995; Gentzler & Kerns, 2004; Simpson & Gangestad, 1991) and are less likely to experience sexual fantasies that involve romantic themes and intimate interactions with their partner (Birnbaum, 2007b). These tendencies are reflected in real life in the form of engaging in uncommitted sex with a variety of partners (Bogaert & Sadava, 2002; Gangestad & Thornhill, 1997; Paul et al., 2000; Stephan & Bachman, 1999). In addition, avoidant people are likely to respond favorably to mate-poaching attempts (i.e., attempts to lure them away from their current partners) in a short-term context, but of course, not when the poaching is for the long-term goal of establishing a committed relationship (Schachner & Shaver, 2002). As might be expected, avoidant people's low commitment to their primary relationship explains such extradyadic desires and affairs (DeWalt et al., 2011). Ironically, this pattern of extradyadic involvement is reinforced by a primary partner's desire for intimacy, which causes the avoidant individual to back further away (Beaulieu-Pelletier, Philippe, Lecours, & Couture, 2011).

The goal of intimacy aversion may also explain avoidant people's initial attraction to partners with similar needs for independence and their sexual disinterest in potential partners who seem to crave closeness (Birnbaum & Reis, 2012; Holmes & Johnson, 2009). Interestingly, although avoidant people express greater willingness to engage in consensual non-monogamous relationships, they are less likely to actually engage in such relationships (Moors, Conley, Edelstein, & Chopik, 2014). They may have a positive attitude toward consensual, nonmonogamous relationships because these relationships offer an opportunity to dilute emotional closeness with a primary partner. At the same time, however, avoidant individuals generally lack the levels of trust and intimacy needed to sustain extradyadic relationships (e.g., Barker, 2005; Moors et al., 2014).

Avoidant people employ other strategies to distance themselves from their primary partner and impede the experience of genuine intimacy. In line with their extreme self-reliance (Mikulincer & Shaver, 2007a), they often masturbate (Bogaert & Sadava, 2002) rather than having frequent sex with their partners (Brassard, Shaver, & Lussier, 2007). When avoidant people do have sex with their partners, they focus on their own sexual needs and are less likely to express physical affection and to attend to their partners' needs. Nevertheless, they are less likely to satisfy their own needs because they tend to experience aversive feelings of estrangement and alienation during sexual interactions, as well as intruding thoughts (Birnbaum & Reis, 2006; Birnbaum et al., 2006). This detached stance even enters into their sexual fantasies, where they play out themes of interpersonal distance and hostility (Birnbaum, 2007b; Birnbaum, Mikulincer, et al., 2011). Such strategies are obviously not conducive to optimal sexual functioning, and like attachment-anxious people, avoidant individuals are inclined to have sexual difficulties (e.g., Birnbaum, 2007a; Burri et al., 2014; Cohen & Belsky, 2008).

Gender Differences in the Sexual Expressions of Attachment Insecurities

Attachment dynamics in the sexual realm may differ for men and women (e.g., Birnbaum & Laser-Brandt, 2002). Although evolutionary models (e.g., Buss & Schmitt, 1993; Ellis & Symons, 1990) and social-psychological conceptions (DeLamater, 1987; Gagnon & Simon, 1973) attribute these differences to distinct sources of influence (i.e., evolutionary vs. cultural), both perspectives agree that women develop a more emotional–interpersonal orientation toward sexuality than do men. For example, women are more likely to associate sex with receiving and expressing love and are therefore more concerned with their romantic relationships during sexual intercourse. For this reason, they also tend to be more affectionate and nurturing than men during sexual interaction. Men, in contrast, are relatively more motivated by physical release and tend to adopt a more individualistic–recreational orientation toward sexuality. For example, they are more likely to be active, to take the initiator role, and to not only focus on satisfying their partner during sexual activity but also be concerned about experiencing sexual variety (Birnbaum & Laser-Brandt, 2002; Byers & Hein-

lein, 1989; Carroll, Volk, & Hyde, 1985; Hatfield, Sprecher, Traupmann-Pillemer, Greenberger, & Wexler, 1988; O'Sullivan & Byers, 1992).

Men and women's different approaches to sexuality seem to affect how their attachment insecurities are manifested in the sexual arena. Specifically, although both avoidant men and women strive to minimize expressions of intimacy in sexual interactions (e.g., Birnbaum et al., 2006; Cooper et al., 2006), avoidance is more marked in men's sexuality than in women's. Avoidant men, for example, are more inclined to approve of casual sex, to engage in extradyadic sex, and to use sex for relationship-irrelevant reasons (e.g., coping with upset feelings) as compared with avoidant women (e.g., Birnbaum, Hirschberger, & Goldenberg, 2011; Cooper et al. 2006; Sprecher, 2013).

Sexual fantasies provide another medium in which avoidant men can become remarkably disengaged from their current partner. Indeed, avoidant men, but not avoidant women, are less likely to fantasize sexually about romantic themes (Birnbaum, 2007b). Avoidant men are also inclined to objectify women and casual partners. In particular, they are more likely to view pornography (Szymanski & Stewart-Richardson, 2014) and to sexually coerce women in casual dating situations (e.g., pickups, first dates; Davis, 2006). This extreme pattern of divorcing sex from emotions suggests that male sex role norms, which emphasize sexual conquest and inhibit expressions of vulnerability, exacerbate the destructive effects of avoidance: the negative view of others, the feelings of sexual entitlement, and the blindness to partners' wishes. Women's habitual nurturing tendencies, in contrast, may mitigate these effects.

Gender differences in the sexual manifestations of attachment anxiety are more noticeable. Because of their insecurity, attachment-anxious men may be overtaxed by the burden of the traditional gender role of male as sexual initiator (O'Sullivan & Byers, 1992). The resulting tension and wariness may interfere with sexual desire, especially in situations that involve vulnerability, for example, when initiating sex with a new partner. Anxious men tend to begin having sex at an older age and are less likely to view casual sex positively or to cheat on their partners. As a result, they have fewer sex partners overall compared with less attachment-anxious men (Allen & Baucom, 2004; Cooper et al., 2006; Gentzler & Kerns 2004). As might be expected, their tendency to suppress extradyadic desires is especially pronounced under relationship-threatening conditions (Birnbaum,

Weisberg, & Simpson, 2011) that probably intensify their insecurity. Hence, attachment anxiety may not only lead men to invest resources in their ongoing relationship but also prevent them from using sex as a source of self-worth (Cooper et al., 2006).

To the extent that fantasies create a safer channel for sexual exploration, one might expect that anxiously attached men's sexual fantasies would compensate for their insecurities; at least in that fantasy realm, they might engage in sex to feel better about themselves. Instead, attachment anxiety colors their fantasy world with desires to satisfy their partners and focus on pleasing them (Birnbaum, 2007b). They do, however, tend to substitute pornography for authentic intimacy, probably because it allows them to gratify themselves, if only partially, without having to risk interpersonal rejection. Unfortunately, choosing this source of sexual outlet is associated with sexual dissatisfaction and poorer relationship quality (Szymanski & Stewart-Richardson, 2014). The most destructive manifestation of attachment anxiety in men is a proclivity toward using coercive sex (Brassard et al., 2007), which reflects their desperate wish to regain proximity to a partner who is perceived as unresponsive.

Attachment-anxious women cope differently with their attachment-related insecurities. Their tendency to conflate sex and love (Birnbaum, 2007a; Birnbaum et al., 2006) can paradoxically increase the likelihood of engaging in unrestricted and risky sexual behavior. Consistent with this reasoning, anxious women begin having sex at a younger age than secure or avoidant women, hold positive attitudes toward uncommitted sex, and are inclined to engage in extradyadic affairs (Allen & Baucom, 2004; Bogaert & Sadava, 2002; Gangestad & Thornhill, 1997; Gentzler & Kerns, 2004). Their tendency to defer to their partners' sexual needs (Davis et al., 2006) often leads them to engage in unprotected and consensual unwanted sex and to have higher frequencies of unintended pregnancies (e.g., Cooper, Shapiro, & Powers, 1998; Impett & Peplau, 2002). It therefore seems that anxious women's relational worries create difficulties in negotiating sexual encounters and motivate them to secure alternatives to their current partners, in both the real and virtual worlds. Indeed, their sexual fantasies are marked by unrestricted sexual themes (i.e., scenes involving a variety of sexual partners, along with less intimate copulatory positions and emotionless sex; Birnbaum, 2007b).

The Joint Contribution of Attachment and Sex to Relationship Quality

Regardless of whether gender-specific construal of sexuality exacerbates or mitigates some of the detrimental sexual implications of attachment insecurities, both kinds of insecurity are associated with aversive sexual experiences and poor relationship quality among men and women (Birnbaum, 2010; Mikulincer & Shaver, 2007a). Their paths of influence are, however, notably different: Attachment anxiety seems to amplify the impact of sexual experiences on the quality of a relationship, whereas avoidance reduces the impact. Attachment-anxious individuals are particularly attuned to cues that indicate whether their partner still has positive regard for them, and they tend to use sexual interactions as a prominent means of such impressions (Birnbaum, 2007a; Davis et al., 2004). Gratifying sexual experiences are likely to instill a sense of being loved and be interpreted as a sign of a good romantic relationship. Conversely, experiencing negative sexual experiences is likely to be taken as a sign of rejection and a symptom of serious relational difficulties. Avoidant people, by comparison, tend to isolate sexuality from psychological intimacy and are thus less likely to associate sexual activity with relationship well-being. Their relationships may therefore neither suffer the adverse effects of frustrating sexual experiences nor benefit from positive sexual experiences.

These findings imply that optimal functioning of the attachment system, as in the case of securely attached partners, involves neither high nor low levels of interdependence between sexual and emotional aspects of a relationship. Rather, intermediate levels of interdependence between these aspects allow sexual interactions to contribute to relationship quality and stability, but not everything depends on the quality of partners' sex lives at a particular point in a relationship. Other aspects of the relationship, such as intimacy, support, communication, and commitment, may be equally or more important to relationship quality in the long run (Birnbaum, 2010, 2014; Birnbaum et al., 2006).

Several dyadic studies have supported this conceptualization. In one study (Birnbaum et al., 2006), both members of heterosexual cohabiting couples reported on their attachment orientations and provided daily diary measures of relationship quality and sexual activity for 42 consecutive days. In addition, each time they had sex, participants

reported their feelings and thoughts during that sexual episode (e.g., "During sexual intercourse, I felt bored and apathetic," "During sexual intercourse, my partner made me feel desired"). The findings indicated that, as expected, sexual experiences were associated with relationship quality among couples with an anxiously attached partner, but were uncorrelated with relationship quality among couples with an avoidant partner. These findings imply that sex might not only be most beneficial but also most detrimental to the relationships of anxiously attached intimates.

A more recent diary study of newlywed couples revealed that under nonthreatening relational conditions, sexual activity might benefit not only the relationships of couples with an anxiously attached partner but also those of couples with an avoidant partner (Little, McNulty, & Russell, 2010). In particular, engaging in highly frequent and satisfying sexual activity may lead insecure partners to expect to be more satisfied with the levels of affection and trust in their relationship, thereby mitigating the adverse relational effects of attachment insecurities. In other words, gratifying sex can cause both anxiously and avoidantly attached partners to feel more satisfied in their relationships, as long as it helps them perceive their partners as more available and responsive to their needs and alleviates the fears that typically damage their relationships.

Unfortunately, in the long run, not only can the relationships of avoidant partners benefit from gratifying sexual activity but they can also be adversely affected by sexual difficulties, as demonstrated in a recent longitudinal study (Szepeswol, Mizrahi, & Birnbaum, 2015). This study examined how chronic deactivation strategies in the sexual and attachment systems interacted within emerging relationships to affect relationship satisfaction over an 8-month period. At the beginning of the study, both members of newly dating couples completed a measure of attachment orientation. They also completed an instrument for assessing *sexual hyperactivation*, which is a predisposition that involves intense but anxious expressions of sexual desire (e.g., "During sexual activity, I worry about my sexual performance"), and *sexual deactivation*, which involves inhibition of sexuality (e.g., "Thoughts about sex do not especially excite or interest me"). In addition, they reported their relationship satisfaction three times during the study period. We found that sexual deactivation had detrimental effects on relationship satisfaction. Unsurprisingly, partners' attachment-related

avoidance perpetuated the sexual deactivation effects over time.

The Coordination of Attachment and Sex in Distress Regulation

The sexual system is particularly susceptible to being subordinated to attachment processes under relationship-threatening circumstances (e.g., insecurity regarding a partner's love, possible mate poaching, prospective separation). Such situations call for distress regulation and activate attachment behaviors such as proximity seeking (e.g., Davis et al., 2003; Mikulincer, Gillath, & Shaver, 2002; Simpson, Rholes, & Phillips, 1996). Because sex is a prominent way for adults to seek physical consolation, under such circumstances, the sexual system may be activated as well to provide the needed closeness and reassurance (Davis et al., 2004). Along with the normative activation of attachment needs, these anxiety-provoking situations are likely to elicit insecurely attached individuals' attachment concerns and related defensive strategies (e.g., Mikulincer & Shaver, 2007a; Simpson & Rholes, 1994). To the extent that sexual behaviors serve the goals of attachment system deactivation or hyperactivation (e.g., limiting intimacy during sexual activity to maintain distance, engaging in sex to avoid rejection, respectively; Birnbaum, 2010; Davis et al., 2006), it is reasonable to expect that under relationship-threatening conditions, the sexual manifestations of these strategies will be especially pronounced.

This theorizing has gained support from several studies that explored sexual responses to a variety of relationship-threatening conditions (e.g., hypothetical relationship threat scenarios, actual troubled interactions). For example, in two series of experiments, participants imagined relationship-threatening scenes (e.g., a partner who considers breaking up, a partner's infidelity), non-relationship-threatening scenes (failure on an examination), or nonthreatening scenarios (e.g., a partner going to a grocery store). Following this procedure, participants rated or described their desire to have sex, reasons for engaging in sex (Birnbaum, Weisberg, et al., 2011), and their sexual fantasies (Birnbaum, Svitelman, Bar-Shalom, & Porat, 2008). We found that anxiously attached people reacted to relationship threat with a mix of insecurity and anger. Specifically, they expressed an intense desire to satisfy partners sexually in their fantasies, but at the same time, they repre-

sented themselves in these fantasies as alienated and hostile (Birnbaum et al., 2008).

Relationship threats obviously exacerbate anxiously attached people's habitual insecurity, motivating them to respond with relationship-maintaining behaviors while forgoing their own sexual preferences and satisfaction. The resulting frustration provokes anger toward the threatening partner and amplifies their habitual negative self-representations (e.g., Campbell & Marshall, 2011; Mikulincer & Shaver, 2007a). The ambivalent reaction that relationship threat invokes in anxiously attached people impedes their ability to pursue sexual gratification, as indicated by their reduced hedonistic motivation (Birnbaum, Weisberg, et al., 2011). This intense emotional reaction is also manifested in relationship-damaging behaviors (e.g., recurring bouts of uncontrollable anger, excessive partner surveillance; Guerrero, 1998; Mikulincer & Shaver, 2005) that eventually sabotage their attempts to repair the threatened relationship, confirming their worst fears of relationship loss (e.g., Campbell & Marshall, 2011; Campbell, Simpson, Boldry, & Kashy, 2005; Simpson et al., 1996). Strangely enough, although anxiously attached people have trouble enjoying sex when being flooded with relationship worries, they seem to change their outlook and adopt a "seize the day" approach when death, the final separation, is salient (Birnbaum, Hirschberger, et al., 2011). It is possible that death awareness releases their fears, allowing them to focus on erotic pleasure, as they are less likely to be threatened by something they will inevitably lose.

Unlike anxiously attached people, who use sex to repair their threatened relationships, avoidant people react to threats by withdrawing sexually from their partners and using sex opportunistically. In particular, relationship threat lessened avoidant people's desire to have sex with their partners (Birnbaum, Weisberg, et al., 2011). Furthermore, reminders of death increased the tendency of avoidant people to have sex for self-affirmation reasons, and that of avoidant men to engage in emotion-free, casual sex (Birnbaum, Hirschberger, et al., 2011). These findings suggest that avoidant people attempt to protect themselves against mortality and attachment concerns by engaging in compensatory self-enhancement, as well as defensive distancing from a potentially rejecting partner.

A similar pattern of intensification of habitual defensive tendencies in the face of threat emerged in a fantasy study, which was conducted

in a more natural context (Birnbaum, Mikulincer, et al., 2011). In this study, both members of heterosexual cohabiting couples reported their attachment orientations, then provided daily diary measures of their relationship interactions for 21 consecutive days. In addition, immediately after every sexual fantasy during the study period, participants described it in narrative form. The findings showed that distressful relationship events led anxiously attached people to switch from fantasizing about attachment themes, in which they expressed a desire for intimacy and represented the object of their fantasies as warm and affectionate, to fantasizing about submission themes that accentuated their neediness (e.g., portrayal of the self as weak and helpless). Avoidant people, by comparison, reacted to troubled real-world interactions with enhancement fantasies (e.g., portrayal of the self as strong and powerful) and distance-related wishes (escaping reality).

These findings demonstrate the involvement of sexual mental imagery in handling attachment-related stressful events and imply that such events induce compensatory processes that amplify typical attachment-related wishes and self-representations. Among avoidant people, threatening events heighten rejection concerns that trigger a self-regulatory mechanism designed to defend the self against rejection. These mechanisms include compensatory self-enhancement (Andersen & Chen, 2002; Bartz & Lydon, 2004) and defensive distancing from the potentially rejecting partner (Murray, Derrick, Leder, & Holmes, 2008; Murray, Holmes, & Collins, 2006). Among anxiously attached people, the same rejection concerns lead to self-minimization, and even humiliation, in the hope of eliciting caregiving from a powerful partner (Birnbaum, 2007b; Davis et al., 2004). These compensatory relational restoration strategies are intended to protect, at all costs, the threatened relationships.

The studies reviewed earlier indicate that reactions to threat are not necessarily uniform because threats may challenge different goals in different people (i.e., goals associated with different attachment orientations). Situations like the ones examined in these studies (Birnbaum et al., 2008; Birnbaum, Weisberg, et al., 2011), in which a partner explicitly considers ending a relationship or engaging in extradyadic affairs, are likely to challenge both relationship-promoting and self-image goals. As such, they may elicit reactions in the individual aimed at fighting for the specific threatened relationship, along with reactions intended

to protect oneself from further losses of self-esteem (e.g., Birnbaum, Weisberg, et al., 2011). Still, reactions to threat may become uniform under certain circumstances, depending on the type of threat and the goals most likely to be challenged by a specific threat. For example, threatening circumstances that bypass the conscious evaluation of attachment-relevant experiences may produce general rejection concerns (e.g., feeling insecure about being loved). These rejection concerns may in turn lead to prioritization of self-protection goals over connectedness goals (Bartz & Lydon, 2004; Cavallo, Fitzsimons, & Holmes, 2010), which resembles the goals that typically motivate avoidant people (Mikulincer & Shaver, 2007a).

This point has been illustrated in a series of studies that examined the effects of activated attachment insecurity on the content of sexual fantasies. In two of these studies (Birnbaum, Simpson, Weisberg, Barnea, & Assulin-Simhon, 2012), participants were subliminally exposed to either a security or an insecurity picture prime (pictorial representations of either maternal caring or maternal rejection), after which they described a sexual fantasy narratively (Study 2) or completed a fantasy checklist (Study 3). The results showed that subliminally activated attachment insecurity exerted a uniformly avoidant effect on the content of sexual fantasies. Specifically, regardless of dispositional attachment orientations, implicit insecurity priming inhibited attachment themes (e.g., portrayal of the self and fantasy partners as affectionate and pleasing) and aroused fantasies that involved interpersonal distance and hostility themes (e.g., portrayal of the self and partners as aggressive and distant). These findings suggest the involvement of unconscious processes in which rejection concerns automatically activate self-protective fantasy responses. Such fantasies entail avoidance motivation that is geared toward protecting the self from further pain of rejection, while inhibiting relationship-promotion goals.

The Contribution of Partner's Attachment Orientation to Sexual Dynamics

Although sex may involve a solitary act of pleasure, sexual experiences are often integrated into a relational context that influences their construal. Hence, sexual responses to both threatening and unthreatening circumstances may be determined, not only by each individual's characteristics, de-

sires, and experiences, but also by those of her or his partner, as illustrated by several studies. These studies indicate, for example, that partners of anxiously attached people do not report greater levels of sexual dissatisfaction compared to partners of less anxiously attached people, at least in nonclinical samples (Butzer & Campbell, 2008; Impett & Peplau, 2002; but see Brassard, Péloquin, Dupuy, Wright, & Shaver, 2012, for different results in couples seeking marital therapy).

Given that anxiously attached people are oriented toward pleasing their partners during sexual interactions and complying with their wishes (e.g., Davis et al., 2006), it is hardly surprising that their partners are satisfied with their sexual lives. This is not to say that an anxiously attached partner's behavior may not cause sexual and relational difficulties, but rather that their conduct in the sexual domain may compensate for some of their relationship deficiencies. To take one example, men with anxiously attached partners do experience relational distress following negative sexual interactions, probably due to the destructive behavior that such experiences trigger in their partners. However, anxiously attached partners' compensatory behavior seems to offset the negative reaction that their behavior initially evokes, at least inside the bedroom (Birnbaum et al., 2006). In contrast, and as might be expected, partners of avoidant people are generally less satisfied with their sex lives compared to partners of less avoidant people (e.g., Butzer & Campbell, 2008). Moreover, unlike partners of anxiously attached men, partners of avoidant men are unlikely to exhibit less relationship-damaging behaviors following sexual interactions and are less likely to gain overall from such interactions, possibly because sex with an avoidant man is unlikely to meet their emotional needs and to console them (Birnbaum et al., 2006).

This dynamic is even more accentuated when couples face a relationship conflict, as illustrated in a recent study exploring the effects of relationship conflict on sexual motivation (Birnbaum et al., 2013). Couples who attended a laboratory session were randomly assigned to one of two conditions: Half were videotaped as they discussed a major problem in their relationship, whereas the others served as a control group and discussed their daily routine. After the discussion, both partners independently completed measures of perceived partner sexual attractiveness and sexual motives. We found that conflict discussions inhibited certain sexual motives (e.g.,

experiencing pleasure, obtaining stress reduction, feeling emotionally valued by partner) among people with avoidant partners but increased the likelihood of engaging in sex to feel better among people with less avoidant partners. These findings imply that people are unlikely to turn to avoidant partners for sexual consolation in what is sometimes "make-up sex." Indeed, avoidant people are inclined to dismiss their partner's sexual and nonsexual needs, as well as to distance themselves during conflictual interactions (Birnbaum et al., 2006; Mikulincer & Shaver, 2007a; Reis, 2007; Simpson et al., 1996). Therefore, they are less likely to be perceived by their partners as responsive, stress-relieving figures, either inside or outside the bedroom.

The studies demonstrate that a dyadic perspective may offer valuable insight into expressions of attachment dynamics in everyday sexual experience. Still, to uncover fully the interactive nature of couples' sexuality, research should take into account the unique configuration of both partners' attachment orientations. The predictive power of this approach has been described in a study in which both members of established couples reported their attachment orientations and sexual experiences (Brassard et al., 2007). This study highlighted a dyadic interaction pattern in which avoidant men were likely to avoid sexual activities in their current relationships, experience sexual difficulties, or have sex less often if their female partner was also avoidantly attached. This is likely the case because intimacy fears, which apparently burden both partners in this case, keep them from resolving their sexual and relationship problems.

Another dyadic pattern demonstrating that avoidant men are more threatened by intimacy than by its loss is that of avoidant men and anxiously attached women. These couples also report having sex less frequently, probably because anxiously attached women's needs for reassurance collide with their avoidant partners' negative stance toward expressions of intimacy. In addition, anxiously attached men have sex less often if their female partner is less anxiously attached. It is possible that anxiously attached men's efforts to have sex deter less anxiously attached partners, who may view such excessive demands as draining and exasperating. Yet the same sexual advances may be well received by partners with similar intimacy needs, as indicated by the finding that two anxiously attached partners have a relatively high rate of sexual intercourse.

The Contribution of Sex to the Development of Attachment Bonds

The literature reviewed thus far shows how attachment processes influence the construal of sexual interactions in various relational contexts. Other studies suggest that influences in the reverse direction, from sexual to attachment processes, are also possible, such that sex can affect the attachment bond during its development. Indeed, although the sexual behavioral system evolved to motivate reproductive acts (Buss & Kenrick, 1998), impregnation was frequently not sufficient in ancestral environments for the survival of human offspring, who have a long period of development and vulnerability. This prolonged altriciality rendered biparental caregiving an adaptive reproductive strategy. That is, selection pressures have produced mechanisms that keep human sexual partners attached to each other so that the two of them can jointly care for their offspring and increase the offspring's chances of survival and reproduction (Birnbaum & Reis, 2006; Eastwick, 2009; Fisher, 1998; Hazan & Zeifman, 1994; see also Zeifman & Hazan, Chapter 20, this volume).

Such mechanisms presumably foster behaviors that promote proximity and affectionate contact (e.g., prolonged eye contact, cuddling, kissing), which distinguish attachment bonds from other types of social relationships (e.g., affiliative relationships) and other types of sexual connections (e.g., one-night stands). This complex constellation of proximity and affectionate contact is crucial for the formation of attachment bonds at any age (Acevedo & Aron, 2014; Hazan & Zeifman, 1994). However, the predominant motivations that enhance closeness frequently differ in infancy and adulthood: Security needs motivate proximity seeking and bond development in both phases of life, whereas sexual needs (or, more specifically, sexual desire) motivate proximity seeking and bond development only in adulthood (Berscheid, 1988; Diamond, 2004; Hazan & Zeifman, 1994).

Unique Features of Human Sexuality and Emotional Bonding

Support for the notion that the sexual system has been “exploited” by evolutionary processes to promote enduring bonds between sexual partners comes from a closer look at the constellation of characteristics that distinguish human sexual-

ity from that of other mammals. Humans tend, for example, to have sex in private and to sleep together afterward (Ford & Beach, 1951). Humans also frequently have sex in the “missionary position” (Ford & Beach, 1951; Reinisch & Beasley, 1991), which, in contrast to the typical sexual positions of most mammals (e.g., canines), enables partners to maintain face-to-face, belly-to-belly contact and look into each other's eyes during sexual intercourse. Such behavioral tendencies increase the likelihood of experiencing extended intimate contact and may therefore strengthen the emotional connection between sexual partners (e.g., Birnbaum, 2014; Hazan & Zeifman, 1994).

Additional suggestive evidence for the sex–attachment link derives from neuroimaging research that indicates certain brain regions activated during the experience of sexual desire (e.g., the caudate, insula, putamen) are also activated during experiences of romantic love (see Diamond & Dickenson, 2012, for a review). This overlap in neurological response suggests the existence of a neurobiological pathway through which sexual desire can affect the experience of love and attachment (and vice versa). Neuropeptides that are involved in both sexual and attachment behaviors modulate the functional connectivity between some of these brain regions (Bethlehem, van Honk, Auyeung, & Baron-Cohen, 2013). In particular, oxytocin and vasopressin—which are secreted in humans during foreplay, sexual intercourse, and the moments preceding orgasm (e.g., Carmichael et al., 1987; Carter, 1992; Filippi et al., 2003; Murphy, Seckl, Burton, Checkley, & Lightman, 1987)—facilitate bonding among both humans and other mammals (e.g., Acevedo & Aron, 2014; Carter et al., 2005; Ditzen et al., 2009).

This research suggests that sexual interactions activate the hormone-mediated mechanisms underlying attachment processes in both humans and other species. Still, distinctive characteristics of human sexuality may further increase the release of oxytocin during sexual intercourse and amplify its emotional bonding effects. For example, humans are the only species in which females show permanent breast enlargement that is independent of lactation. This sexually attractive feature furthers nipple stimulation during sexual activity, thereby reinforcing the release of oxytocin. Moreover, humans are rare among mammals in that they experience an extended exposure to oxytocin and vasopressin due to their tendency to

have sex throughout the menstrual cycle rather than just prior to ovulation. Overall, the tendency to engage in regular sexual activity that often involves nipple stimulation may enhance sexual bonding in humans and, over time, promote enduring attachment bonds between sexual partners (Young & Wang, 2004).

Mental Representations of the Sex–Attachment Link

Another line of evidence for the theorized link between sex and emotional bonding comes from phenomenological accounts of sexual experiences. In these studies, participants have been asked to describe the meanings they attach to sexual intercourse (Birnbbaum, 2003) and their feelings, expectations, and beliefs about sexual activity (Birnbbaum & Gillath, 2006; Birnbbaum & Reis, 2006). The results indicate that both men and women commonly mention that sexual activity fosters intimacy between partners (e.g., “To me, sex is an important part of becoming really close to my partner”) and nurtures their emotional bond (e.g., “To me, sexual activity is a way of forming an affectionate relationship”).

A similar picture has emerged in research exploring people’s descriptions of sexual motives. A broad array of potential goals motivates people to engage in sex (e.g., Cooper, Shapiro, et al., 1998; Hill & Preston, 1996; Meston & Buss, 2007). These goals vary across individuals, contexts, and partners (e.g., Birnbbaum et al., 2013; Birnbbaum, Weisberg, et al., 2011). For example, reasons for engaging in sex with an extradyadic partner (e.g., the desire for novelty and sexual variety) may differ from those that motivate sex in the context of an ongoing romantic relationship (e.g., deterring the partner from seeking sexual gratification elsewhere). Still, some of the most frequently endorsed reasons for having sex among both men and women reflect relationship-based motivation, such as the desire for emotional closeness and for intensifying the relationship (e.g., Meston & Buss, 2007). Viewed together, these phenomenological accounts of sexual experiences, meanings, and motives illustrate that people habitually associate sex with relationship promotion.

Subsequent research has extended these studies by providing evidence for the proposed causal pathway from activation of the sexual system to attachment formation and maintenance. In one series of experiments, participants were subliminally exposed to erotic words or pictures

(vs. neutral words or pictures), then completed measures of willingness to initiate a relationship (e.g., self-disclosing to a potential romantic partner) or to engage in activities that increase the likelihood of maintaining an existing romantic relationship (e.g., sacrificing for one’s partner). The findings indicate that subliminal exposure to sexually arousing stimuli (vs. neutral stimuli) increases willingness both to self-disclose intimate information to a potential new partner and to engage in relationship-promoting behaviors with current partners (Gillath, Mikulincer, Birnbbaum, & Shaver, 2008). Hence, merely thinking about sex, even without being aware of it, may amplify relationship-promoting goals that encourage the use of strategies that allow people to get closer to potential new partners or to intensify a relationship with an existing partner.

The Relationship Stage Model of Sexual Desire

Building on the argument that the sexual behavioral system has been altered by evolutionary forces to promote enduring bonds between sexual partners, Birnbbaum and Finkel (2015a, 2015b) developed a model that delineates the functional significance of sexual desire in relationship development. The central tenet of this model is that sexual desire is among the most important contributors to the initiation, development, and maintenance of attachment bonds in adult romantic relationships. In particular, sexual desire for one’s partner (or for a potential partner) serves the functions of assessing gut-level compatibility and determining relationship persistence at all stages. The dominance of these functions, however, varies substantially from one stage to the next. This model clarifies for whom, under which circumstances, and at which relationship stage sexual desire is most likely to influence the bonding process and the fate of the relationship.

When considering how the effects of sexual desire on relationship dynamics vary across relationship stages, the model delineates five such stages. In the *unilateral awareness stage*, A is aware of and forms some evaluative attitudes about B, but the two have not interacted (e.g., A has seen B’s online dating profile). In the *surface contact stage*, A and B have interacted, but their level of interdependence is very limited (e.g., A and B have met for a cup of coffee). In the *emerging re-*

relationship stage, A's behaviors and experiences are becoming influenced by B's behaviors and experiences, and vice versa (e.g., A and B have started spending several nights a week together). In the *established relationship stage*, A's behaviors and experiences have become strongly influenced by B's behaviors and experiences and vice versa (e.g., A and B have bought a condo together and recently adopted a puppy). In the *fiery limbo stage*, A and B have broken up, but they continue to experience sexual desire for each other (e.g., A and B have broken up and live in separate residences, but they remain attracted to each other).

Of course, the desire for sex, in a general sense, can encourage relationship initiation even before A is aware of the existence of any particular partner. For example, if A is romantically unattached, she might be more likely to go out to a bar if she is experiencing strong rather than low sexual desire (Birnbau, 2014, 2015). In this case, her desire is not directed toward any person in particular. Instead, the desire for sex functions to facilitate the pursuit of a potential partner who might serve (among other things) as a short-term or long-term sexual outlet (e.g., Fisher et al., 2002). In this way, these sexual urges increase A's tendency to put herself in contexts where she might meet such a partner. The following more detailed discussion of functional value of sexual desire across the five relationship stages focuses exclusively on sexual desire that is directed toward a specific person.

Unilateral Awareness

In this stage, which represents the minimal definition of a relationship, one individual becomes cognizant of the other individual's existence under any of a wide range of possible circumstances (e.g., an online dating profile, a college course, a local dance club). At this stage, several factors influence how likely the individual is to initiate contact with the other individual to explore the possibility of a romantic connection (e.g., assessment of this individual's romantic availability and interest in him or her). According to the relationship stage model of sexual desire, one of the key predictors of the willingness to exert effort to meet a prospective partner (e.g., sending a first contact message) is the extent to which the individual experiences sexual desire for this person. In other words, the likelihood of initiating potentially romantic contact with a specific person is much higher if he or she arouses one's sexual desire.

Surface Contact

In this stage, which represents a slightly less minimal definition of a relationship, the two individuals have interacted at least once but are only marginally interdependent. When the individual encounters the other person, he or she assesses the extent to which this prospective partner meets the standards required for further exploring the possibility of a romantic liaison (e.g., Li et al., 2013). In this mate-selection context, the desire to have sex with a potential partner may serve as a means of evaluating this partner's mate value and relationship compatibility (Birnbau & Reis, 2006). As such, it functions as a gatekeeper that ensures that only compatible partners will be pursued (see also Bredow, Cate, & Huston, 2008). Increased sexual desire for a new acquaintance may signal high mate value or compatibility and is therefore likely to motivate the individual to exert effort to start pursuing a relationship with this desirable person (e.g., asking for a follow-up date). A lack of sexual desire, by contrast, may signify incompatibility and therefore motivate withdrawal from future interactions with this person (Birnbau & Reis, 2006, 2012).

If so, partner traits that signal mate value, such as those that are theorized to promote reproductive success via parental investment or "good genes" (e.g., warmth-trustworthiness, attractiveness-vitality; Eastwick & Finkel, 2008; Fletcher, Simpson, Thomas, & Giles, 1999) may heighten sexual interest in pursuing individuals who have these traits and increase the desire to bond with them (Fletcher, Kerr, Li, & Valentine, 2014; Lemay, Clark, & Greenberg, 2010). Nevertheless, potential partners are likely to arouse sexual interest only as long as their demeanor indicates that they are compatible mates who will support one's goals (see also Holmes & Johnson, 2009). Support for this claim comes from research that explored sexual responses to a potential partner's provision of responsiveness (Birnbau & Reis, 2012). Although perceiving a prospective partner as responsive to one's needs may signal that this partner is willing to invest resources in the relationship, not all people react to such expressions of intimacy in the same way. In particular, partner responsiveness heightens sexual interest in this person among less avoidant people, but decreases sexual interest among more avoidant people. Hence, people who typically pursue intimacy goals are likely to view responsiveness as an asset in a potential partner, whereas people who pursue the goal of in-

dependence rather than intimacy are likely to be threatened by the emotional closeness imposed by responsiveness.

Emerging Relationship

Once a suitable partner is found, sexual desire for this partner may motivate a person to exert effort to build a deeply intimate relationship (e.g., spend more meaningful time together; Birnbaum & Gillath, 2006; Gillath et al., 2008). Then, as the relationship progresses from initial encounters to steady dating, partners ordinarily exhibit a rise in relationship maintenance behaviors and in their love for each other (e.g., Berg & McQuinn, 1986). At this stage of relationship emergence, sexual desire and the resulting sexual activity may function as one such ties-strengthening tool. Specifically, the more people desire their partners, the less they are likely to think about ending their relationship and beginning a new one (Regan, 2000). Although these findings imply that desiring one's partner helps a person focus resources on this partner, they do not indicate the emotional processes by which sexual desire contributes to consolidating attachment to a partner in the early stages of dating.

A recent longitudinal study has pointed to such mechanisms (Mizrahi, Hirschberger, Mikulincer, Szepsenwol, & Birnbaum, in press). In this study, both members of couples who had been dating for less than 4 months completed measures of sexual desire, frequency of sexual intercourse, and relationship-specific attachment anxiety and avoidance three times over an 8-month period. We found that relationship-specific attachment insecurities declined over time, but only among individuals who reported relatively high levels of sexual desire and high frequency of sexual intercourse. These findings imply that sexual activity carries the potential to reduce attachment defenses in the early phases of dating, which are inherently characterized by relationship insecurity (Eastwick & Finkel, 2008). By doing so, it produces a relationship environment conducive to the formation of genuine intimacy (see also Rubin & Campbell, 2012).

Established Relationships

Once the attachment between partners has become well consolidated, sexual desire may still help to maintain the relationship (e.g., Bell, Daly,

& Gonzalez, 1987; Birnbaum et al., 2006), but may become less important to its quality than other aspects of the relationship (e.g., Kotler, 1985; Sternberg, 1986). However, sex may turn out to be especially beneficial to the relationship of most people in relationship-threatening situations, when attachment-related goals of proximity seeking are particularly salient. In these situations, people may use sex to restore their endangered relationships (e.g., Birnbaum, 2014; Birnbaum et al., 2008). Frequent sexual activity can also buffer against the detrimental relational consequences of more chronic relationship deficiencies (e.g., neuroticism, poor communication; Litzinger & Gordon, 2005; Russell & McNulty, 2011). Such findings suggest that the intimacy inherent in sexual contact offers a compensatory route for satisfying the otherwise unmet attachment needs for security and love.

Fiery Limbo

Relationship restoration is not always feasible and partners may drift apart. Following a relationship breakup, ex-partners may never see each other. However, ex-partners frequently stay in touch over the course of days, weeks, or longer, and can still experience deep emotional intimacy. Moreover, they may continue to experience sexual desire for each other and even have sex (Davis et al., 2003; Mason, Sbarra, Bryan, & Lee, 2012; Spielmann, Joel, MacDonald, & Kogan, 2013). The fiery limbo stage is this postbreakup state. One of the most important predictors of the willingness to consider getting back together rather than solidifying the breakup is sexual desire: If sexual desire is weak during this period, then the partners are likely either to become friends or to part ways altogether. If, in contrast, sexual desire is strong, then the partners are likely either to return to their established relationship or hover in fiery limbo and exert effort to continue experiencing intimate contact, pending a decision about whether they are willing to get back together.

Concluding Comments and Future Directions

Sex has the potential to motivate intensely meaningful experiences whose nature and quality may vary across individuals and contexts. Sex may evoke both positive and negative affect, and it

can affirm one's desirability or threaten one's self-worth. Sex may serve as a binding force that encourages emotional bonding between sexual partners. Yet sex may be what causes partners to grow apart, such as when sexual indifference motivates them to look for partners who are more desirable or compatible. As indicated in this chapter, attachment processes may explain some of the individual differences in such sexual experiences. Specifically, mental representations of self and other, developed from early interpersonal experiences that each individual carries forward into adult interactions, apparently determine what people want out of sexual encounters, how they get their needs met, and the functional significance of sex in their close relationships.

Obviously, other forces influence the underlying functions of sex and its contribution to relationship development. The person \times context \times time interactive framework offered in this chapter can clarify for whom, under what circumstances, and at which relationship stage sex is likely to affect relationship development. As discussed earlier, sex may serve attachment-based goals and assuage attachment insecurities when the relationship is relatively vulnerable, such as in the early stages of emerging relationships, and in partners who have certain negative characteristics or undergo relationship-threatening events. In such cases, sex is most needed as a relationship promoter and is therefore most likely to function as such.

Authors of most chapters in this volume were asked to say how research has developed and theory has changed since 2008, the year the second edition of this handbook was published. In the case of attachment and sexuality, most of the published research has appeared since that date. This new chapter is being included because the subject matter is theoretically and clinically important, and because the groundwork has now been laid for future theoretical and empirical developments. More research is needed to specify mechanisms through which sex influences emotional bonding and to further clarify how early attachment experiences interact with current experiences (e.g., provision of responsiveness, safe-haven caregiving) to affect the construal of sexuality during relationship development. Future studies should also explore the dual potential of the sexual system—on the one hand, to serve as a potent relationship maintenance mechanism and, on the other, as a force motivating people to pursue alternative partners in a world of changing societal trends (e.g., new patterns of sexual communication and “advertis-

ing,” and an increase in the social acceptability of alternative lifestyles, such as open relationships and polyamory). This is a topic area in which researchers have barely scratched the surface.

Chapter 23

Same-Sex Romantic Attachment

Jonathan J. Mohr
Skyler D. Jackson

Without warning as a whirlwind swoops on an oak love shakes my heart.
—SAPPHO

Same-sex romantic relationships appear to have existed in most cultures throughout recorded history, regardless of prevailing attitudes toward homosexuality and bisexuality (Vasey & VanderLaan, 2014). The scientific study of same-sex couples has evolved over the past several decades from an early emphasis on atheoretical, descriptive research to application of theories that were originally developed to explain different-sex relationship functioning (Kurdek, 1995). The emerging empirical literature on sexual orientation and romantic relationships provides strong evidence that the similarities between different-sex and same-sex relationships far outweigh the differences (Fingerhut & Peplau, 2013).

This chapter provides a basis for applying John Bowlby's attachment theory to same-sex love relationships. The now substantial body of research using attachment theory as a framework for investigating adult romantic relationships has shown not only that romantic love may be profitably conceptualized as part of an attachment-related process but also that diverse aspects of relationship functioning can be reliably predicted by differences in the ways individuals internally represent their attachment relationships (i.e., differ-

ences in their working models of attachment; for a review of this literature, see J. A. Feeney, Chapter 21, this volume).

The vast majority of work on adult romantic attachment has focused on different-sex relationships. Although strong arguments have been made concerning the ethical importance of including lesbian, gay male, and bisexual (LGB) individuals in mainstream psychological research (Herek, Kimmel, Amaro, & Melton, 1991), relatively few publications have acknowledged the potential relevance of attachment theory to LGB people or included empirical investigations focusing on this population. Conducting research with same-sex couples may be more challenging than that with other-sex couples (e.g., may require more effort in recruiting participants) and may seem unnecessary to some, given the small numbers of same-sex couples relative to other-sex couples—particularly in light of evidence of similarities between couple types. However, we believe including same-sex partnerships in attachment research can deepen understanding of adult attachment processes. For example, the study of same-sex attachments may help to illuminate ways gender and attachment interact in the dynamics of relationship functioning.

Furthermore, relationship difficulties associated with the enduring societal intolerance of same-sex partnerships may provide an opportunity to understand the role of attachment in how couples manage chronic stress and stigma.

This chapter first explores the evolutionary basis for same-sex attraction and provides an argument for the relevance of the attachment system for LGB adults. The current empirical literature on same-sex couples is then reviewed, with an emphasis on results suggestive of attachment-related processes. Finally, Bowlby's work on fear and loss is used to illustrate ways in which the study of same-sex couples may provide fertile ground for exploring points of intersection between cultural and intrapersonal forces.

Evolution, Sexual Orientation, and Same-Sex Attachment

Perhaps one of the cleverest challenges to confront evolutionary theory is homosexuality. Homosexuality seems to be a tailor-made rebuttal of the great evolutionary credo—survival of the fittest. How do we explain what is often a lifelong preference for nonreproductive sex?

—JIM MCKNIGHT (1997, p. x)

At the core of Bowlby's (1969/1982) theory is the idea that the human propensity for establishing affectional bonds is adaptive from an evolutionary perspective: The infant-caregiver bond, the romantic partnership, and the intimate friendship all ultimately serve to enhance reproductive success. From an evolutionary perspective, the survival of an infant is usually in the best interests of both infants and their parents because they all have a stake in passing along their genes. Bowlby reviewed evidence that the attachment system in infants is activated most strongly in situations that are potentially threatening to the infant's well-being. The infant, at such times, engages in attachment behaviors that increase proximity to the parent—a figure who could provide protection in dangerous or novel situations. Attachment relationships in adulthood may serve the same adaptive function that they do in infancy. West and Sheldon-Keller (1994) argued that the “function of attachment, the provision of safety and security, remains constant throughout the life span, although the mechanisms of achieving this function change and develop with maturation” (p. 22). Thus, from an attachment perspective, romantic attachments provide adults with reliable

relationships upon which they can depend for protection, care, and support during times of greatest need (e.g., sickness, economic hardship, violent attack). Such protection increases the likelihood that adults will live longer lives, reproduce and raise children into their healthy adulthood, and possibly even provide care for the children's children. From this viewpoint, the establishment of stable romantic attachments may increase the likelihood of surviving into old age and enjoying the reproductive advantage this affords. Furthermore, the reciprocal attachments that characterize adult romantic relationships may serve to discourage dissolution and therefore provide a more secure environment for children.

The existence of same-sex romantic relationships and homoerotic attraction and behavior has long posed a vexing problem for evolutionary theorists. As one writer put it, “Homosexuals were with us through antiquity and, if recent history is any guide, are a robust minority within society. So why hasn't male homosexuality died out as a less reproductive strain of humanity?” (McKnight, 1997, p. 1). Some of the earliest uses of evolutionary theory to address same-sex attractions appeared in the medical literature of the late 19th century (Gibson, 1997). At that time, a common explanation for mental disorders was degeneration theory, which proposed that weakness of the nervous system caused individuals to be especially vulnerable to the primitive impulses constituting our evolutionary legacy. Individuals unable to resist the “beast within” were thought to fall several notches on the evolutionary ladder. Homosexuality was almost always viewed as a form of degeneration in which the original “bi-sexuality of the ancestors of the race, shown in the rudimentary female organs of the male, could not fail to occasion functional, if not organic, reversions when mental or physical manifestations were interfered with by disease or congenital defect” (Kierman, 1888, quoted in Gibson, 1997, p. 115). Although such reversions were viewed in quite negative terms (and, as demonstrated below, were often linked with masturbation), some doctors recognized the existence of genuine romantic attachments between members of the same sex:

[Sexual perversions are] frequently produced on the neurotic soil of the male and female masturbator. The female masturbator of this type usually becomes excessively prudish, despises and hates the opposite sex, and frequently forms a furious attachment for another woman, to whom she unselfishly devotes herself. (Kierman, 1888, quoted in Gibson, 1997, p. 116)

It is likely that this form of “furious” attachment was no more intense than those exhibited in other 19th-century sexual relationships. By focusing on same-sex love as a form of deviant sexuality, doctors were unable to recognize that such love was much more than a pitiable and loathsome expression of primitive sexual instincts. Although the outdated language of this example may make its absurdity evident, one does not need to look far to find similar examples from our own time. For example, same-sex couples are sometimes accused of flaunting their sexuality when exhibiting normative attachment or courting behavior, such as holding hands in public (Herek, 1991).

Bowlby also discussed homosexuality from an evolutionary perspective, but his thinking was markedly different from that of the degeneration theorists. Whereas 19th-century doctors viewed same-sex attraction as a lapse into brutish instinctive behavior, Bowlby appeared to think of homosexuality as the product of an efficient but functionally ineffective behavioral apparatus. In the first volume of his trilogy, he observed that the sexual behavioral system in same-sex dyads works perfectly well, in that the predictable outcome of orgasm is routinely achieved (Bowlby, 1969/1982). The puzzle, according to Bowlby (1969/1982), is why the sexual system would ever be organized in a way that runs explicitly counter to intuitive notions of reproductive fitness: “What makes it [same-sex attraction] functionally ineffective is that for some reason the system has developed in such a way that its predictable outcome is unrelated to function” (pp. 130–131). He illustrated this notion of misguided behavior by comparing homosexual sex to an anti-aircraft gun that works perfectly, except that it consistently destroys friendly planes rather than enemy ones. This analogy may lack appeal for individuals in same-sex relationships, but it conveys Bowlby’s idea that the sexual behavioral system of homosexuals is not serving its functional goal of reproduction.

Although Bowlby clearly saw homosexual desire as evidence of a functional mistake in the evolutionary sense, his limited discussion of the topic at no time denied that legitimate, psychologically healthy same-sex romantic attachments exist. Indeed, his writings about same-sex sexual behavior in a variety of animals primarily reveal his curiosity about the degree to which the sexual behavioral system is environmentally labile. He did not explicitly discuss same-sex couples, but it is likely that he viewed their relationships as subject to the same psychological principles as different-

sex romantic attachment relationships. Bowlby maintained that the attachment behavioral system is active from “the cradle to the grave” (1988, p. 82), and he never gave any indication that he believed this to be true only for individuals in different-sex couples. In her initial writings about adult attachment, Mary Ainsworth, Bowlby’s collaborative partner, noted that same-sex romantic attachments are likely to function in the same manner as different-sex attachments (Ainsworth, 1985, 1989). She stated that one of the main differences between these two kinds of romantic attachment is that only one of them (i.e., different-sex attachment) is sanctioned by society. This observation points to the importance of context in the development of attachment bonds—a topic discussed later in this chapter.

Bowlby’s (1969/1982) discussion of homosexuality was based on his understanding of evolutionary theory, which was not informed by the currently accepted notion that evolutionary success is focused on the survival of the gene (Dawkins, 1976; Kirkpatrick, 1998). As noted below, evolutionary theorists have described possible scenarios wherein homosexuality may contribute to reproductive fitness even when lesbians and gay men do not have children themselves.

If homosexuality is indeed “one of the clearest challenges to confront evolutionary theory” (McKnight, 1997, p. 1), then it is not surprising that attempts to explain it in terms of reproductive fitness have created such controversy. Bowlby (1969/1982) himself noted that the “task of determining precisely what the function of a certain piece of instinctive behavior is may be considerable” (p. 133). Within the past several decades, a number of interesting and provocative propositions have been made regarding the evolutionary basis of homosexuality (e.g., McKnight, 1997; Miller, 2000), and these have been met with strident opposition and critique (Dickemann, 1995; Santtila et al., 2009; Weinrich, 1995). A complete discussion of recent evolutionary theories of homosexuality is beyond the scope of this chapter, but a few of the most frequently noted theories are mentioned here.

Evolutionary theorists, faced with the puzzle of explaining the continued appearance of same-sex attraction throughout history, have assumed that there is a genetic component to same-sex sexuality (an assumption that has been supported by several twin studies; Hill, Dawood, & Puts, 2013). Although many specific theories have been advanced to address this issue, a number of them

come down to the proposition that “gay genes” might offer a direct reproductive advantage to women and men who engage in different-sex relations. Hutchinson (1959) was one of the first theorists to offer a scientifically grounded discussion of this possibility (McKnight, 1997). He applied then-current ideas about the adaptive value of the sickle-cell mutation prevalent in some African and Asian populations to evolutionary explanations of homosexuality. The sickle-cell mutation was found to increase resistance to malaria. Although homozygous sickle-cell children (i.e., children with two sickle-cell genes) exhibited strong resistance to malaria, they would often die of severe anemia before reaching puberty. Heterozygous children (i.e., children with one sickle-cell gene and one “normal” gene) would gain a measure of protection from malaria without developing the lethal anemia. These children therefore had an advantage over both the children with two sickle-cell genes and those with two non-sickle-cell genes. Arguments regarding homosexuality can, at least in theory, be made along similar lines: In this case, the assumption is that there exists genetic material that when present to a limited extent, increases the chances a person will have children, but, when present to an even greater extent, increases the chances that a person will have same-sex attractions. Thus, even if homosexuality itself reduces a person’s odds of having children (and is thus disadvantageous from a reproductive fitness perspective), the person’s biological relatives should produce a higher than average number of children.

Despite the potential for this perspective to explain the persistence of nonheterosexuality in humans over time, no “gay gene” has been identified—though several have been proposed and continue to be investigated (for a review of research on the biology of sexual orientation, see Hill et al., 2013). Some behavioral research, however, has tested hypotheses regarding genetically based characteristics that could both increase reproductive fitness among heterosexuals and increase the expression of same-sex desire in other family members. For example, Zietsch and colleagues (2008) used data from a large community data set of twins to investigate gender atypicality (i.e., the extent to which one possesses physical and behavioral characteristics associated with a different sex). The study was based on the notion that genetic material associated with gender atypicality may both increase a person’s attractiveness to potential different-sex partners, and, when present to an even greater extent, increase a person’s like-

lihood of having same-sex attractions. Zietsch and colleagues viewed this scenario as plausible given empirical evidence (largely correlational) of links between gender atypicality, attractiveness, and sexual orientation. Statistical modeling of twin data revealed that sex-atypical gender identity (i.e., the tendency to view oneself as having characteristics of a different sex) was positively linked both with nonheterosexuality and, among heterosexuals, with the lifetime estimated number of different-sex sexual partners. Analyses also suggested that these associations were driven partly by genetic material common to the characteristics. Data from female, but not male, participants supported the hypothesis that heterosexuals with a nonheterosexual twin would report a higher than average number of lifetime different-sex sexual partners.

Kin selection theory is the evolutionary perspective that has dominated much of the discourse on sexual orientation (Hill et al., 2013). Kin selection is an evolutionary strategy favoring behavior that improves the reproductive fitness of an organism’s biological relatives, even if that behavior comes at a cost to the organism’s own reproductive fitness. Wilson (1975) proposed that kin selection may explain the regular presence of homosexuality among humans, offering a view that might well be called the “helpful gay uncle and lesbian auntie” hypothesis. From this perspective, “the homosexual members of primitive societies may have functioned as helpers.... Freed from the special obligations of parental duties, they could have operated with special efficiency in assisting close relatives” (p. 555). The help provided to relatives would presumably increase the number of children who survive to reproductive age, have their own children, and pass along genetic material related to homosexuality. Empirical support for kin-selective explanations for homosexuality has been equivocal at best, with some studies aligning with the theory (e.g., Vasey, Pocock, & VanderLaan, 2007) and others casting doubt on its utility (Bobrow & Bailey, 2001; Santtala et al., 2009). These mixed results have challenged the kin selection hypothesis as an organizing theory of sexual orientation, and have led some scientists to draw on cultural and anthropological perspectives to explain mixed findings across samples and between cultures. For example, VanderLaan, Ren, and Vasey (2013) highlighted the potential importance of considering the cultural context in which kin-directed altruism may have originally evolved, and provided some evidence that humans’ ances-

tral cultures may have featured socially sanctioned male transgender roles consistent with the kin selection hypothesis.

Another theory regarding the adaptive nature of homosexuality stems from a surprisingly consistent finding related to birth order. Many studies have indicated that a man's likelihood of having same-sex attractions is directly related to the number of older biological male siblings he has (for a review, see Bogaert & Skorska, 2011). This finding is clearly sex specific because it has emerged only with respect to men and their older male siblings. Moreover, research has suggested that a similar finding does not emerge when considering older male siblings who are not genetically related. The currently favored explanation for the fraternal birth order effect is based on the idea that in childbirth, mothers come in contact with their son's blood and produce antibodies to male-specific antigens. In subsequent pregnancies with a male fetus, the antibodies cross the placental barrier and somehow influence the developing fetus in a way that increases the likelihood of future homosexuality. Although intriguing, this hypothesis remains speculative (Bogaert & Skorska, 2011). Regardless of the biological processes underlying this birth order effect, how might the link between number of older biological male siblings and same-sex desire be adaptive from an evolutionary perspective? Some scientists have proposed that homosexuality in younger male siblings may decrease the extent to which they compete with their older male siblings for female mates, as well as for the familial resources, such as property and wealth, that may increase their chances of securing mates (Apostolou, 2013; Miller, 2000). However, this hypothesis has received little direct support. Instead, proponents of this theory generally base its validity on the fact that it explains various patterns in reproduction related to homosexuality (e.g., presence of a birth order effect among men but not women).

Despite uncertainty regarding the reproductive advantages associated with the hypothesized "gay" gene or genes, many evolutionary theorists agree on the mechanisms that maintain this genetic material in the gene pool (McKnight, 1997). A form of natural selection called *balance selection* is thought to favor a heterozygous genetic blend, in which men and women possess some homosexual genetic material, but not so much that they will favor homosexual relationships. Balance selection acts to harmonize the forces of *diversifying selection*, which creates great variation in the genetic code related to sexual orientation, and

directional selection, which removes genes of lesser overall adaptive value (i.e., homosexual genes). The existence of a continuum of sexual preference among humans is considered to be evidence of diversifying selection, whereas the greater number of different-sex partnerships compared to same-sex partnerships is taken as evidence of directional selection (McKnight, 1997). According to this general approach, evolution performs a balancing act in which so-called "gay genes" are actively maintained in the gene pool, while minimizing the extent to which individuals engage in exclusively same-sex sexual behavior. The potentially adaptive nature of same-sex sexual behavior has been suggested by its occurrence even in many nonhuman animals (for a review, see Bailey & Zuk, 2009), including evidence of enduring same-sex sexual pair bonding among nonhuman primates (Pavelka, 1995).

Most evolutionary theories of same-sex attraction tend to focus on the sexual behavioral system and do not explicitly address the formation of same-sex romantic attachments. What is clear from studies of love, satisfaction, and commitment, however, is that adult same-sex romantic attachments exist (Fingerhut & Peplau, 2013). Although the sexual attractions that precede or follow the formation of same-sex attachments may be the by-products of functional "mistakes" in the evolutionary sense (Bowlby, 1969/1982), no evidence exists to suggest that same-sex romantic attachment functions in inherently different ways than different-sex attachment (see the next section for a review of this empirical literature). Regardless of the precise evolutionary significance of same-sex attractions, it is apparent that LGB individuals have made important contributions to their families, to their communities, and to society. The attachment system offers these individuals the capacity to enjoy greater safety and security through intimate bonds, and thus increase their chances of surviving into old age and making contributions to others' lives over time. Also, given the great variability in sexual behavior among LGB-identified individuals, as well as developments in artificial insemination and family structures, significant numbers of LGB people have children (Patterson, 2013). Thus, romantic attachments may also increase these individuals' ability to provide for their children, as appears to be the case for different-sex couples (Weiss, 1982).

This discussion suggests that an evolutionary perspective on same-sex romantic couples must account for two separate but related phenomena: (1) sexual attraction toward a person of the same

sex, and (2) pair bonding with a person of the same sex. Diamond (2003) has provided considerable evidence to support the idea that distinct evolutionary and biobehavioral processes underlie sexual desire and romantic love (see also Birnbaum, Chapter 22, this volume). The main evolutionary function of the sexual system seems clear: to increase inclusive fitness by orienting individuals toward potential reproductive mates. Perhaps the clearest evidence for this proposition is the rather pedestrian observation that most sexual behavior occurs between individuals of different genders (i.e., between individuals who, in principle, are capable of having offspring). Thus, the sexual system has evolved to encourage different-sex attractions. In contrast, as noted earlier, the romantic attachment system is thought to have evolved so as to encourage long-lasting relationships that can serve a protective function in childrearing. Unlike reproduction, which requires partners of different genders, the provision of protection is not tied to gender. An implication of this fundamental difference between the sexual system and romantic attachment system is that the two systems have different evolutionary roots.

Diamond (2003) described a number of studies suggesting that romantic attachment has much more in common with the infant-caregiver attachment system than with the sexual system. Her review indicates that there are substantial parallels between the emotional, biological, and behavioral processes underlying infant attachment and the corresponding processes in romantic attachment. Also, it is generally believed that the capacity for adult pair bonding evolved from the infant attachment system (Fraleigh, Brumbaugh, & Marks, 2005). Diamond (2003) argued that if these two manifestations of attachment do in fact operate similarly, then, just as the attachment system is not gender-specific for infants, the romantic bonding system should not be gender-specific among adolescents and adults. From this perspective, the tendency to form romantic attachments should not be limited to partners of different genders, and fundamental attachment-related processes should not vary according to the gender composition of a romantic dyad.

Furthermore, because the romantic attachment system is functionally distinct from the sexual system, it should be possible for same-sex attachments to be formed in the absence of sexual desire. In fact, as Diamond (2003) noted, nonsexual attachments between people of the same sex have been documented across diverse cultures

and historical periods. These passionate friendships appear to function similarly to attachment relationships that include a sexual component, featuring basic attachment behaviors such as proximity seeking in stressful situations and separation protest. Some of these nonsexual attachment relationships can even begin with the feelings of infatuation that are often associated with the early phases of traditional romantic courtships. The fact that nonsexual relationships can be “romantic,” whereas sexual liaisons can occur in the absence of love, highlights the functional independence of the attachment and sexual systems.

Adding further complexity to this picture is the reality that sex and love are not altogether unrelated. Diamond (2003) offers an interesting discussion of processes through which love may lead to sex and vice versa. Examples of the former are found in Diamond’s (2000) longitudinal study of women, all of whom self-identified as lesbian, bisexual, or “questioning” when the research first began. Some participants shared that their only experiences of same-sex attractions were in relation to emotionally intense friendships with specific women. Five years after the first interview, several participants had assumed a heterosexual identity. In these cases, the end of the passionate friendship marked the end of same-sex attractions. In contrast, a few of the lesbian-identified participants shared that they had become sexually involved with a close male friend with whom they had fallen in love, despite remaining mostly sexually attracted to women. Such examples underscore the importance of examining the effects of both intimate friendships and sexual attractions on the development of same-sex romantic relationships, all while keeping in mind the biological, interpersonal, and cultural influences on both sexual orientation and attachment bonds.

Charles Darwin (quoted in Rosario, 1997, p. 9) may not have guessed how long same-sex attractions would remain a mystery when he wrote, “We do not even in the least know the final cause of sexuality: The whole subject is hidden in darkness.” Although the evolutionary significance of sexual orientation is still unknown, there appears to be no reason to assume that same-sex romantic attachments operate according to a set of different principles (e.g., set-goals, functions) from those operating in different-sex attachments. However, the unique cultural, interpersonal, and societal dynamics that differentially affect same- and different-sex romantic relationships (e.g., gender power dynamics, social stigma, history of HIV-

related loss) may mean that, at times, attachment manifests differently and predicts distinct outcomes among these different populations. Much of the remainder of this chapter, then, compares current knowledge regarding different-sex romantic couples to emerging scholarship on male and female same-sex couples—highlighting areas of convergence, points of divergence, and areas ripe for future research.

Attachment and Same-Sex Relationship Quality

We have been together 40 years and in these 40 years we were waiting for this.

—EIGEL AXGIL (quoted in Rule, 1989, p. A8)

This statement was made by a 67-year-old Danish citizen after marrying his longtime partner, Axel Axlil, 74, in 1989. They were the first officially registered same-sex couple in modern history. Perhaps the most remarkable feature of the modern same-sex romantic partnership is its resilience in the face of widespread societal condemnation. Despite recent victories in the fight for legalization of same-sex marriage and a broader trend toward the acceptance of LGB relationships in the United States, many same-sex couples still experience stigma, discrimination, and challenges to their legitimacy (McVeigh & Maria-Elena, 2009). In spite of this hostile climate, many LGB individuals manage to forge long-term intimate relationships and enjoy the sense of security afforded by growing older with a person who is invested in one's well-being over time (Fingerhut & Peplau, 2013).

The study of romantic relationships from an attachment perspective was stimulated by the seminal work of Hazan and Shaver (1987; Shaver & Hazan, 1988), who demonstrated that the patterns of attachment found in studies of infant behavior could be profitably applied to investigations of adult love experiences. Since that time, a considerable amount of research has investigated romantic attachment and suggested that it is best conceptualized in terms of two dimensions: attachment avoidance and attachment anxiety (Brennan, Clark, & Shaver, 1998; Mikulincer & Shaver, 2007). Individuals who rely on avoidant strategies minimize their attachment needs due to expectations of rebuff or rejection by romantic partners, especially in times of stress. Thus, high avoidance is associated with discomfort with closeness and interdependence. In contrast, anxious attachment

strategies are conceptualized as a hyperactivation of the attachment system, wherein one's expression of and vulnerability to distress are exaggerated to gain the attention of partners who are believed to be inconsistently available (Pietromonaco & Barrett, 2000). High attachment anxiety is characterized by fear of abandonment, a desire to merge with one's partner, and chronic frustration with what is perceived as a lack of closeness. A sizable body of research indicates the relevance of these attachment strategies in predicting indices of relationship quality such as satisfaction and commitment (e.g., Collins & Read, 1990; Hazan & Shaver, 1987; Kirkpatrick & Davis, 1994), as well as secure-base behavior in stressful situations (e.g., Simpson, Rholes, & Nelligan, 1992; Simpson, Rholes, & Phillips, 1996; for extensive reviews, see J. A. Feeney, Chapter 21, this volume; Mikulincer & Shaver, 2007).

Little empirical work on same-sex romantic relationships has been conducted from an attachment perspective. In what may be the first such study, Ridge and Feeney (1998) collected data from individuals associated with LGB organizations in Australian universities on attachment, romantic and sexual relationships, and—to be discussed later in this chapter—self-disclosure of sexual orientation. A main goal of the study was to replicate basic attachment findings from studies on different-sex couples among a sample of individuals in same-sex relationships. As a whole, results were consistent with findings based on different-sex samples, adding to the considerable evidence that same-sex couples and different-sex couples function similarly (Fingerhut & Peplau, 2013). Attachment security was positively associated with current romantic relationship satisfaction among participants in dating relationships. Individuals endorsing an attachment pattern of high anxiety and low avoidance were more likely than others to report a history of intense love experiences—a finding compatible with the view that anxious strategies involve hyperactivation of the attachment system. The opposite was true for individuals endorsing a pattern of low anxiety and high avoidance, consistent with the view that avoidant strategies involve suppression of intense attachment-related feelings.

Other researchers have provided data on similar links between attachment patterns and romantic relationship variables in LGB individuals. These studies have found associations between attachment security and relationship quality (Elizur & Mintzer, 2003; Kurdek, 2002; Mohr, Selterman,

& Fassinger, 2013), likelihood of being partnered (Brown & Trevethan, 2010), commitment (Kurdek, 1997, 2002; Mohr et al., 2013), communication patterns (Gaines & Henderson, 2002; Mohr et al., 2013; Starks & Parsons, 2014), and partner violence (Craft, Serovich, McKenry, & Lim, 2008). These studies indicate that attachment anxiety and avoidance are linked with less positive relationship evaluations and experiences, mirroring research on different-sex couples.

A few attachment studies have directly compared heterosexual and LGB-identified individuals. Ridge and Feeney (1998) addressed the basic question of whether the relative prevalence of attachment patterns differs in LGB individuals and heterosexuals. Using both dimensional and categorical measures of attachment style, the researchers found no differences between their samples of LGB and heterosexual college students. Kurdek (1997, 2002) examined links between dimensions of attachment and relationship functioning in samples of same-sex and different-sex couples. In neither of the studies did these associations differ for the two couple types. In short, those engaging in same- and different-sex relationships have been found to be similar both in attachment style and in relational correlates of attachment style.

The development and quality of romantic relationships is believed to be a function of not only a person's own attachment pattern but also the corresponding pattern of his or her partner (J. A. Feeney, 2003). Studies of different-sex couples have suggested that people may tend to seek relationships with partners who confirm their attachment-related schemas. For example, individuals with high attachment anxiety have been found to be involved with avoidantly attached partners, who corroborate their belief that they want more closeness than their partners do (Collins & Read, 1990; Kirkpatrick & Davis, 1994). Data from a large community sample of same-sex couples suggest that this may also be true for individuals in same-sex romantic relationships (Mohr et al., 2013). Results provided evidence of partner similarity on attachment anxiety and, to a lesser extent, avoidance. Moreover, people who were highly anxious over relationships tended to have partners who reported higher-than-average levels of avoidance. These partner-matching effects were equally strong for female and male couples, and remained significant even after researchers controlled for relationship length, suggesting that similarity was not due to mutual influence over time.

For different-sex couples, there is ample evidence that partner attachment plays a role in shaping individuals' relationship experiences and evaluations; this speaks to the value of viewing attachment-related processes as part of a dynamic and potentially complex system of mutual influence in romantic relationships (J. A. Feeney, 2003). Mohr and colleagues (2013) provided evidence of similar dynamics in same-sex couples. Results were particularly robust for attachment anxiety: Both own anxiety and partner anxiety were negatively associated with indicators of relationship quality (satisfaction, commitment, trust, intimate everyday discussion), and positively associated with indicators of relationship difficulties (intensity of relationship problems, communication problems). Similar results were obtained for own avoidance, although it was unrelated to relationship satisfaction and commitment. Contrary to hypothesis, partner avoidance was negatively related to ratings of aversive communication and unrelated to all other relationship variables.

Increasingly, research is examining the intersection of attachment and sexual behavior among LGB people. In one example, Ridge and Feeney (1998) found that dismissing participants were most likely to endorse casual sex and view sex solely in terms of its physical rewards, just as has been found in studies of heterosexuals (see J. A. Feeney, Chapter 21, this volume). Findings in a similar vein emerged in a study of male couples (Starks & Parsons, 2014), which found that avoidant men and their partners were more likely than others to report having unprotected anal intercourse with casual sex partners. Another recent study investigated links between sexual exclusivity and same-sex romantic relationship quality, examining the possibility that these links are influenced by attachment security (Mohr et al., 2013). As hypothesized, exclusivity and relationship quality were unrelated for secure participants but positively related in dyads in which either partner was high in attachment anxiety. Thus, although LGB people are less likely than their heterosexual counterparts to prefer exclusivity (Fingerhut & Peplau, 2013), high levels of attachment anxiety may increase the likelihood that outside sexual partners are viewed as threats to the primary relationship.

Several investigations of attachment and relationship satisfaction in different-sex couples have uncovered ways in which gender and attachment interact in predicting satisfaction. Probably the most robust result is that participants' and partners' ratings of relationship quality are best

predicted by females' levels of abandonment anxiety and males' levels of avoidance (J. A. Feeney, Chapter 21, this volume). It has been hypothesized that these effects may be due to processes related to gender role socialization, such as a "wife demands, husband withdraws" style of conflict that has been linked with relationship dissatisfaction (Heavey, Layne, & Christensen, 1993). This relational dynamic is strongly suggestive of a female anxious and male avoidant pairing, and couples with this combination of attachment styles are precisely those that have been found to give the lowest ratings of relationship satisfaction in some studies (J. A. Feeney, 1994; Kirkpatrick & Davis, 1994). In addition to gender differences in the links between attachment and relationship functioning, differences have been found in ratings of attachment itself. For example, a study of romantic attachment across 62 cultures indicated that men reported higher levels of dismissing avoidance than women in virtually all regions sampled (Schmitt et al., 2003).

Do similar gender-related patterns emerge in same-sex couples? Even for those acquainted with the sexual orientation literature, it is difficult to make an educated guess about the answer to this question. One might guess that there would be fewer gender-related patterns in same-sex couples given evidence that same-sex couples are less likely than different-sex couples to base their relationships on traditional gender roles (Peplau & Fingerhut, 2007). However, research has indicated that lesbians and gay men differ in ways that are consistent with gender socialization processes (Fassinger & Arseneau, 2007), which might suggest that attachment-related dynamics in same-sex couples may be influenced by traditional gender patterns. Given these opposing perspectives, it is perhaps fitting that the limited empirical data on this topic offer an unclear answer to the question of gender. Contrary to gender stereotypes, studies have provided evidence of higher levels of attachment anxiety in gay and bisexual men than in lesbian and bisexual women (Mohr et al., 2013; Ridge & Feeney, 1998). Fear of abandonment may be especially high in male same-sex partners for a variety of reasons, including greater prevalence of non-monogamy in male couples (Fingerhut & Peplau, 2013), expectations of lack of intimacy based on restrictive male gender roles (Brown, 1995), and exposure to the particularly negative attitudes and stereotypes associated with male homosexuality and bisexuality (Kite & Whitley, 1996). Findings from one study indicate that the general patterns

of results regarding attachment and relationship functioning tend to be quite similar for female and male same-sex couples (Mohr et al., 2013). The main gender difference was the stronger relation for men between attachment security and indicators of relationship quality.

Dynamics reminiscent of traditional gender norms emerged in one study that examined attachment strength—as opposed to attachment style—in a sample of heterosexual and LGB youth (Diamond & Dubé, 2002). Each participant named individuals with whom he or she was most likely to exhibit four classes of attachment behavior: proximity seeking, separation distress, safe-haven, and secure-base behavior. The individual who was named in relation to the most classes of attachment behavior was viewed as the participant's principal attachment figure. Strength of attachment to the attachment figure was measured as a function of the number of classes of attachment behavior in which the participant engaged with the attachment figure. When the principal attachment figure was a romantic partner (as opposed to a platonic friend), the strength of attachment was significantly higher for lesbian and bisexual women than for their gay and bisexual male counterparts. For male participants, attachment strength was somewhat higher for heterosexual youth than for sexual minority youth when the attachment figure was a romantic partner, but somewhat lower when the attachment figure was a friend. For female participants, attachment strength was somewhat higher for sexual minority youth than for heterosexual youth when the attachment figure was a romantic partner. Diamond and Dubé (2002) speculated that these differences in strength of attachment may reflect gender role socialization practices, wherein expression of tender feelings and intimacy needs is discouraged in males and encouraged in females. Restrictive male gender role norms may explain why attachment strength was lowest in romantic relationships with two men and highest in relationships with two women. Of course, research is needed to determine the degree to which these gender differences were in part a function of the age group studied.

One unexplored area in which attachment-related gender differences may be expected in same-sex couples is sexual exclusivity. Male same-sex couples have been found to be more likely than any other type of couple to engage in sexual activities outside the couple relationship, and no significant differences in relationship satisfaction have been found among male couples based

on sexual exclusivity (Fingerhut & Peplau, 2013; Kurdek, 1995). This finding suggests a few interesting hypotheses about the possible moderating role of gender in links between nonmonogamy and attachment. First, sex outside of the relationship may be more likely to be perceived as a threat to the attachment relationship in different-sex and female couples than in male couples. If this is true, then nonmonogamy should be more likely to activate the attachment system in different-sex and female couples than in male couples. Second, although attachment security has been linked to sexual exclusivity in a primarily different-sex sample (Hazan, Zeifman, & Middleton, 1994), this connection may not be as strong for men in same-sex relationships (Ramirez & Brown, 2010). Of course, the extent to which these hypotheses are confirmed may depend on cultural norms regarding monogamy, particularly given evidence that cultures vary substantially in views about and engagement in sex outside of a primary relationship (Munsch, 2012).

In short, these findings suggest that basic propositions regarding attachment dynamics in romantic relationships have been supported for same-sex couples, as well as for different-sex couples. Individuals in same-sex couples who are able to establish closeness with their partners and have trust in their partners' availability tend to be more satisfied with their relationships and to report more positive communication patterns. Furthermore, individuals' reports of relationship quality appear to be related to their partners' capacity for closeness and trust. A curious mixture of results has been found regarding the interplay between gender and attachment—some consistent with traditional gender roles, and others inconsistent. Greater clarity may be gained through couple research including assessment of variables that may moderate gender effects, such as adherence to gender role norms, adherence to traditional relationship values, and belief in negative stereotypes about same-sex couples. Differences between male and female same-sex couples with regard to sexual exclusivity may prove to be an area worthy of investigation from an attachment-theoretical perspective. Also, although it seems likely that attachment patterns play a role in the trajectory of same-sex romantic relationships (as has been found for different-sex couples; see J. A. Feeney, Chapter 21, this volume), longitudinal studies of same-sex couples are needed to confirm this proposition. Finally, caregiving dynamics in same-sex couples have been little studied, and would be valuable

to examine from an attachment-theoretical perspective, as suggested by research on caregiving in different-sex couples (e.g., B. C. Feeney & Collins, 2001; see also B. C. Feeney & Woodhouse, Chapter 36, this volume).

Fear, Safety, and Same-Sex Relationships

There were too many of them and they just knocked me to the floor. I couldn't get up and then they started kicking me in the back and the head. There was a group of people nearby who just stood there and did nothing, that's the worst thing about it.

—TONY MINION (who, with his same-sex partner, was attacked by five youth; quoted in James, 2012)

LGB individuals have achieved substantial political and social gains in the past several decades, but institutional oppression and social stigma toward the expression of same-sex desire remain realities throughout much of the world (Ahmad & Bhugra, 2010). Clinical theory and empirical research suggests that the climate of intolerance does indeed affect same-sex couple functioning, despite the movement toward greater acceptance of homosexuality and bisexuality. For example, clinical writings have suggested that both external manifestations of anti-LGB prejudice (e.g., violence, discrimination, rejection) and the internalization of negative views of same-sex attraction (e.g., internalized homonegativity, discrimination expectations) can lead to diminished satisfaction and greater conflict in same-sex couples (Brown, 1995), especially when partners differ with regard to their levels of internalized homonegativity and comfort with being "out of the closet" (Brown, 1995; Patterson & Schwartz, 1994). Such propositions are beginning to receive empirical support: Research findings have suggested that same-sex relationship quality is inversely related to perceived discrimination and stigma sensitivity (Mohr & Fassinger, 2006; Otis, Rostosky, & Riggle, 2006), internalized homonegativity (Balsam & Szymanski, 2005; Elizur & Mintzer, 2003), parental disapproval of individuals' sexual orientation (Smith & Brown, 1997), and chronic nondisclosure of sexual orientation (Berger, 1990).

Understanding the context of LGB individuals' lives is a prerequisite to articulating the unique ways in which attachment variables may play roles in determining same-sex romantic relationship

functioning. The LGB identity development process often involves confusion, anxiety, and internal conflict. Many adolescents experiencing same-sex attractions hide this aspect of their lives and thereby suffer from a profound sense of emotional isolation (Savin-Williams, 1995). Those who do openly express their sexual orientation run the risk of ridicule, rejection, and threat. Data from large-scale studies in public high schools provide evidence that LGB youth experience higher levels of bullying, sexual harassment, coercive sex, dating violence, and threat or injury involving a weapon than do heterosexual youth (Goodenow, Szalacha, & Westheimer, 2006; Williams, Connolly, Pepler, & Craig, 2005). Not surprisingly, these studies also indicate that LGB youth are more likely to skip school due to feeling unsafe, as well as to report poor psychosocial functioning and little social support. The climate for LGB individuals is, to a great extent, a function of formal policies regarding homosexuality. Although a number of countries have introduced LGB-affirming policies over the past several years, same-sex sexual activity is criminalized in over 70 countries globally (Itaborahy, 2012). In some countries, homosexuality or same-sex sexual behavior is punished by flogging or death. The accumulated findings of studies such as these provide a sobering view of the difficult circumstances faced by many LGB individuals.

Given these precarious conditions, LGB individuals must learn to identify potential sources of threat and to manage the fear, shame, and anger associated with pervasive anti-LGB stigma and hostility (de Monteflores, 1993; Troiden, 1993). The process of learning to identify sources of possible danger is an important component of the fear behavioral system. Bowlby (1973) wrote extensively about humans' predisposition to react in a self-protective fashion to certain natural or innately recognized clues to danger (e.g., darkness, sudden noise, aloneness), as well as to cultural clues to danger that are learned by observation or personal experience. According to Bowlby, fear reactions are activated both by threatening stimuli (e.g., the approach of a hostile peer) and by inaccessibility of attachment figures (including perceived threats to the accessibility of attachment figures). An individual's total fear reaction at a given time is thought to be an additive function of all the fear stimuli present in the situation. Bowlby identified three behavioral outcomes of fear reactions: immobility (i.e., freezing), increased distance from the feared situation (i.e., fleeing), and increased proximity to one's attachment figure (i.e., seek-

ing). Individuals who are able to use their attachment figures as a secure base for exploration are believed to be less susceptible to fear stimuli than those with insecure attachments.

How might the attachment and fear systems come into play in the process of LGB identity development? If LGB identity development is conceptualized as an exploratory process, then attachment insecurity "may increase susceptibility to fear with regard to the tasks of identity development and curtail the exploration that is often critical in forging a positive LGB identity" (Mohr & Fassinger, 2003, p. 483). Support for this hypothesis has been found in a number of studies indicating that attachment insecurity is linked to negative identity and nondisclosure of sexual orientation (Jellison & McConnell, 2003; Mohr & Fassinger, 2003; Wells & Hansen, 2003). Although the data from these studies did not provide a means of exploring causal relations between attachment and LGB identity variables, the results suggest that attachment insecurity is associated with heightened fear and anxiety about behaviors that are thought to reflect acceptance and openness regarding one's sexual orientation. Responses to this fear and anxiety may involve actively "fleeing" the challenging tasks of LGB identity development, as well as "freezing" one's identity formation process.

The developmental tasks faced by LGB individuals may present what, from an attachment perspective, might be considered double-bind situations. For example, the process of *coming out* (i.e., disclosing one's sexual orientation) to one's parents may involve risking rejection from the very figures to whom one turns in times of distress. Although disclosure to parents is probably challenging for most LGB individuals, the difficulty of the coming-out process is probably even greater to the extent that the parent and child have insecure attachment patterns. Attachment insecurity could exert this effect not only through the poorer interpersonal skills associated with higher levels of anxiety and avoidance but also diminished capacity to negotiate intergroup contact (such as that between LGB youth and their heterosexual parents). This latter possibility is underscored by research suggesting that attachment insecurity is associated with higher levels of outgroup devaluation and threat appraisal (Mikulincer & Shaver, 2001). Few data are available on parent and child attachment dynamics in the coming-out process. However, research suggests that perceptions of early parental caregiving style are linked to likelihood of coming out and degree of parental rejection for one's

sexual orientation (Carnelley, Hepper, Hicks, & Turner, 2011; Mohr & Fassinger, 2003). Parents with anti-LGB values may reject their children, regardless of the degree to which they provided a good early caregiving environment. This may help to explain research suggesting that LGB adults are less likely than their heterosexual counterparts to see their parents as a defining feature of their self-concept (Wilson, Zeng, & Blackburn, 2011).

An interesting implication of this possibility is that parent reactions to an LGB youth's coming-out process may alter his or her working models of attachment. A study of gay and bisexual men supported a model in which the association between memories of childhood gender nonconformity and current attachment security was explained by degree of anti-LGB rejection from parents and peers (Landolt, Bartholomew, Saffrey, Oram, & Perlman, 2004). The impact of parental reactions to coming out on LGB individuals' working models of attachment need not be only negative: LGB children may actually come to view their parents as more responsive and reliable as a result of a positive coming-out experience. Such changes may then broaden into a more positive general working model of attachment. Indeed, Carnelley and colleagues (2011) demonstrated that among sexual minorities, positive reactions from one's mother were negatively associated with romantic anxiety among adult gay men. Similarly, our work has indicated that parental support for one's LGB sexual orientation is related to current romantic attachment security, identity, and outness—even when we controlled for memories of early caregiving environment (Mohr & Fassinger, 2003). Although these models have yet to be tested through longitudinal research, the cross-sectional data are consistent with Bowlby's (1988) assertion that working models of attachment can change—for better or for worse—in response to significant experiences with caregivers throughout the lifespan. Regardless of the direction of causal influence between working models and experiences with caregivers, there is little question that LGB youth benefit from parental support. Hershberger and D'Augelli (1995) provided evidence that perceived familial support can serve as a buffer against the deleterious effects of victimization, particularly in regard to more threatening acts of violence.

Just as in the parent-child relationship, same-sex romantic relationships are not immune from double-bind situations. Consider, for example, the case in which one or both partners in a same-sex couple have internalized societal anti-

LGB values and attitudes (i.e., have high internalized homonegativity). Such individuals are in the position of desiring romantic attachment relationships that go against their own value systems. Those who develop romantic relationships with same-sex partners may experience a push-pull dynamic, in which they simultaneously desire same-sex intimacy while wishing for distance from partners whose sex embodies the very opposite of what they view as acceptable. As noted earlier, indirect evidence for this proposition has been provided by studies showing that internalized homonegativity is a risk factor for romantic relationship difficulties in same-sex couples. The potential complexity of stigma-related dynamics is underscored by evidence that stigma functions at the dyadic level in same-sex romantic relationships (Mohr & Fassinger, 2006).

Such findings, taken together with attachment research, suggest ways in which attachment and stigma-related variables may be intertwined in determining same-sex relationship functioning. For example, as noted earlier, several studies have found an association between attachment insecurity and internalized homonegativity. One interpretation of this association is that internalized homonegativity may discourage the formation of same-sex bonds in which intimate closeness and trust can be tolerated. Although this proposition has not been tested directly, one study indicated that internalized homonegativity predicted decreases in closeness and commitment over a 2-month period among college students in same-sex dating relationships (Mohr & Daly, 2008). The irony of such a state of affairs is that the inability to use a partner as a secure base for exploration of an LGB identity may prevent an individual from gaining the experiences necessary to decrease levels of internalized homonegativity.

Acute stressors, such as the experience of anti-LGB violence or threats of violence, may also serve to activate the attachment behavioral system. The attachment system is believed to have evolved to ensure individuals' safety at times of greatest threat (Bowlby, 1973). Individual differences in attachment representations are expected to lead to differences in responses to threat (Simpson & Rholes, 1994). Research on responses to acute stress suggests that avoidant victims of anti-LGB violence may be expected to minimize both the impact of such an event and the need for support, whereas anxious victims may be expected to focus on their distress, to blame themselves, and to experience an intense need for soothing from their

attachment figures (Mikulincer, Florian, & Weller, 1993; Simpson et al., 1992). Secure victims, however, may be expected to seek direct support for their distress (i.e., to use their partners as a safe haven) and to experience less symptomatology than their insecure counterparts. These different attachment-related strategies for coping may directly affect relationship functioning, or they may affect relationship functioning indirectly through the degree to which they maintain levels of symptomatology resulting from the traumatic stressor. For example, increased use of avoidant behaviors after an incident of anti-LGB violence may affect relationship quality directly through greater avoidance of intimacy and interdependence, and indirectly by maintaining depression levels, which in turn affect couple functioning.

A recent study, however, did not support the hypothesis that attachment security mitigates the negative effects of stigma on same-sex relationship quality (Mohr et al., 2013). Specifically, attachment security did not moderate links between minority stressors (e.g., experiences of anti-LGB violence and discrimination, internalized stigma) and relationship functioning. Similarly, another study failed to support the hypothesis that attachment security buffers the impact of perceived discrimination on distress among LGB people (Zakalik & Wei, 2006). Taken together, these two studies suggest that attachment and minority stress may influence well-being independently rather than interactively. That said, both studies had design elements limiting their ability to provide a strong test of the security-as-buffer hypothesis, including low levels of minority stress and omission of significant sources of minority stress (e.g., chronic self-concealment of sexual orientation). Perhaps most notably, reports of prejudice and discrimination in both studies were retrospective and focused on events that may have occurred many months or years prior to participation. Attachment may reduce the negative impact of specific stressors on psychosocial functioning at the time of the events rather than a substantial time after their occurrence. This possibility seems theoretically plausible because the attachment system itself is a dynamic system that is activated in response to perceived threat.

Finally, the relative invisibility of committed same-sex couples may make LGB individuals more vulnerable to negative societal messages regarding prospects for long-term relationships (Brown, 1995). For example, individuals may in-

ternalize the message that same-sex partnerships are primarily defined by sex, and are therefore under continual jeopardy of dissolution due to sexual temptations outside of the relationship or to sexual boredom. Individuals may also believe that same-sex relationships are less legitimate than different-sex relationships because of the relative lack of public, legal, and, in many cases, familial recognition of such relationships (Ainsworth, 1985; Brown, 1995). For LGB people with high levels of attachment anxiety, these beliefs may pose serious threats to their sense of security and lead to chronic activation of the attachment behavioral system. Avoidantly attached people, on the other hand, may respond to such beliefs by maintaining even greater distance than usual from attachment figures. Brown speculated that individuals who have internalized these types of societal messages may be vulnerable to romantic jealousy because they typically view same-sex partnerships as inherently less stable than different-sex relationships. Evidence that insecurely attached individuals are more susceptible to romantic jealousy (Collins & Read, 1990) and to maladaptive responses to jealousy (Sharpsteen & Kirkpatrick, 1997) suggests that the forces of societal heterosexism and attachment may be intertwined in complex ways.

Although the focus of this discussion has been on attachment, it is worth noting that similar dynamics may occur with respect to caregiving processes in same-sex couples. Research on different-sex couples has indicated that avoidant individuals tend to demonstrate lower levels of emotional support and responsiveness compared to others, particularly when their partners are viewed as distressed and needy (B. C. Feeney & Collins, 2001). There is no reason to believe that this basic dynamic would differ in same-sex couples. However, such dynamics would be expected to emerge not only in the stressful situations that all couples face but also in the manifestations of minority stress that are specific to same-sex couples (e.g., anti-LGB rejection, discrimination, violence).

This section has featured examples of attachment-related issues that are common among same-sex couples through their association with the enduring invisibility and hostility faced by LGB individuals. These examples may have given the impression that societal heterosexism, internalized homonegativity, and romantic attachment insecurity weave a web so pervasive and formidable that no same-sex couple can escape a miserable

fate. As noted earlier, however, same-sex couples appear to be as satisfied and well adjusted as different-sex couples (Fingerhut & Peplau, 2013). Brown (1995) observed that all same-sex couples must face heterosexism and internalized homonegativity, even couples that have long and happy histories: “I ... know firsthand the challenges that an oppressive reality can throw in the faces of the most happy and well-functioning couples, even when both partners are skillful communicators with a strong commitment to the functioning and health of the relationship” (p. 276). Perhaps, as Simpson and Rholes (1994) have suggested, successfully facing adversity may actually strengthen such a couple’s functioning. Learning with one’s same-sex partner to negotiate the challenges posed by heterosexism and internalized homonegativity may provide a basis for revising and improving working models of attachment.

Despite such possible benefits of facing adversity, same-sex couples would probably benefit even more from systematic efforts to reduce sources of adversity through legal recognition of same-sex romantic relationships. Public legitimization of same-sex couples may strengthen relationship functioning in a number of ways (e.g., through larger support networks for couples, greater visibility of couple role models, and increased valuing of same-sex relationships). Legal recognition may also create structural barriers to relationship dissolution by increasing the seriousness with which partners take their commitment and requiring more effort of partners who wish to end a relationship. Indeed, evidence suggests that, for same-sex partners, legal recognition is associated with greater investment in the relationship (Fingerhut & Maisel, 2010) and increased relationship continuity (Balsam, Beauchaine, Rothblum, & Solomon, 2008).

Such findings raise the possibility that legal recognition may even lessen the effects of insecure attachment on risk of breakup. Legislation granting same-sex couples legal recognition has been passed in approximately 30 countries, starting with Denmark in 1989 (“Timeline of same-sex marriage,” 2014). At this writing, 19 states in the United States provide some type of mechanism for same-sex couples to receive all or most of the state-level rights associated with different-sex marriage (CNN Library, 2014). Despite these developments, it is worth noting that same-sex couples are not given any legal recognition in most parts of the world.

Loss in Same-Sex Relationships

Several weeks later I was cleaning the garage and found one of his old shirts tossed in a corner. It still smelled like him—that light orange odor. I also found our old beach ball, but I could not let the air out—his breath was in it.

—KENNETH MCCREARY (1991, p. 144)

Bowlby was deeply concerned with the psychological repercussions of losing one’s attachment figure—a fact that is not surprising given the central role he accorded to achieving a sense of security and safety through attachment bonds. The final volume of his *Attachment and Loss* trilogy, *Loss: Sadness and Depression*, is devoted to the study of loss and mourning. Bowlby (1980) attempted to explain the process of bereavement from an ethological perspective, and therefore to normalize the intense affective, cognitive, and behavioral shifts that commonly accompany loss. He suggested that reactions to loss can be viewed as part of a broader category of separation from one’s attachment figure. From an attachment perspective, the specific sequence of numbing, protest, despair, and reorganization found in infants following a prolonged separation is evidence of an innate behavioral system that has evolved to maximize proximity to caregivers (Bowlby, 1980); this cycle has been amply documented among infants, children, and heterosexual adults (Bowlby, 1980; Fraley & Shaver, Chapter 3, this volume).

Working models of attachment are viewed as moderators of the bereavement process. Anxious attachment, for example, has been linked to chronic mourning in adults (Bowlby, 1980). A person with high attachment anxiety who has lost a romantic partner through either death or relationship dissolution is likely to experience an extended period of yearning for the missing partner, characterized by high levels of anxiety and depression, as well as by unusual difficulty in resuming normal daily routines (Fraley & Shaver, Chapter 3, this volume). Conversely, an avoidant individual is likely to have minimal grief reactions to loss. Although Bowlby believed the suppression of grief to be associated with problems adjusting to loss, debate still continues about the degree to which this is the case (Fraley & Shaver, Chapter 3, this volume).

The attachment literature on loss and bereavement has not yet included reference to same-sex couples, but results from empirical studies of relationship dissolution can be interpreted

from an attachment perspective. For example, one study of adjustment to dissolution of romantic relationships indicated that male and female same-sex couples did not differ from different-sex couples with regard to reasons for separation or levels of separation distress (Kurdek, 1997). The finding of no difference in distress levels among types of couples suggests that the attachment system may operate similarly for same-sex and different-sex couples in the context of relationship dissolution. Kurdek also found that predissolution levels of neuroticism (a correlate of attachment anxiety; Noffle & Shaver, 2006) predicted post-dissolution levels of separation distress. This result is consistent with the notion that high attachment anxiety is associated with especially difficult recovery from loss and prolonged separation. In an earlier study of relationship dissolution, Kurdek (1991) found that participants who reported experiencing few postdissolution adjustment difficulties placed a low value on dyadic attachment and reported low levels of psychological distress. Given that avoidance is associated with devaluing attachment needs and underreporting symptomatology (Dozier & Lee, 1995), this result may suggest that avoidant LGB individuals tend to report low levels of adjustment problems after ending a romantic relationship. Similar findings have emerged in research with individuals in different-sex relationships. For example, Simpson (1990) found that avoidant men reported especially low levels of emotional distress 6 months after ending a romantic relationship.

The AIDS epidemic forced many gay male couples to confront issues of death and bereavement prematurely. The literature that has emerged from this epidemic provides ample evidence of loss and grieving in the context of same-sex romantic love. Folkman, Chesney, Collette, Boccellari, and Cooke (1996) conducted one of the most intensive studies of AIDS-related bereavement. This study examined preloss predictors of the course of postloss depression in 110 gay men whose partners died of AIDS-related complications. Each man was assessed bimonthly for a 10-month period, starting 3 months before the partner's death. The findings, described below, are consistent with many of Bowlby's assertions regarding loss.

First, although not surprising, the levels and persistence of depression found in this study were comparable to those found in bereaved partners of different-sex married couples, suggesting that few differences exist in the degree to which bereaved

partners in same- and opposite-sex couples experience despair. Folkman and colleagues (1996) constructed a predictive model of postloss depression that included variables representing a variety of domains: demographic, mental health, physical health, stress, resources, and coping. The only significantly predictive demographic variable was length of relationship. Interestingly, caregiver burden did not predict the course of postloss depression. However, the ability to view caregiving in positive terms was linked with faster recovery from postloss depression, consistent with the idea that people who are compulsive or anxious caregivers may be especially vulnerable to chronic mourning (Bowlby, 1980).

One important finding of Folkman and colleagues (1996) is that participants who reported high levels of preloss depression were more likely to have a rapid recovery from postloss depression than those who reported low levels of preloss depression. Interview data indicated that the caregivers were largely preoccupied with the ongoing losses associated with their partners' illness. Depressive mood in response to these losses may indicate a process wherein individuals were beginning to disengage from their partners in preparation for the impending death. This process of beginning bereavement prior to the loss of a partner may be viewed as an early phase of what Bowlby (1980) referred to as the stage of "reorganization." According to Bowlby, healthy recovery from loss requires an acknowledgment that the deceased is no longer available, combined with the ability to maintain a continuing secure bond with the deceased. Thus, beginning to disengage from one's partner before the partner's death may facilitate the process of reorganizing one's life and working models of the partner after the loss. Evidence of continuing bonds with deceased partners is found in such important symbols as the AIDS Memorial Quilt, commemorating those who have died of AIDS-related causes in the United States through panels created by the bereaved (Shelby, 1994).

Folkman and colleagues (1996) also found that levels of depression in bereaved partners who were HIV-positive did not decrease over the 7-month period following the loss. Similar results were found in another longitudinal study, wherein gay male participants who were both bereaved and HIV-positive reported the highest levels of distress (Martin & Dean, 1991). From an attachment perspective, these HIV-positive caregivers may have

felt the need to serve as strong, reliable figures for their partners, while simultaneously experiencing attachment distress related to their own illness and the unavailability of their partners as caregivers for them. Thus, HIV-positive caregivers may feel compelled to hide their own attachment distress, which may subsequently lead to difficulties in processing the impending loss.

It is worth noting that what little scholarship exists on same-sex partner bereavement disproportionately focuses on partner loss due to HIV-related illnesses. A number of scholars have highlighted the inappropriateness of generalizing such results to other experiences of same-sex romantic loss (e.g., Bent & Magilvy, 2006; Hornjatkevyc & Alderson, 2011). For example, theoretical and qualitative scholarship has begun to explore the unique bereavement needs and barriers faced by lesbians (e.g., Broderick, Birbilis, & Steger, 2008; Jenkins, Edmundson, Averett, & Yoon, 2013). Lesbians typically do not face HIV-related stigma upon the loss of a partner and are theorized to construct relationship dynamics that differ from gay male relationships in emotional intimacy and balance of power, all of which may influence the experience of loss (Broderick et al., 2008). Gay men who have lost their partners to non-HIV-related causes are also theorized to face unique concerns, such as a lack of resources or support groups for gay men dealing with non-HIV-related bereavement (Hornjatkevyc & Alderson, 2011). They may face stigma due to the erroneous assumption that their partner died of HIV-related causes (and that they, therefore, are likely HIV-positive) and may feel compelled to distinguish their loss from HIV-related losses.

Finally, it is important to highlight the potential role of normative stigma-related hardships (e.g., peer rejection, social discrimination) in the bereavement process of LGB people who have lost a same-sex partner. Facing these hardships may help LGB people build resilience and resources for coping with a traumatic loss (Grossman, D'Augelli, & Dragowski, 2007); however, such challenges also may present unique barriers in the bereavement process. For example, some writers have suggested that loss of a same-sex partner may trigger feelings associated with earlier losses due to sexual orientation stigma (e.g., family and peer rejection, disconnection from racial/ethnic roots; Broderick et al., 2008). Also, being LGB and bereaved may be complicated given the potential for encountering prejudice (Almack, Seymour, & Bel-

lamy, 2010; Fenge & Fannin, 2009). For example, individuals may choose to meet their bereavement needs by accessing social support, which generally requires a disclosure of one's sexual minority status and may lead to invalidation or rejection as an LGB person. Indeed, qualitative research has suggested it is not unusual for bereaved LGB elders to find that heterosexual peers, family members, and mental health service providers fail to recognize the significance of their partnership—or, in some cases, serve as sources of anti-LGB condemnation. A grieving individual from a same-sex couple may attempt to preempt such experiences by concealing or minimizing their bereavement from people to whom they would otherwise disclose their loss. Those who either trivialize or distort the nature of their same-sex partnership (e.g., referring to a partner as a roommate) may experience decreased support during bereavement (Hornjatkevyc & Alderson, 2011). LGB people who choose to completely hide their bereavement may be at risk for *disenfranchised grief*, which refers to “a loss that is not or cannot be openly acknowledged, publically mourned or socially supported” (Doka, 1989, p. 4). Disenfranchised grief has a growing presence in the literature on same-sex partner loss and bereavement because it is theorized to compound the difficulties of the grief process.

Although research is equivocal on the relation between social support and bereavement symptomatology (Stroebe, Folkman, Hansson, & Schut, 2006), theoretical work and empirical studies on same-sex bereavement suggest that lacking support or facing rejection may prolong or complicate the grieving process (Bent & Magilvy, 2006; Jenkins et al., 2013). Of course, opportunities for receiving support are naturally influenced by the extent to which LGB persons have revealed their sexual minority status to others. When individuals facing a loss are not “out” to those from whom they would seek support, then they must make a difficult decision: Conceal the loss and relinquish opportunities for support, or disclose their sexual orientation at what is already a distressing time. Differences in disclosure have been linked with attachment avoidance level (Mohr & Fassinger, 2003) and sociocultural variables associated with environmental support for LGB people, such as age cohort (Almack et al., 2010) and race/ethnicity (Moradi et al., 2010). Such findings highlight the potentially complex interplay between attachment and culture in the bereavement process for those who have lost a same-sex partner.

Looking Back, Looking Ahead: Summary and Conclusions

Our purpose in this chapter has been to articulate ways in which attachment theory may both contribute to and profit from the study of same-sex romantic relationships. Attachment-relevant research in this area has progressed in a slow but steady fashion in recent years. This gradual and incremental progress is evident when comparing this version of the chapter with the version in the 2008 edition of the *Handbook of Attachment*. Little has changed, for example, in research and theory on the evolutionary basis of sexual orientation, aside from new evidence that cultures vary widely in the extent to which the social roles of homosexual men are consistent with the kin selection hypothesis. New research on romantic relationship functioning has continued to support the view that attachment functions similarly in same-sex and mixed-sex relationships, broadening knowledge through the study of intimate partner violence, relationship status, communication patterns, and partner effects on relationship quality. To a lesser extent, new research in this area has provided insight regarding issues that differentiate same-sex couples from mixed-sex couples, such as work testing attachment security as a relational resilience factor with respect to effects of nonmonogamy and minority stress on relationship quality. The empirical literature on attachment and stigma now features additional findings consistent with the view that parental rejection based on a child's LGB orientation can influence the child's romantic attachment security. New work also raises questions about whether attachment security can mitigate the adverse effects of LGB minority stressors. Finally, this updated chapter features new work on loss and grief in same-sex couples, reflecting an increase in research on loss unrelated to HIV (including a welcome greater focus on female couples). New research and theory in this area has illuminated ways anti-LGB stigma may give rise to the experience of "disenfranchised grief" among people who have lost a same-sex partner.

The relatively slow pace of progress in these research areas is likely due to multiple factors, some of which may differ across specific areas of investigation. However, in no case is the slow pace due to a lack of potential new directions for research. For example, although scholarly interest in the evolutionary basis of homosexuality is not new, nearly all the literature on this topic prior to 2004 has been described as "overwhelmingly theo-

retical and speculative, with no grounding in any quantitative data whatsoever" (Vasey & VanderLaan, 2014, p. 369). Genetic and cross-cultural research on sexual orientation over the past decade has highlighted potentially useful future directions and may generate greater enthusiasm for this area of scholarship. Beyond the methods explored to date, we believe cross-species research methods have potential for testing hypotheses regarding the evolutionary function of homosexuality and bisexuality. Fraley and colleagues (2005) used comparative and phylogenetic methods to identify characteristics of species exhibiting adult attachment, and to determine whether those species-level associations were due to shared ancestry or convergent evolution (the latter indicating a functional relation). Similar methods could be used to provide an entirely new perspective on kin selection processes and other characteristics hypothesized to accompany same-sex desire and pair bonding.

The study of same-sex couples promises to illuminate points of intersection between attachment processes and stigma, stress, and societal oppression in the functioning of romantic relationships. We believe longitudinal and macro-level research can contribute to understanding in this area of scholarship. For example, although recent research has indicated that attachment is related to variables associated with the LGB identity formation process, it is unclear whether attachment insecurity increases difficulties in the identity process, whether identity difficulties lead to changes in working models of attachment, or whether a third variable influences both attachment and identity. It is equally unclear what implications this may have for the formation, maintenance, and dissolution of same-sex couples. Furthermore, gender differences may contribute to the complexity of this picture. For example, research has indicated that women and men differ with regard to whether same-sex dating relationships begin via certain routes. One older study found that lesbians were more likely to have met their partners in work settings, and gay men were more likely to have met their partners in bars (Bryant & Demian, 1994). Such potential differences in the contexts of romantic relationship formation for lesbians and gay men suggest the possibility that the role and salience of working models of attachment in the early stages of LGB identity formation are moderated by gender. Also, the considerable variation among states and countries in legal status of same-sex couples—from jurisdictions that recognize same-sex marriage to those in which homo-

sexuality is punishable through imprisonment or murder—offers a unique opportunity to examine ways institutional discrimination may influence romantic attachment, romantic relationship quality, and even the extent to which romantic attachment is linked to relationship functioning.

Why have such potentially rich areas for inquiry regarding same-sex couples received relatively little attention by scholars? We suspect the answer to this question may be related to both the continuing lack of interest in sexual minority issues among behavioral scientists and the growing acceptance of same-sex couples. On the one hand, the body of research on same-sex couples is still surprisingly small, a state of affairs made evident by a recent content analysis of 18 journals that publish scholarship on couples and family therapy (Hartwell, Serovich, Grafsky, & Kerr, 2012). The study revealed that 173 articles with significant focus on LGB issues had been published between 1996 and 2010, which reflects an average of less than one article per year in each of the 18 journals studied. Although this number reflects substantial growth in the study of LGB issues (an increase of over 200% in LGB-related publications relative to a similar content analysis covering the years 1975–1995), it is still relatively small. In short, the slow pace of attachment research on same-sex couples is not surprising in light of the slow pace in the greater literature on same-sex couples. Moreover, the small set of scholars who conduct research on same-sex couples may not be well acquainted with attachment theory and research.

On the other hand, we wonder whether the apparent lack of motivation to conduct attachment research with same-sex couples may also be driven by the increasing acceptance of same-sex couples and empirical findings of similarity between same-sex and different-sex couples. These trends may suggest to scholars that any findings for different-sex couples should translate to same-sex couples and therefore no need exists to test for differences or investigate the applicability of theories of romantic relationship functioning to same-sex couples. However, as described earlier, recent research has demonstrated ways that studying same-sex couples can enhance understanding of attachment processes. Despite the clear value of such studies, the modest amount of attachment research on same-sex couples suggests that the potential contributions of such research are not yet viewed by attachment scholars as sufficiently compelling to divert their attention from the many interesting questions that can be more

easily studied in different-sex couples. We suspect romantic attachment researchers often recruit or retain only different-sex couples for their studies because of an unexamined assumption of similarity between couple types, combined with a sense of unease about mixing couple types. One interesting question raised by this practice is whether different-sex and same-sex couples should be combined within the same study. In cases where differences between couple types are not expected, perhaps a case could be made for eliminating couple type as an inclusion or exclusion criterion. After all, participants diverse in race, ethnicity, and age are often combined within a single sample. However, in cases in which a scholar feels reluctant to combine the two couple types into a single sample, this may suggest that the area of inquiry is one in which the study of same-sex couples may be of particular interest to attachment researchers. It is our hope that awareness of such research areas increases among romantic attachment scholars, and motivates scholars to broaden their focus to same-sex romantic partners.

The examples offered in this chapter constitute a first step in identifying some possibilities for future study, but the list is hardly exhaustive. For example, longitudinal research on relationships between lesbian ex-lovers (a little-studied but much-discussed phenomenon; see Weinstock & Rothblum, 2004) may contribute to the growing literature on jealousy and attachment. Furthermore, knowledge about the interplay among the attachment, affiliative, and sexual systems may benefit from intensive study of the considerable diversity in the arrangements that LGB adults create to satisfy their emotional, romantic, and sexual needs (for an interesting discussion of such arrangements, see Rust, 1996). Another potentially interesting line of investigation may be to study the ability of LGB communities to promote secure romantic attachments through their role as a safe haven for LGB individuals and same-sex couples, particularly given evidence that individuals experience anxiety and avoidance in relation to their group attachments that are distinct from the corresponding dimensions of attachments to romantic partners (Smith, Murphy, & Coats, 1999). Furthermore, with a growing number of same-sex couples becoming parents, researchers may profit from examining existing theories of parent-child attachment among same-sex couples engaged in childrearing, due to the unique gender makeup of such families and the controversy that has historically surrounded same-sex parenthood (Goldberg,

2010). These examples, along with those discussed earlier, indicate that the study of same-sex couple functioning provides a rich forum for exploring the complex interplay of forces at the individual, dyadic, and societal levels—an interplay that potentially involves the attachment, fear, sex, and exploration behavioral systems. Mapping of this uncharted territory will both enhance attachment theory and provide much-needed data on same-sex romantic relationships.

Acknowledgments

We would like to thank Jude Cassidy, Henry Hogue, Phillip R. Shaver, and Susan Woodhouse for their helpful comments on an earlier draft of this chapter.

Chapter 24

Adult Attachment and Emotion Regulation

Mario Mikulincer
Phillip R. Shaver

The titles of the second and third volumes of Bowlby's (1973, 1980) trilogy on attachment—*Separation: Anxiety and Anger* and *Loss: Sadness and Depression*—make clear that emotions were among his central concerns. He was interested in the causes and consequences of emotions aroused by attachment to, and reunion with, attachment figures (e.g., love, tenderness, joy); separation from them (anxiety, anger); and permanent loss of them (grief, sadness, despair). Attachment theory is an attempt to explain how secure attachments develop; how they help people survive temporary bouts of pain, fear, discomfort, and distress; and how they help people emerge from distress and reestablish confidence, hope, optimism, and emotional balance. It also explains how various forms of attachment insecurity develop and interfere with emotion regulation, social adjustment, and mental health—as explained in this and several other chapters in this volume.

Especially in early childhood, but also later in life (“from the cradle to the grave,” in Bowlby's frequently quoted words; 1979, p. 129), human beings rely on attachment figures (e.g., parents, spouses/partners, mentors, therapists) for help with emotion regulation. When a security-providing mother reassuringly touches her anxious child or holds the child's hand in a novel or worrisome situation, the child's previously heightened auto-

nomic arousal subsides (e.g., Field, 2002). When a loving husband holds his wife's hand in a painful or anxiety-provoking medical situation, fMRI images of the wife's brain reveal that her physiological arousal is lower than in control conditions (e.g., Coan, Schaefer, & Davidson, 2006; see also Coan, Chapter 12, this volume). (Interestingly, less caring, less supportive husbands' hands do not have as strong a beneficial effect.)

In this chapter, we summarize our model of attachment-system activation and dynamics in adulthood—a model based on what we call “adult attachment theory,” which has inspired a large body of research (for more extensive reviews, see Mikulincer & Shaver, 2003, 2013, 2016). The goal of this revised and updated version of our 2008 chapter is to use concepts and findings from attachment research, which originally focused primarily on the mother-child relationship and on children's attachment orientations (as explained in Part III in this volume), to understand the role of emotion regulation in adult attachment relationships and mental representations of attachment experiences. To accomplish this goal, we rely mainly on the large research literature created by social/personality psychologists who use self-report measures of attachment-figure hierarchies and “adult attachment styles,” combined with a variety of other measures and experimental research

methods, to uncover and illuminate the dynamics of the attachment behavioral system in adulthood (Mikulincer & Shaver, 2016; Shaver & Mikulincer, 2002a, 2002b). There are parallel studies based on interview measures of adult “states of mind with respect to attachment” (the Adult Attachment Interview [AAI]; see Hesse, Chapter 26, and Crowell, Fraley, & Roisman, Chapter 27, this volume), many of which we review in our comprehensive book on adult attachment (Mikulincer & Shaver, 2016). But here, to comply with page limits and focus on our own theoretical model and related research, we review mainly research conducted by social/personality psychologists, occasionally referring to corroborative AAI studies.

Research by social/personality psychologists on dyadic, relational processes related to attachment (and also to caregiving) is reviewed in this volume by J. A. Feeney, Chapter 21; B. C. Feeney and Monin, Chapter 40; B. C. Feeney and Woodhouse, Chapter 36; and Shaver, Mikulincer, Gross, Stern, and Cassidy, Chapter 38. Here we consider mainly the individual psychology of attachment-related emotion regulation processes in adulthood, which are a joint product of previous experiences in attachment relationships and current cognitive and social contexts, including contexts that can be systematically manipulated in a laboratory. (There is presumably also a role for genes in the processes we examine, but there is not enough space here to consider it here. For examples and references, see, e.g., Crawford et al., 2007; Donnellan, Burt, Levendosky, & Klump, 2008; see also Bakermans-Kranenburg & Van IJzendoorn, Chapter 8, this volume.)

The concept of “adult attachment style” explored in this chapter emerged from research by Hazan and Shaver (1987, 1990, 1994), who applied attachment theory to the study of adolescent and adult romantic and marital relationships. In their early studies, Hazan and Shaver employed a simple three-category measure of attachment style based conceptually on Ainsworth’s descriptions of three major attachment patterns in infancy (Ainsworth, Blehar, Waters, & Wall, 1978). In an influential 1991 article, Bartholomew and Horowitz argued for a more complete four-category typology based on two dimensions suggested by Bowlby’s (1969/1982) analysis of internal working models of self and other. (Bartholomew and Horowitz divided each of these two dimensions, model of self and model of others, into two regions: positive models and negative models, thereby creating four types.)

Bartholomew and Horowitz’s theory and measures (Bartholomew & Horowitz, 1991; Griffin & Bartholomew, 1994) inspired numerous other measures and studies, which in 1998 led Brennan, Clark, and Shaver (1998) to factor-analyze all of the self-report items written up to that time. Based on their analyses and on Bartholomew and Horowitz’s (1991) findings, Brennan and colleagues (1998) created two 18-item self-report scales (the Experiences in Close Relationships [ECR] scales) to measure attachment-related *anxiety* and *avoidance*. The two dimensions are similar to the two that defined Ainsworth’s infant attachment categories (see Ainsworth et al., 1978, Figure 10, p. 102). The ECR scales allow researchers to place adolescent and adult research participants into a two-dimensional attachment-style space defined by attachment anxiety and avoidance. Thousands of studies (summarized and reviewed in Mikulincer & Shaver, in press) have used this approach to study adult attachment phenomena, including many issues related to emotion regulation. (Several alternative measures have been developed along the lines of the ECR and are discussed by Crowell et al., Chapter 27, this volume.)

We begin our review of theory and research with a description of our model of attachment-system activation and functioning in adulthood. Next, we focus on the self- and emotion-regulatory function of attachment-system activation. We review studies of preconscious activation of attachment-related mental representations under threatening conditions and the associated use of support seeking as an emotion regulation strategy. We then review studies concerning the beneficial effects of attachment security on emotion regulation and mental health, as well as the psychological mechanisms that sustain these effects. We consider the distinction between anxious/hyperactivating and avoidant/deactivating strategies that are put into play when no security-providing figure is available or responsive, and we summarize evidence regarding the implications of these strategies (which are associated with attachment anxiety and avoidance, respectively) for emotion regulation and mental health. We also explain briefly how these two kinds of insecurity can be beneficial at a social-group level, even though they are generally troublesome for individuals and for couple relationships. At the end of the chapter, we briefly summarize developments that have occurred since 2008, when the previous version of this handbook appeared, and we outline some future directions.

A Model of Attachment System Activation and Functioning in Adulthood

In 2003, based on a review of adult attachment studies, we (Mikulincer & Shaver, 2003) proposed a three-phase model of attachment-system activation and dynamics (Figure 24.1). The model comprises three main components or modules. The first involves the monitoring and appraisal of threatening events, which often activate the attachment system (see Cassidy, Chapter 1, this vol-

ume). This component includes the major normative (i.e., pan-human, cross-culturally universal), biologically functional (i.e., adaptive) features of the attachment system as conceptualized by Bowlby (1969/1982), who proposed that the attachment system evolved because it increased infants' chances of survival and eventual reproduction by making it likely that vulnerable infants would seek and maintain proximity to stronger and wiser attachment figures, thereby receiving protection, emotional support, encouragement, guidance, and help with emotion regulation—especially when

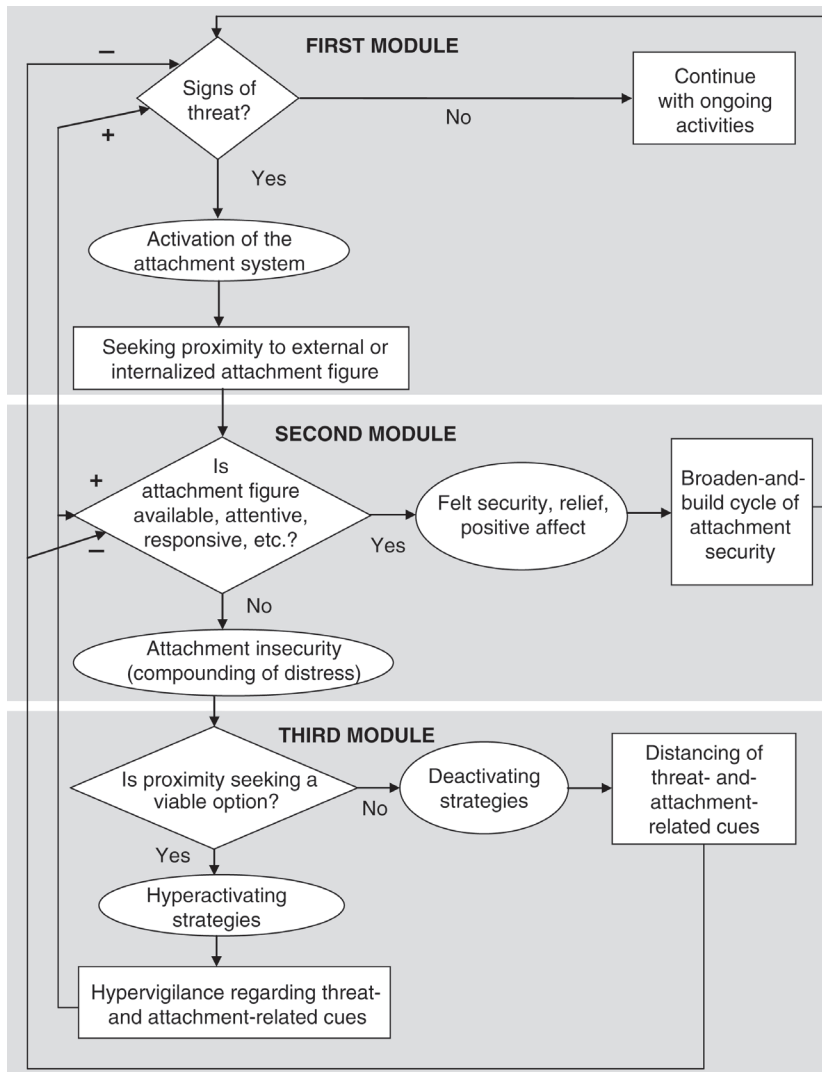

FIGURE 24.1. A model of attachment system activation and functioning in adulthood. From Mikulincer and Shaver (2007, p. 31). Copyright 2007 by The Guilford Press. Reprinted by permission.

confronting threats, stressors, or pain. Bowlby believed that the attachment system continues to develop while operating in conceptually similar ways across the lifespan.

The second component of the model deals with the monitoring and appraisal of attachment figure availability and responsiveness. This component is responsible for individual differences in the sense of attachment security (“felt security”; Sroufe & Waters, 1977), which is shaped by repeated experiences with primary attachment figures, whose effective or ineffective caregiving behavior causes a child to become more or less secure. By the time a person reaches adulthood, this component of the attachment system is highly elaborated, based on thousands of experiences. It includes a vast store of conscious and unconscious memories related to encounters with threats and experiences with attachment figures, as well as schematic, script-like mental representations of those experiences—the “internal working models” referred to by Bowlby (1969/1982) and discussed by Bretherton and Munholland in Chapter 4, this volume. Repeated security-restoring and security-enhancing experiences with attachment figures create a dispositional (i.e., fairly stable) sense of felt security, which sustains what we call a “broaden-and-build” cycle of security (following Fredrickson, 2013; see Mikulincer & Shaver, 2016). This cycle influences many aspects of emotion regulation, mental health, personal growth, and social adjustment.

The third component of the model concerns the monitoring and appraisal of the likely utility of seeking proximity to an attachment figure (either a particular figure or such figures in general) as a way of coping with threats to safety and well-being. This component is responsible for individual differences in attachment style and in corresponding strategies of emotion regulation, which can be characterized as secure, hyperactivating, or deactivating (Cassidy & Kobak, 1988).

Hyperactivating strategies are thought to derive from previous experiences in which inattentive, self-preoccupied, or anxious attachment figures were perceived by a child as more likely to respond favorably if the normative strategies of calling, crying, contacting, and clinging were up-regulated to the point of demanding a response (a behavior pattern that Bowlby, 1969/1982, called “protest”). Because such behavior, when addressed to a less than fully sensitive and responsive caregiver, is sometimes effective in relieving distress and sometimes not, according to an unpredict-

able partial reinforcement schedule, it is highly resistant to extinction. When consolidated over months and years, hyperactivating strategies and their effects on subjective experience and observable behavior amount to an *anxious*, *anxious-ambivalent*, or *anxious-resistant* pattern of attachment (Ainsworth et al., 1978), which in adolescents and adults we refer to simply as an *anxious* attachment style.

Deactivating strategies are thought to derive from previous experiences in which emotionally cool, distant, rejecting, or hostile caregivers reacted to normative bids for help and support by withdrawing, disapproving, or reacting with anger. This kind of behavior, if common and persistent, makes it likely that a child will inhibit, suppress, or deactivate normal attachment behavior, resulting in an *avoidant* attachment pattern (Ainsworth et al., 1978), which Bowlby (1969/1982) called “compulsive self-reliance.”

It is possible for a person to score high on both anxiety and avoidance, a pattern that Bartholomew and Horowitz, 1991, called “fearful avoidance.” This is conceptually similar, although not identical, to what is called “disorganized attachment” in the child literature (as discussed by Lyons-Ruth & Jacobvitz, Chapter 29, this volume), but we do not have space here to explain this idea in detail.

Our model includes hypothesized excitatory and inhibitory feedback loops (shown as upward arrows on the left-hand side of Figure 24.1), which result from recurrent use of hyperactivating or deactivating strategies. These loops affect the monitoring of threats and the appraisal of attachment figures’ availability or unavailability. In particular, hyperactivating strategies lead to persistent vigilance to threats; being exceptionally expressive of fears, needs, and doubts; and being continually worried about attachment figures’ availability and responsiveness. These tendencies predispose a person to engage in excessively dependent behavior, intense and frequent proximity seeking and contact maintenance, and clinginess (Ainsworth et al., 1978; Fraley & Shaver, 1998). Deactivating strategies, in contrast, lead to dismissal or downplaying of potential threats; suppression or denial of worries, needs, and vulnerabilities; and disavowal of the need for an attachment figure’s presence or support. These processes sometimes cause a person to ignore attachment figures, reject their offers of assistance, and reduce expressions of affection and intimacy (Edelstein & Shaver, 2004).

Scripts as Components of Working Models

Theoretically, individual differences in the activation and functioning of the attachment system, as described in Figure 24.1, depend on the extent to which attachment figures are (or were) sensitive and responsive to bids for protection and support. During such interactions, people develop expectations (working models) about the self as lovable and about others as harboring goodwill. Moreover, these interactions provide valuable information about the effectiveness of support seeking as an emotion-regulation device and therefore facilitate the consolidation of procedural knowledge in the form of mental scripts concerning how to deal with threats and adversities. These mental scripts, once activated in a threatening situation, shape a person's reactions to the situation and allow him or her to forecast how the situation will develop and whether the threat will or will not be removed. Depending on the details of a particular individual's script, activation of the script can be beneficial or detrimental to emotion regulation in a particular situation.

The Secure-Base Script

According to Waters and Waters (2006) and Mikulincer, Shaver, Sapir-Lavid, and Avihou-Kanza (2009), secure adults' interactions with responsive attachment figures and the resulting positive working models of self and others are organized around a relational prototype or *secure-base script*, containing something like the following if-then propositions (which are not necessarily articulated consciously): "If I encounter an obstacle and/or become distressed, then I can approach a significant other for help; he or she is likely to be available and supportive; I will experience relief and comfort as a result of proximity to this person; I can then return to other activities." Once activated, this script, by itself, can mitigate distress, promote optimism and hope, and help a person cope effectively with stressors.

Mikulincer, Florian, and Tolmacz (2009) found that young adults who scored lower on the two self-report scales of the ECR (Brennan et al., 1998)—Attachment Anxiety and Avoidance—were more likely to include elements of the secure-base script (support seeking, support provision, and distress relief) when writing a story about a fictional person under threat (Studies 1 and 2).

Moreover, the two kinds of insecurity—*anxiety and avoidance*—were associated with different gaps in the secure-base script. People who scored relatively high on attachment anxiety tended to omit or deemphasize the final step in the script (relief and return to other activities), whereas those who scored relatively high on avoidance tended to omit the part about seeking and benefiting from others' support. That is, whereas anxious participants in the studies more often wrote about a threatened or injured protagonist who was seeking support and not achieving relief, avoidant participants more often wrote about a person achieving relief without seeking or receiving support.

Mikulincer and colleagues (2009, Studies 3–8) also reported evidence concerning the cognitive properties of the secure-base script and the ways in which it organizes expectations, memories, and judgments, thereby affecting emotion elicitation and regulation. For example, more secure individuals had greater access to the secure-base script when dreaming about distressing events (Study 4), and they expected to find more secure-base script components (support seeking, support availability) in an imagined story that began with a distressing experience (Study 3). They were also more likely to go beyond the script-relevant information they received and generate additional security-supporting inferences and conjectures (Study 5). This tendency was evident even 5 days after being exposed to the information (Study 7) and was not affected by the depletion of cognitive resources caused by an effortful task—a sign that secure-base-script information was processed easily and automatically (Study 8). Moreover, relatively secure participants were quicker and more confident in making judgments concerning secure-base-script-related information (Studies 6–7). Overall, the findings indicated that secure individuals are experts in the use of the secure-base script for coping with threatening events, which can be of considerable help when they are attempting to maintain emotional balance in threatening situations.

This conclusion is reinforced by findings that attachment security is positively associated with the degree to which the secure-base script underlies dreams in general (Mikulincer, Shaver, & Avihou-Kanza, 2011), dreams about romantic partners (Seltman, Apetroaia, & Waters, 2012), narratives about current relationships (McLean, Bailey, & Lumley, 2014), and interpersonal stories that research participants create based on word prompts (Steele et al., 2014).

Attachment Insecurity and the “Sentinel” and “Rapid Fight–Flight” Scripts

Besides having gaps in their secure-base scripts, anxious and avoidant individuals possess scripts that guide emotion regulation and coping behavior in threatening situations (Ein-Dor, Mikulincer, & Shaver, 2011a). We call them *sentinel* and *rapid fight–flight* scripts (typical of anxious and avoidant adults, respectively). Attachment anxiety is associated with ready access to a sentinel script (e.g., noticing danger before other people do, warning others about the danger) when writing a story about a threatening event (Ein-Dor et al., 2011a, Study 1), and with better memory for recently encountered sentinel-script information (Study 3). Participants who scored higher on attachment anxiety were also more likely to process sentinel-script information in a deep way and to generate more inferences and conjectures (Study 4). They also had poorer and shallower recall of information that was congruent with the (avoidant) rapid fight–flight schema (Studies 2 and 5), suggesting that they do not possess or use that script.

More avoidant participants proved to have ready access to a rapid fight–flight script of emotion regulation (e.g., escaping a dangerous situation without helping others, acting rapidly without depending on others’ actions, not deliberating or cooperating with others) when thinking and writing a story about threatening events (Study 1). Moreover, avoidance was associated with better memory for information relevant to the rapid fight–flight script (Study 3) and with processing this information in a deep way (Study 5). More avoidant participants also exhibited poorer memory for information congruent with the (more anxious) sentinel script (Study 4).

The hypothesis that the sentinel and rapid fight–flight scripts might exist was based originally on thinking about ways in which anxious and avoidant individuals can sometimes benefit the groups to which they belong, despite the usual negative characterizations (including ours) of anxious and avoidant mental emotion regulation strategies and associated coping behavior. In one study, Ein-Dor, Mikulincer, and Shaver (2011b) examined behaviors associated with the two kinds of scripts in a group context. A total of 46 groups of three participants each were unobtrusively observed in a threatening laboratory situation: The room gradually filled with smoke, apparently because of a malfunctioning computer. Group members’ attachment anxiety was associated with quicker

detection of the danger, and group members who scored higher on avoidance more quickly devised and executed escape responses to the danger, and other group members were quick to follow.

Ein-Dor and colleagues have collected additional evidence for anxious adults’ reliance on the sentinel script. For example, Ein-Dor and Perry (2014) studied deceit detection: Attachment anxiety predicted more accurate detection of deceitful statements made during social interactions and also with winning more money while playing poker—a game based on one’s ability to detect bluffing. In another study, Ein-Dor and Orgad (2012) focused on the “warning others about danger” component of the sentinel script. Study participants were led to believe they had accidentally activated a computer virus, and they were asked to alert the department’s computer technicians in another part of the building. On the way to the technicians’ office, they encountered various obstacles that might have caused them to delay or give up. But, as expected, more anxious individuals were less willing to be delayed on their way to deliver a warning message.

Regarding avoidance and the associated rapid fight–flight script, Ein-Dor, Reizer, Shaver, and Dotan (2012) examined two domains in which avoidant people might be especially likely to succeed: professional singles tennis tournaments (requiring travel away from home and competing alone) and computer science. These fields reward self-reliance, independence, and the ability to work without emotional expressions and interpersonal closeness—core components of the rapid fight–flight script. As expected, avoidance predicted higher standing in a series of singles tennis tournaments, and also predicted greater career choice satisfaction among computer science students.

For present purposes, the most important implication of the script findings is that attachment security, anxiety, and avoidance are associated with mental representations—scripts of various kinds—that affect emotion-related appraisals of situations and different kinds of behavior following threats. In many situations, being overly vigilant and sensitive to threats (which in some cases may merely be imagined), or overly self-reliant and uncommunicative about feelings, is stressful for the individual in question and damaging to his or her relationships, but in other situations these examples of hyperactivation and deactivation of the attachment system can benefit a person’s groups. This is worth keeping in mind when characterizing anxious and avoidant attachment as subopti-

mal, and when considering why the existence of these insecure patterns was not eliminated during human evolutionary history.

The Attachment System and Support Seeking

A core contention of attachment theory (Bowlby, 1969/1982) is that reactions to perceived threats and dangers include not only the traditionally emphasized “fight-or-flight” responses (Cannon, 1939) but also seeking proximity to a “stronger and wiser,” supportive, and protective attachment figure as a way of protecting and emotionally calming oneself. Main (1990) called this the “primary” attachment strategy. In adulthood (and probably in childhood as well, although our concern here is adulthood), people can seek proximity to and support from an attachment figure either by requesting actual support from a real, flesh-and-blood, physically present relationship partner or by calling on mental images, prototypes, schemas, or specific memories of interactions with human or nonhuman attachment figures (e.g., pets, spiritual beings). Adults can also engage in self-soothing routines learned in interactions with attachment figures (Mikulincer & Shaver, 2004).

In constructing a model of attachment system functioning, we (Mikulincer & Shaver, 2003) postulated a two-stage process by which threat appraisals lead to activation of the primary attachment strategy. In the first stage, threat appraisals trigger preconscious activation of the system, which brings about an automatic increase in the accessibility of attachment-related mental representations in an associative memory network. In the second stage, this preconscious activation, if sufficiently robust, results in conscious thoughts about seeking proximity to attachment figures, behavioral intentions to seek proximity and support, and actual seeking of proximity and support.

We believe that preconscious activation of the attachment system involves heightened access to mental representations (not necessarily conscious) of available and responsive attachment figures; episodic memories of supportive and comforting interactions with these figures; thoughts and images related to closeness, love, comfort, relief, and support; and proximity-seeking goals. These mental processes and contents become automatically available for use in further information processing and can color a person’s state of mind and influence his or her behavioral intentions and

actual behaviors, even before they are consciously formulated. This model fits with many findings from more general social-cognitive research, which indicates that accessible cognitive-affective mental contents shape a person’s state of mind before they appear in the stream of consciousness (Bargh & Morsella, 2010).

Both stages of attachment-system activation can be affected by a person’s dispositional attachment style, which reflects long-term experiences with attachment figures (Mikulincer & Shaver, 2003, 2016; Zayas, Mischel, Shoda, & Aber, 2011). A secure person’s history of interactions with available and responsive attachment figures and the resulting secure-base script make it more likely that support seeking will occur in times of need as the default means for emotion regulation. In contrast, insecure people have learned through painful experiences with unavailable or unresponsive attachment figures that the primary attachment strategy (proximity seeking) often fails to accomplish its emotion regulation goal. As a result, insecure individuals rely on alternative ways of regulating emotion rather than directly and confidently seeking proximity to an attachment figure. Avoidant adults are likely to deactivate their attachment system, forgo support seeking, and rely on themselves to deal with threats. Anxious adults are likely to regulate their emotions by signaling or expressing needs and fears, exaggerating their distress, and presenting themselves as extremely vulnerable to pain and injury (Shaver & Mikulincer, 2002a).

Preconscious Activation of the Attachment System in Adulthood

Preconscious activation of the attachment system was first studied in two series of experiments (Mikulincer, Birnbaum, Woddis, & Nachmias, 2000; Mikulincer, Gillath, & Shaver, 2002) in which young adults were subliminally primed with threat-related words (e.g., *death*, *failure*) or neutral words (e.g., *table*, *hat*). The mental accessibility of cognitive and affective elements related to attachment was assessed with two well-validated cognitive techniques: a lexical decision task (deciding quickly whether particular strings of letters are or are not words), and the Stroop color-naming task (naming, as quickly as possible, the color in which a particular word is printed on a computer screen, which requires inhibiting the overlearned tendency to read the word and activate its associations in memory). These tasks allow researchers to gauge

the accessibility of particular mental contents at a given moment, even if these contents are not experienced consciously. Researchers can therefore examine the effects of threatening words on the availability of attachment-related concepts, without research participants knowing what is being examined.

In Mikulincer and colleagues' (2000) studies, young adults performed a lexical decision task in which the letter strings they saw included proximity-related words (e.g., *love*, *hug*), separation-related words (e.g., *separation*, *rejection*), neutral words (e.g., *office*, *table*), positive non-attachment-related words (e.g., *honesty*, *efficacy*), negative non-attachment-related words (e.g., *cheat*, *lazy*), and nonwords (created by scrambling the letters of actual words—e.g., “btale” [*table*], “vleo” [*love*]). Before each letter string was presented, a threatening word (e.g., *failure*, *illness*) or a neutral word (*hat*) was flashed on the screen for 20 milliseconds—too short a time to allow a participant to perceive the stimulus consciously. (This procedure is called *subliminal priming* because it operates below the level of consciousness and is analogous to priming a pump to stimulate the flow of water.) Reaction times (RTs) serve as a measure of the accessibility of thoughts related to the target words: The quicker the RT, the greater the accessibility.

In the Mikulincer and colleagues (2000) studies, subliminal threat stimuli resulted in faster identification (implying greater mental availability) of proximity-related words, and the effect did not extend to neutral words or positive words with no obvious attachment-related connotations. Moreover, this heightened accessibility occurred regardless of attachment style (although individual differences in attachment style also had effects, as explained below), suggesting that everyone is subject to preconscious activation of the attachment system, as would be expected if such activation is a species-universal, biologically functional mental process.

Extending these studies, we (Mikulincer et al., 2002) conducted three experiments focused on mental access to the names of attachment figures, with names being, we assume, only small but central parts of the mental representations of these figures. Each study participant completed the WHOTO questionnaire (Hazan & Zeifman, 1994), which identifies people to whom one turns for proximity and support (e.g., “Whom do you like to spend time with?”), a safe haven (e.g., “To whom do you turn for comfort when you’re feeling down?”), and a secure base (e.g., “Whom do you

feel you can always count on?”). Each participant also named potentially close others who were not viewed as attachment figures (e.g., father, sibling, friend—if not mentioned in the WHOTO questionnaire). And they named acquaintances who were not emotionally close (e.g., coworkers, casual friends). They also selected names that did not apply to anyone they knew personally. Each participant then performed either a lexical decision task or a Stroop color-naming task. In the lexical decision task, they were presented with the names of their own attachment figures, names of close people who were not attachment figures, names of acquaintances, names of unknown persons, and nonword letter strings. They were asked in each case to indicate as quickly as possible whether each string of letters was or was not a person’s name. In the Stroop task, participants were exposed to the same four categories of names, each printed in one of several colors, and were asked to indicate the color in which each name was printed. Before each trial, a threat stimulus (the word *failure* or *separation*) or a neutral word (*hat*, *umbrella*) was presented subliminally for 20 milliseconds.

Across the three experiments, participants reacted to subliminal threats with heightened mental access to attachment figures’ names. As compared with emotionally neutral words, subliminal threat words resulted in (1) faster identification of the names of attachment figures in the lexical decision task, and (2) slower color designations of attachment figures’ names in the Stroop task. In both cases, short lexical decision RTs and slow color-naming RTs were interpreted as indicating heightened activation of mental representations of attachment figures’ names in threatening contexts. Subliminal threat words had no effect on mental representations of close others or acquaintances who were not mentioned in the WHOTO questionnaire. Thus, heightened accessibility of mental representations of a particular person under threatening conditions depended on the extent to which the person was viewed as a safe haven and a secure base (i.e., an attachment figure).

Individual Differences in Preconscious Activation of the Attachment System

In addition to obtaining the predicted overall effects, we found that more secure adults had readier access to thoughts about proximity and to the names of their attachment figures, *but only in a threatening context* (Mikulincer et al., 2000, 2002);

that is, secure adults were not chronically or continually preoccupied with attachment-related themes or particular attachment figures. Rather, attachment-related cognitions were activated only by signals that protection might be needed. In addition, Mikulincer and colleagues (2000) found that more secure individuals' reactions to subliminal threats were limited to attachment themes with positive connotations; they displayed relatively little activation of words related to separation or rejection. We interpret these results as indicating that secure adults' favorable attachment histories resulted in a distinction in their memories between attachment system activation on the one hand, and worries about rejection on the other.

Attachment-anxious individuals' pattern of attachment-system activation was essentially the opposite of the secure individuals' pattern (Mikulincer et al., 2000, 2002). First, the more anxious people (as indicated by their scores on the ECR Attachment Anxiety scale) displayed heightened mental access to attachment-related themes and attachment figures' names in both *threatening* and *nonthreatening* contexts. Second, they also displayed readier access to words related to separation and rejection. We interpret these findings as indicating hyperactivation of attachment-related thoughts, which seems to occur even in nonthreatening contexts (or perhaps alters the threshold for perceiving a situation as threatening).

Avoidant individuals produced a more complicated set of results. In general, their pattern of access to attachment-related mental contents resembled that of secure people. However, there were important differences. For avoidant people, thoughts about rejection and separation were relatively inaccessible, even following subliminal exposure to the word *death*, which is usually a potent activator of attachment-related fears (Kalish, 1985). Moreover, these worries suddenly became accessible to avoidant individuals in response to subliminal threats if a "cognitive load" was added to the lexical decision task; that is, when avoidant adults had to engage in an additional cognitively demanding task (rehearsing and remembering a long series of digits), they seemed to lack the resources necessary to maintain their usual defensive exclusion of attachment-related concerns. These results support the theoretical notion that avoidant people are insecure, like anxiously attached people, but are generally using defensive means to suppress or deny their insecurity.

We (Mikulincer et al., 2002) also found that when the threat word was *separation*, secure indi-

viduals exhibited enhanced access to the names of their attachment figures, whereas avoidant individuals exhibited *decreased* access. There was no such difference when the subliminal threat word was *failure*, which is not as closely related to attachment. It therefore seems that the attachment system is pre-consciously activated under attachment-unrelated threatening conditions in both avoidant and non-avoidant people, but is pre-consciously inhibited or deactivated under attachment-related threatening conditions (or at least following the threat of separation) if a person is avoidant. It seems likely that avoidant adults have learned not to appeal to attachment figures when these figures threaten to leave. This result is compatible with Ainsworth and colleagues' (1978) statement that "avoidance short circuits direct expression of anger to the attachment figure, which might be dangerous, and it also protects the baby from re-experiencing the rebuff that he has come to expect when he seeks close contact with his mother" (p. 320). We believe this might be the main reason for avoidant individuals' persistent attempts to divert or suppress feelings of vulnerability and negative emotions when attempting to regulate distress and inner pain.

Individual Differences in Support-Seeking Tendencies and Behavior

Several studies have confirmed the predicted link between attachment insecurities and lower scores on self-report scales that tap support seeking (see Mikulincer & Shaver, 2016, for a comprehensive review). These attachment-related differences have also been noted in observational studies of the actual seeking of support from relationship partners. In two studies, one member of a dating couple (women in Simpson, Rholes, & Nelligan, 1992; men in Simpson, Rholes, Oriña, & Grich, 2002) was told that she or he would undergo a painful laboratory procedure after waiting with a partner for 5 minutes. During this period, participants' behavior was unobtrusively videotaped, and raters later coded the extent to which each participant sought his or her partner's support. Among women, avoidance inhibited support seeking mainly when their level of distress was high. In such cases, avoidant women often attempted to distract themselves by reading magazines instead of asking for support. For men, however, there was no association between attachment and support seeking. Simpson and colleagues (2002) attributed this lack of association to social norms that inhibit

men's seeking of support from women or to men's tendency to perceive the experimental tasks as less threatening. Similar findings have been obtained using the AAI or a secure-base script methodology (e.g., Crowell et al., 2002; Waters, Brockmeyer, & Crowell, 2013).

Two other observational studies provide additional evidence for avoidant and anxious people's problematic attitudes toward support seeking. Fraley and Shaver (1998) unobtrusively coded expressions of desire for proximity and support when romantic or marital partners were about to separate from each other at a metropolitan airport, and Collins and Feeney (2000) coded support-seeking behavior while members of seriously dating couples talked about a personal problem in the laboratory. In both studies, avoidance was associated with less frequent seeking of proximity or support. In addition, although attachment anxiety did not affect direct requests for partner support, more anxious people were more likely to use indirect methods of support seeking, such as asking for help through nonverbal distress signals (crying, pouting, or sulking).

Several other studies using self-report attachment measures have shown that more avoidant, compared with less avoidant, individuals are less likely to benefit from imagined or actual support when coping with stress (e.g., Bodie et al., 2011; Mikulincer & Florian, 1997; Milyavskaya, McClure, Ma, Koestner, & Lydon; 2012). Using the AAI as a measure of security, Simpson, Winterheld, Rholes, and Oriña (2007) found that the specific type of support is critical for understanding the problems insecure people encounter when involved in potentially supportive interactions. Dating couples were videotaped while trying to resolve their most important relationship problem. At peak distress points during each discussion, coders rated the extent to which one partner displayed emotional or instrumental support behaviors, and the other partner was calmed by the partner's support attempts. Whereas securely attached individuals were rated as calmed when their partners provided either emotional or instrumental support, avoidant individuals were rated as calmed when their partners delivered less emotionally imbued and more instrumental support (e.g., giving concrete advice or suggestions concerning how to solve the problem). Similar findings were obtained by Girme, Overall, Simpson, and Fletcher (2015) in an analysis of avoidant adults' reactions to instrumental support offered by their romantic partner during support-related discussions and in

daily life. These findings suggest that in order to be effective, supportive efforts need to be tailored to the specific concerns and defenses of avoidant people.

Secure individuals' reliance on supportive interactions has been noted in a series of studies of attachment-style differences in heart rate and blood pressure in a stressful situation (e.g., performing a stressful arithmetic task) in the presence of or in response to the supportiveness of a relationship partner (Carpenter & Kirkpatrick, 1996; B. Feeney & Kirkpatrick, 1996). These studies indicated that the physiological responses of avoidant and anxious women were heightened rather than mitigated by the presence of their romantic partner (compared with a no-partner condition). In another study, Meuwly and colleagues (2012) found that a partner's supportiveness lowered the intensity of cortisol responses to a public speaking task only among relatively secure participants, not among more attachment-anxious participants. This is an example of the role of attachment-related experiences and resulting differences in attachment security in being able, or not, to enlist others in efforts to regulate negative emotions.

Regulation of Stressful Events and Attachment-Related Threats

In this section, we review evidence concerning ways in which attachment style shapes a person's appraisal and coping strategies for dealing with distressing events, which influence the experience and expression of negative emotions. We also review studies concerning attachment-related differences in (1) the regulation of distress caused specifically by separation or loss, and (2) emotional and physiological reactions to attachment-relevant and attachment-irrelevant stressful events.

Appraisal of Distress-Eliciting Events

Attachment orientations are related to people's beliefs and expectations about threatening events and their ability to avoid stress or cope effectively with it. With regard to threat appraisals, studies have shown that attachment security is associated with appraising potentially stressful events in less threatening ways. With regard to what Lazarus and Folkman (1984) called "secondary appraisal," there is evidence that secure attachment is related to appraising oneself as able to cope effectively

with threats. Specifically, attachment security is associated with higher scores on scales measuring ego resilience, perceived coping resources, and stress-resistant hardy attitudes (e.g., Caldwell & Shaver, 2012; Jones, Brett, Ehrlich, Lejuez, & Cassidy, 2014; Karreman & Vingerhoets, 2012). Attachment security is also associated with more positive expectations about regulating negative moods, and more optimistic and hopeful attitudes toward confronting adversities (e.g., Carnelley, Hepper, Hicks, & Turner, 2011; Han & Pistole, 2014; Jankowski & Sandage, 2011). For example, Jones and colleagues (2014) found that mothers who reported greater attachment-related avoidance and anxiety reported having greater difficulties with emotion regulation 1 year later, and these difficulties, in turn, predicted more distressed, harsher, and less supportive maternal responses to adolescents' negative emotions the following year.

In contrast, people scoring higher on attachment anxiety tend to appraise potentially stressful events in amplified, sometimes catastrophic ways, overemphasizing the imagined danger, and perceiving themselves as unable to cope effectively (see Mikulincer & Shaver, 2016, for a review). For avoidant individuals the findings are more complex. With regard to appraising one's own coping abilities, most studies have found that avoidant people's appraisals are similar to those of secure people (appraising coping resources as adequate). With regard to threat appraisals, however, most studies have found that avoidant attachment, like attachment anxiety, is associated with appraising stressful events as highly threatening. Such appraisals have been noted mainly when avoidant people confronted undeniable and prolonged stressful events, such as impending divorce or caring for a child with a congenital heart defect (e.g., Berant, Mikulincer, & Florian, 2001a, 2001b; Birnbaum, Orr, Mikulincer, & Florian, 1997). These findings have been replicated in longitudinal studies. For example, Berant and colleagues (2001b) found that avoidance predicted increasingly pessimistic appraisals of stressful events over a 1-year period.

Ways of Coping with Distress-Eliciting Events

Several studies have included assessments of participants' use of particular coping strategies (e.g., problem solving, emotion-focused coping, reappraisal, distancing coping). With regard to prob-

lem-focused coping, some researchers have found that secure people are more likely than insecure ones to use this generally effective strategy (e.g., Bazzarian & Besharat, 2012; Deniz & Işık, 2010; Raskin, Kummel, & Bannister, 1998), but other studies have not found a significant association between attachment style and problem-focused coping (e.g., Berant et al., 2001a; Mikulincer & Florian, 1995; Mikulincer, Florian, & Weller, 1993). Some of the latter studies focused on stressful events for which people received extensive problem-solving instructions, such as media information about what to do in case of missile attacks or officers' instructions about how to solve problems during combat training. This may have caused most study participants, regardless of attachment style, to deal with the stressful events in a problem-focused way.

Several studies have found links between avoidant attachment and reliance on distancing coping strategies, such as stress denial, diversion of attention, and behavioral or cognitive disengagement (e.g., Holmberg, Lomore, Takacs, & Price, 2011; Marshall Serran, & Cortoni, 2000; Shapiro & Levendosky, 1999). Also compatible with theory, avoidance has been associated with repression (e.g., Gjerde, Onishi, & Carlson, 2004; Mikulincer & Orbach, 1995; Vetere & Myers, 2002). Moreover, Turan, Osar, Turan, Ilkova, and Damci (2003) found that diabetic persons scoring higher on avoidance relied more on cognitive distancing and passive resignation as coping strategies, which in turn were associated with poor adherence to medical regimens.

Relations between attachment style and distancing coping were also examined in two longitudinal investigations. In a 31-year study, Klohnen and Bera (1998) found that women with an avoidant attachment style at age 52 had scored higher on repressive defensiveness at ages 21 and 43 than women who exhibited a secure style at age 52. Similarly, Zhang and Labouvie-Vief (2004) conducted a 6-year longitudinal study of people ranging in age from late adolescence to late adulthood, and found that although attachment style was relatively stable over the 6-year period, there was some fluidity associated with variations in coping strategies and mental health. An increase in attachment security over the 6-year period covaried with decreased use of distancing coping and increased use of constructive, flexible, and reality-oriented coping strategies. These findings fit well with the theoretical notion that felt security is a resilience resource that helps people maintain

emotional balance without having to use avoidant defenses.

In only one study (Berant et al., 2001a, 2001b) were secure individuals more likely than their avoidant peers to rely on distancing coping. Secure mothers of both healthy infants and infants with a mild coronary heart defect (CHD) relied on support seeking and problem solving, but secure mothers of infants with a severe CHD tended to rely on distancing strategies. This suggests that secure mothers can employ distancing coping when thoughts about the stressful condition might impair effective functioning. Suppression of painful thoughts about their infants' illness might have allowed secure women to maintain a positive appraisal of motherhood. As a result, the overwhelming demands of the infants' illness might not have been so discouraging, allowing mothers to mobilize internal and external resources for taking care of their babies. Consistent with this reasoning, Schmidt, Nachtigall, Wuethrich-Martone, and Strauss (2002) and Cohen and Katz (2015) found that attachment security is associated with greater coping flexibility.

Most of the studies that involved the assessment of emotion-focused coping (e.g., wishful thinking, self-blame, rumination) have found that attachment-anxious adults are more likely than secure ones to direct their attention toward their own distress rather than focusing on possible solutions to the problem at hand. For example, several studies have established that people scoring higher on attachment anxiety are more likely to engage in distress-exacerbating mental rumination—moody pondering or thinking anxiously or gloomily about life events (e.g., Caldwell & Shaver, 2012; Garrison, Kahn, Miller, & Sauer, 2014; Reynolds, Searight, & Ratwik, 2014). There is also evidence that anxious attachment is associated with higher levels of worrying about the causes and consequences of threatening events (e.g., Consedine, Tuck, & Fiori, 2013; Warren et al., 2010). For example, Mikulincer and Florian (1998) assessed worrying in the laboratory and found that experimentally induced failure evoked more worries mainly among attachment-anxious people. In addition, more anxiously attached adults scored higher on a scale assessing crying proneness (Denckla, Fiori, & Vingerhoets, 2014) and actually cried more in response to sad music and reported more negative emotions during these crying episodes (Laan, van Assen, & Vingerhoets, 2012).

Anxious people's tendency to direct attention toward distress was also noted in an experi-

ment conducted by Silva, Soares, and Esteves (2012). Participants were asked to search for a target image, while ignoring a previously presented neutral or distress-eliciting prime. The distress prime interfered with image search (lower accuracy), but this interference was stronger among participants who scored higher on attachment anxiety; that is, anxious people's attention was automatically directed toward distress, which in turn interfered with task performance.

Interestingly and unexpectedly, some studies have yielded associations between avoidance and emotion-focused coping (e.g., Berant et al., 2001a, 2001b; Birnbaum, Orr, Mikulincer, & Florian, 1997; Lussier, Sabourin, & Turgeon, 1997). These findings suggest that there are limits to deactivating strategies. For example, Berant and colleagues (2001a, 2001b) found that avoidant mothers of newborns tended to rely on distancing coping if their infant was born healthy or with only a mild CHD, but they used emotion-focused coping if their infant was diagnosed with a life-threatening CHD, and they showed a notable increase in the use of this coping strategy a year after the diagnosis. Thus, avoidant defenses, which may be sufficient for dealing with minor stressors, can fail when people encounter severe and persistent stressors. This conclusion is consistent with Bowlby's (1980) idea that avoidant people's segregated mental systems cannot be hidden from conscious awareness indefinitely, and that traumatic events can resurrect distress that had been sealed off from consciousness.

The Regulation of Attachment-Related Distress

Attachment orientations are particularly relevant for understanding individual differences in the ways in which people experience and react to attachment-related sources of distress (separation, loss). With regard to attachment anxiety, there is consistent evidence for a pattern of hyperactivation of attachment-related painful emotions and thoughts that exacerbate rather than mitigate distress. Using functional magnetic resonance imaging (fMRI) to observe brain processes while recalling a painful separation, Gillath, Bunge, Shaver, Wendelken, and Mikulincer (2005) found that attachment anxiety was associated with higher activation of the left anterior temporal pole and left hippocampus, areas associated with the recall of sad thoughts, and lower activation of the orbito-

frontal cortex, an area associated with emotional control. That is, anxious people seemed unable to control the reactivation of separation memories. This conclusion is reinforced by findings from Bailey, Paret, Battista, and Xue (2012), who used a Stroop task and found that attachment anxiety was associated with greater interference in naming the color in which separation-related words were printed—indicating a lack of control over intrusions by separation-related thoughts.

Neural signs of distress hyperactivation by attachment-anxious adults have also been reported by DeWall and colleagues (2012). They found that in response to a simulated experience of social exclusion while lying in an MRI scanner, self-reports of anxious attachment were related to heightened activity in regions involved in distress activation: the dorsal anterior cingulate cortex (dACC) and the anterior insula. Importantly, these brain reactions to social exclusion were attenuated by asking people to reflect on their security-providing attachment figure (Karremans, Heslenfeld, van Dillen, & Van Lange, 2011).

For avoidant people, the main method of dealing with separation-related thoughts is to suppress them. In a pair of experimental studies, Fraley and Shaver (1997) asked participants to write about whatever thoughts and feelings they experienced while being asked to suppress thoughts about a romantic partner leaving them for someone else. The ability to suppress these thoughts was assessed by the number of times they appeared in participants' stream of consciousness following the suppression period and by the level of physiological arousal (skin conductance) during the suppression task. As expected, more avoidant people were more able to suppress separation-related thoughts, as indicated by less frequent thoughts of loss following the suppression task and lower skin conductance during the task. In accord with this finding, Edelstein and Gillath (2008) used a Stroop task and found that avoidance was associated with reduced interference (faster RTs) in naming the color in which separation-related words were printed, reflecting avoidant people's tendency to block access to separation-related thoughts.

Mikulincer, Dolev, and Shaver (2004) replicated and extended Fraley and Shaver's (1997) findings while assessing, in a Stroop task, the cognitive activation of previously suppressed thoughts about a painful separation. Avoidant individuals were able to suppress thoughts related to the breakup; for them, such thoughts were relatively inaccessible, and their own positive self-traits be-

came more accessible than usual (presumably for defensive reasons). However, their ability to maintain this defensive stance was disrupted when a cognitive load—remembering a seven-digit number—was added to the experimental task. Under high cognitive load, avoidant individuals suddenly evinced high availability of thoughts of separation and negative self-traits; that is, the suppressed material resurfaced in experience and behavior when a high cognitive demand was imposed. This fragility of avoidant defenses has been further documented in more recent studies. Kohn, Rholes, and Schmeichel (2012) found that whereas avoidant attachment was associated with less access to early memories of negative attachment experiences in a neutral condition, a cognitive-depletion induction led to heightened access to these memories among more avoidant people. Similarly, Chun, Shaver, Gillath, Mathews, and Jorgensen (2015) found that more avoidant participants' ability to disengage attention from contemptuous faces was impaired (compared to the ability of less avoidant participants) when they were asked to rehearse a seven-digit number while performing the attention task.

While probing further into the regulatory mechanisms underlying avoidant defenses, Fraley, Garner, and Shaver (2000) asked whether they function in a preemptive manner (directing attention away from the information or encoding it in a shallow way) or in a "postemptive" manner (repressing material that has already been encoded). Participants listened to an interview about the loss of a relationship partner and were asked later to recall details of the interview, either soon after hearing them (Study 1) or at various delays ranging from half an hour to 21 days (Study 2). An analysis of forgetting curves revealed that (1) avoidant people initially encoded less information about the interview, and (2) people differing in attachment styles forgot encoded information at the same rate. Thus, avoidant defenses sometimes act preemptively by blocking threatening material from being encoded. In a subsequent study, Fraley and Brumbaugh (2007) found that more avoidant individuals performed worse on tasks assessing both explicit and implicit memories of information about the loss of a sister.

These findings imply that avoidant people are likely to be vigilant to attachment-related information so that its encoding can be blocked. In support of this idea, Maier and colleagues (2005) found that avoidant attachment (assessed with the AAI) was associated with lower identification

thresholds (less exposure time needed to identify a picture) for pictures depicting emotion-laden human faces and social interactions. In a more direct test of avoidant people's preemptive vigilance, Zheng, Zhang, and Zheng (2015) found that avoidant people (assessed with the ECR) tended to allocate more cognitive resources when encoding emotional faces at an early stage (170 milliseconds) during an old/new evoked-related potentials task. Similarly, Chun and colleagues (2015) found that more avoidant people (based on the ECR) were more vigilant toward contemptuous faces when the faces were presented for 100 milliseconds but quickly disengaged from them when the faces were presented for 750 milliseconds. Thus, avoidant defenses seem to demand perceptual vigilance to emotional stimuli at an early stage of information processing, in order to keep them from being processed further. We suspect that this is the default avoidant defense. Postemptive strategies are likely to be called upon only if the preemptive approach fails or when a threatening memory is aroused by association.

Emotional Reactions to Stressful Events

Several researchers have collected participants' reports of psychological distress during stressful events. Across these studies, attachment security has been associated with lower levels of distress, whereas attachment insecurities—*anxiety*, *avoidance*, or both—have been associated with heightened distress (see Mikulincer & Shaver, 2016, for a review). The link between attachment security and adaptive emotional reactions to stress has also been validated in experimental studies showing that temporarily activating mental representations of available and responsive attachment figures (a process we call *security priming*) can augment a person's emotional balance, even under fairly stressful circumstances (e.g., Mikulincer, Gillath, et al., 2001; Mikulincer, Hirschberger, Nachmias, & Gillath, 2001; Mikulincer & Shaver, 2001). In these experiments, mental representations of supportive attachment figures have been activated by well-validated social-cognitive techniques, such as subliminally presenting pictures suggestive of attachment figures' availability (e.g., a Picasso drawing of a mother lovingly cradling an infant, a couple holding hands and gazing into each other's eyes), names of people who were designated by participants as security-enhancing attachment figures, positive attachment-related words (e.g.,

love, *closeness*, *hug*), guided images of available and supportive attachment figures, and visualization of security-enhancing attachment figures' faces. In all of these studies, portrayals of attachment figures' availability led to more positive moods than priming with attachment-unrelated stimuli, even ones suggesting positive emotion (e.g., the word *success*).

Mikulincer, Hirschberger, and colleagues (2001) also found that priming with representations of supportive attachment figures infused formerly neutral stimuli with positive qualities, even when the priming was done subliminally. For example, subliminal presentation of the names of people who were designated by participants as security-enhancing attachment figures, compared with the names of close others or mere acquaintances who were not designated as attachment figures, led to greater liking of previously unfamiliar Chinese ideographs. Moreover, subliminally priming mental representations of available attachment figures induced more positive evaluations of neutral stimuli, even in threatening contexts, and eliminated the detrimental effects that threats otherwise had on liking for neutral stimuli. Thus, priming with mental representations of security-enhancing attachment figures has a calming, soothing effect, similar to the effects of actual interactions with available and responsive relationship partners.

There is also evidence that avoidance can be associated with negative emotional reactions to stressful events. For example, Berant and colleagues (2001b) and Berant, Mikulincer, and Shaver (2008) found that avoidance in mothers of infants with severe forms of CHD was a stronger predictor of deteriorated mental health 1 and 7 years later than was attachment anxiety. Similarly, Reizer, Possick, and Ein-Dor (2010) found that avoidance was associated with heightened distress among couples living in life-endangering areas of Israel (Jewish settlements in the West Bank) but not among couples living in less threatening areas. That is, under chronic, demanding stressful conditions, avoidant deactivating strategies seem to collapse, causing avoidant people to have as high or even higher levels of distress than anxious people. This is reminiscent of laboratory studies showing that avoidant defenses collapse under an experimentally imposed cognitive load (Mikulincer et al., 2004).

The vulnerability of avoidant defenses to collapse has also been noticed in studies assessing physiological responses to stressful events. For example, in two studies, avoidant people (assessed

with the AAI) had increased levels of physiological arousal (heightened electrodermal activity) when talking about painful childhood memories or during exposure to infant crying (e.g., Ablow, Marks, Feldman, & Huffman, 2013; Roisman, Tsai, & Chiang, 2004). Similarly, higher self-reported avoidant attachment was associated with heightened physiological reactivity—decreased heart-rate variability (Maunder, Lancee, Nolan, Hunter, & Tannenbaum, 2006), increased skin conductance (Diamond, Hicks, & Otter-Henderson, 2006), and heightened diastolic blood pressure (Kim, 2006)—in response to various laboratory stressors (e.g., recalling a stressful situation, performing demanding tasks, discussing relationship problems with a dating partner). In addition, Kim (2006) found that avoidance was associated with a decrease in *rate-pressure product* (pulse rate multiplied by systolic blood pressure) during a couple discussion, indicating an inability to supply oxygen to cardiac muscles while coping with stress that can “heighten the risk for hypertension and other cardiovascular diseases” (p. 111).

Interestingly, Maunder and colleagues (2006) found that attachment-anxious people’s responsiveness to stressors was manifested in higher levels of reported distress but not in heart rate measures, again suggesting that anxious people exaggerate their distress. In Kim’s (2006) study, anxious participants’ physiological reactivity was observed only when they also reported high levels of distress. This tendency contrasts with avoidant individuals’ dissociation between subjective reports of lack of distress and heightened physiological reactivity.

Several studies have assessed attachment-related differences in the activity of the hypothalamic–pituitary–adrenal (HPA) axis—indexed by salivary cortisol levels during and following laboratory-induced stressors. Two studies indicated that avoidant attachment was associated with increased levels of salivary cortisol (Kidd, Hamer, & Steptoe, 2011; Pierrehumbert, Torrisi, Ansermet, Borghini, & Halfon, 2012), two studies (Pierrehumbert et al., 2009; Quirin, Pruessner, & Kuhl, 2008) found a positive association between attachment anxiety and heightened cortisol reactivity, and two studies found no significant attachment–cortisol link (Ditzen et al., 2008; Smeets, 2010). These inconsistencies might have been due in part to variations in the stressors (e.g., aversive noise, the Trier Social Stress Test) and participants’ ages (young adults, midlife adults). More research is needed to determine the link between attachment insecurities and HPA dysregulation.

Kidd, Hamer, and Steptoe (2013) went beyond examining acute cortisol responses to stress and assessed cortisol levels across the day. Attachment anxiety was associated with both increased stress perceptions and higher levels of cortisol throughout the day. In addition, anxious attachment was related to heightened bedtime cortisol levels. It seems that anxious attachment strategies not only elevate cortisol levels during waking hours but also interfere with the inability to reduce levels of arousal when preparing to sleep (Maunder, Hunter, & Lancee, 2011).

There is also some evidence concerning attachment-related differences in brain responses to stressful events. Using event-related fMRI, Lemche and colleagues (2006) found that self-reports of attachment anxiety or avoidance were associated with heightened activation in bilateral amygdalae to a stressful stimulus; that is, less secure people tended to react to stress with increased amygdala activity—a neural indication of distress-related arousal.

More information about the brain mechanisms underlying insecure people’s regulatory strategies was provided by Vrtička, Bondolfi, Sander, and Vuilleumier (2012), who scanned the brains of people who were asked to attend naturally or cognitively reappraise their emotional responses to unpleasant scenes. Avoidant participants showed increased prefrontal and anterior cingulate activation in response to unpleasant scenes and exhibited increases in dorsolateral prefrontal cortex and left amygdala activity during reappraisal. These results suggest that avoidant people may be less efficient in using reappraisal strategies and need to engage in more effortful control for dealing with distress. Anxious participants showed increases in the right amygdala across the conditions—another sign of their heightened reactivity.

In a recent fMRI study, Moutsiana and colleagues (2014) provided evidence that infant attachment assessed at 18 months predicts neural responses to positive affect inductions at age 22 years. Specifically, adults who had been insecurely attached as infants showed greater activation in prefrontal regions and lower co-activation of nucleus accumbens with prefrontal cortex than adults who had been securely attached as infants. That is, attachment insecurity during infancy seems to be associated with relative inefficiency in the neural regulation of positive emotions during adulthood, and with the need to devote more effortful control during positive emotion inductions.

Considering longer-term neural effects of attachment insecurities, Quirin, Gillath, Pruessner,

and Eggert (2010) found that self-reports of attachment anxiety and avoidance were associated with reduced hippocampal cell density, which was associated with poorer emotion regulation. Whereas avoidance was associated with bilateral hippocampal cell reduction, anxiety was related to reduced cell concentration in the left hippocampus. These findings are compatible with a neurotoxic model of stress-induced cell reduction in the hippocampus, contributing to poorer emotion regulation abilities in individuals with insecure attachment orientations. In addition, Moutsiana and colleagues (2015) found that attachment insecurity at 18 months was associated with larger amygdala volumes at 22 years. However, they did not find evidence linking infant attachment status and hippocampal volume in young adulthood.

Attachment strategies are also manifested in emotional reactions to physical illnesses. There is evidence that attachment insecurities, mainly of the anxious kind, are associated with heightened distress among people suffering from physical illness (e.g., Bazzarian & Besharat, 2012; Vilchinsky et al., 2010; Vilchinsky, Dekel, Asher, Leibowitz, & Mosseri, 2013). However, in a prospective 6-month study of patients with acute coronary syndrome, Vilchinsky and colleagues (2010) found that a partner's supportiveness can buffer the observed link between attachment anxiety and distress. Attachment anxiety predicted heightened distress only when spouses did not actively support the patients. This detrimental effect of anxiety evaporated when spouses engaged in more supportive behavior, thereby providing a greater sense of security for the anxious patient.

Overall, data support the hypothesis that secure adults' optimistic appraisals of situations and reliance on constructive ways of coping mitigate distress during periods of stress. They also indicate that attachment anxiety or avoidance can interfere with effective coping and increase distress intensity. In the long run, this means that attachment insecurities increase people's risk for developing serious emotional and physical health problems.

Cognitive Access to and Structure of Emotional Experiences

Theoretically, attachment strategies should influence a person's access to emotion-related information, that is, the ways in which he or she attends to,

encodes, retrieves, understands, and reacts to such information; and the extent to which he or she is aware of emotional states and their fluctuations. In this section, we review some of the studies that have examined attachment-related individual differences in cognitive access to and architecture of emotional experiences, which is likely to be important for both personal understanding and regulation of one's emotions and the ability to discuss such emotions with relationship partners.

Access to Emotional Memories

In an early study of emotional memories, Mikulincer and Orbach (1995) noted attachment-related differences in the ways people retrieve early memories of specific emotions. Participants were asked to recall early experiences of anger, sadness, anxiety, or happiness, and their memory retrieval latencies were recorded as indicators of cognitive accessibility. Participants also rated the intensity of emotions in each recalled event.

Avoidant individuals exhibited the poorest access (longest latencies) to sad and anxious memories; anxious people had the quickest access to such memories; and secure people fell in between. Secure people took less time to retrieve positive than negative emotional memories, whereas anxious people had quicker access to negative than to positive memories. Moreover, avoidant people rated focal emotions (e.g., sadness when instructed to retrieve a sad memory) and nonfocal emotions (e.g., anger when instructed to retrieve a sad memory) as less intense than secure people. Anxious people reported experiencing very intense focal and nonfocal emotions when asked to remember instances of anxiety, sadness, and anger. In contrast, secure people rated focal emotions as much more intense than nonfocal emotions.

The findings suggest that secure people rely on more constructive and effective emotion regulation strategies. They acknowledge distress, retain access to negative memories, and process these experiences fully. However, they also have better access to positive memories and tend not to suffer from a spread of activation from one negative memory to another. Van Emmichoven, Van IJzendoorn, de Ruiter, and Brosschot (2003) noted this open attitude toward distress-eliciting information even in a sample of patients with anxiety disorders. It is possible that this open and adaptive pattern of emotion regulation explains Behringer, Reiner, and Spangler's (2011) finding that

secure new mothers (as assessed by interviews during pregnancy) displayed heightened sadness and anxiety 2 weeks postpartum and following a return to baseline following 2, 4, and 6 months. Insecure mothers exhibited a stable increase in negative emotions after delivery that did not return to baseline even after 6 months. That is, attachment security seems to help new mothers express and recover from negative emotions.

Mikulincer and Orbach (1995) found that avoidant people's reduced access to negative emotional memories is another indication of their attempts to inhibit the cognitive processing of distress-eliciting outer or inner stimuli. This finding was replicated by Dykas, Woodhouse, Jones, and Cassidy (2014) using the AAI to assess adolescents' state of mind with respect to attachment. Edelstein and colleagues (2005) also found evidence for avoidant people's poor access to negative memories (with avoidance being measured by the ECR) in a study of a sample of child sexual abuse (CSA) survivors. More avoidant people were less accurate in recalling specific, well documented, severe CSA incidents that had occurred approximately 14 years earlier. Interestingly, these memory problems were reduced among avoidant people who reported relatively high levels of maternal support after the abuse, highlighting the buffering effect of security-enhancing interactions.

In a related study, Haggerty, Siefert, and Weinberger (2010) instructed adults to freely recall childhood experiences before the age of 14 years, without explicitly asking them to remember a particular emotionally laden memory. Whereas both attachment anxiety and avoidance were linked to remembering more negative childhood experiences, only avoidance was associated with reduced emotional intensity of these memories, a finding similar to that reported by Mikulincer and Orbach (1995). Other studies have shown that avoidance is associated with less coherent memories of interactions with romantic partners (Sutin & Gillath, 2009) and lower levels of narrative elaboration of both childhood and adolescent memories (McCabe & Peterson, 2011). Interestingly, Sutin and Gillath (2009) found that exposure to insecurity primes (i.e., thinking about a nonresponsive relationship partner) led to less coherent memories.

Mikulincer and Orbach's (1995) finding that attachment anxiety is linked to easy access to negative emotional memories and impaired control of the spread of activation from focal emo-

tions to nonfocal emotions suggests that attachment-anxious people have a somewhat undifferentiated, unregulated organization of emotional memories. This fits with Roisman and colleagues' (2004) findings about people's facial expressions during the AAI. Whereas secure people's facial expressions were congruent with the valence of the childhood events they were describing, anxious people exhibited angry or anxious facial expressions while speaking about neutral or positive childhood experiences. According to Roisman and colleagues, these discrepancies reflect anxious individuals' confusion and emotional dysregulation when being asked to talk about emotionally charged experiences.

Pereg and Mikulincer (2004) studied the cognitive effects of induced negative mood, providing further evidence of insecure people's problems in processing emotional experiences. In two studies, participants were assigned to a negative mood condition or to a control condition, then incidental recall of positive and negative information (Study 1) or causal attributions of a negative event (Study 2) were assessed. The negative mood condition (as compared to the control condition) led secure participants to recall more positive information and less negative information, and to attribute a negative event to less global and stable causes. This mood-incongruent pattern of cognition is likely to inhibit the spread of negative emotions and activate competing positive cognitions (positive recalled information, attributions that maintain a positive view of a partner). As a result, secure people are able to work against the pervasive effects of the negative mood induction and maintain or restore emotional equanimity. In contrast, more anxious participants reacted to the induced negative mood with heightened recall of negative information and an increased tendency to attribute a negative event to more global and stable causes. This mood-congruent pattern of cognition favors the spread of negative emotions in memory and heightens access to distress-eliciting thoughts. These negative cognitions can exacerbate anxious people's chronic distress and negative views of others, and therefore contribute to continued activation of the attachment system.

Findings from Pereg and Mikulincer's (2004) studies also indicated that the memories and causal attribution patterns of avoidant people were not significantly affected by induced negative mood. Avoidant people seemed to exclude negative emotions from awareness and were therefore less likely to use it in cognitive processing.

Cognitive and Brain Reactions to Emotional Stimuli

There is growing evidence that attachment strategies are manifested in the ways people react to emotional stimuli. Atkinson and colleagues (2009) examined mothers' attention to emotional information using a Stroop task and reported that insecure mothers (assessed with the AAI) showed greater Stroop interference for negative emotion words, reflecting heightened difficulty in disengaging attention from these emotions. Similarly, using data from participants who completed a Stroop task during fMRI, Warren and colleagues (2010) found that attachment insecurities are associated with heightened color-naming interference for negative emotional words and increased activity in prefrontal cortical regions associated with emotion regulation (e.g., right orbitofrontal cortex) and cognitive control (e.g., left dorsolateral prefrontal cortex) during exposure to these words. Again, it seems that attachment insecurities involve vulnerability to distraction by negative emotional clues, and that greater cognitive control is required to attend to task-relevant, nonemotional information.

However, the kind of insecurity, anxious or avoidant, influences the specific ways in which people react to this vulnerability. Whereas avoidant individuals attempt to control the expression of emotion and distance themselves from it, anxious individuals' physiological and behavioral reactions exacerbate difficulties in disentangling attention from the emotional experience. For example, Rognoni, Galati, Costa, and Crini (2008) assessed electroencephalographic (EEG) frontal asymmetry while participants watched video clips inducing happiness, fear, or sadness. Whereas more avoidant people showed no fluctuation in frontal asymmetry in response to depictions of negative emotions, more anxious people exhibited wider frontal right activation in response to these emotions—a sign of threat-related activation in the brain. Similarly, Zilber, Goldstein, and Mikulincer (2007) found that more anxious participants (assessed with the ECR) showed greater brain-related late positive potential (LPP) amplitudes to distress-eliciting pictures—another sign of persistent attention. This response was not observed for positive or neutral pictures.

Avoidant people's tendency to control attention has been observed in a series of studies by Gillath, Giesbrecht, and Shaver (2009). They examined associations between ECR scores and

performance on attachment-unrelated attention tasks—a psychological refractory period (PRP) task assessing ability to switch attention rapidly from one stimulus to another and a flanker task assessing ability to resist distracters. As expected, avoidant attachment predicted better performance on both tasks, and the effects remained significant even after the researchers controlled for other personality traits. However, findings also revealed that thinking about a past attachment-related injury eliminated avoidant participants' superior attentional performance. In summary, avoidant people are generally skilled at regulating their attention, but their performance can be hampered by reminders of episodes of rejection, separation, or loss.

There is also evidence that avoidant people's attentional control includes the ability to inhibit brain and cognitive responses to distress-eliciting stimuli. For example, Suslow and colleagues (2009) used fMRI to examine differences in automatic brain reactivity to sad and happy faces as a function of attachment-related avoidance. As expected, avoidance was inversely associated with activity in the amygdala, the insula, and the primary somatosensory cortex (Brodmann area 3 [BA 3]) to sad faces. Subsequently, Suslow, Dannlowski, Arolt, and Ohrmann (2010) found that avoidant attachment was associated with inhibition of affective priming effects of subliminal presentations of sad faces on liking of neutral faces; that is, avoidant defenses seemed to block access to sadness-inducing information, thereby preventing the transfer of negative affect to a neutral stimulus.

Avoidant Attachment and Lack of Psychobiological Coherence

Avoidant people's reduced access to emotions is also evident in studies examining the coherence between self-reports of emotional experiences and less conscious, more automatic indicators of these experiences. (We assume that higher concordance between these measures implies greater access to emotional experience.) For example, avoidant people score relatively low on self-reports of death anxiety or anger but implicitly reveal these emotions in Thematic Apperception Test (TAT) stories or measured heart rate (Mikulincer, 1998; Mikulincer et al., 1990). Three related studies examined access to emotions during the AAI, and all found that avoidant people verbally expressed few negative feelings during the interview but at the

same time exhibited higher levels of physiological arousal (heightened electrodermal activity; Dozier & Kobak, 1992; Roisman et al., 2004) and more intense facial expressions of negative emotions (Zimmermann, Wulf, & Grossmann, 1996).

Spangler and Zimmermann (1999) examined attachment-related differences (based on the AAI) in the coherence of facial muscle reactions (measured with electromyography of the smile and frown muscles) and subjective reactions (pleasantness ratings) to 24 film fragments. For each study participant, they computed the correlation between muscular and subjective reactions across the 24 scenes, with higher positive correlations reflecting higher psychobiological coherence. Attachment security was positively associated with psychobiological coherence, but avoidance was associated with less accurate awareness of physiological states. Zimmermann, Maier, Winter, and Grossmann (2001) extended these findings to the experience of emotions during a problem-solving task: Avoidant people were characterized by a greater discrepancy between self-reported anger and sadness and congruent facial expressions. Similar findings were reported by White and colleagues (2012), who found that avoidant adolescents (in the Child Attachment Interview) reported relatively low levels of distress during a rejection episode, although their brains showed a strong negative reaction to this episode (stronger negative left-frontal slow wave).

Sonnby-Borgstrom and Jonsson (2004) provided further evidence of avoidant individuals' lack of psychobiological coherence when undergoing negative emotions. In their study, people were exposed to pictures of happy and angry faces at three different exposure times (17, 56, and 2,350 milliseconds), and their facial muscle reactions were continuously assessed. When the pictures were presented subliminally and participants could not recognize the faces (at exposure times of 17 or 53 milliseconds), both avoidant and secure individuals activated muscles involved in negative emotional displays (corrugator or "frowning" muscles) when they were presented with angry faces. However, when participants were able to recognize the faces (at an exposure time of 2,350 milliseconds), avoidant participants evinced lower levels of corrugator activity and increased zygomaticus muscle responses (a "smiling" reaction) when exposed to angry faces. In contrast, secure people reacted to these pictures by mimicking them (heightened corrugator activity). Avoidant people's heightened corrugator reaction to sublim-

inal exposure to angry faces seems to indicate that these pictures had automatically elicited negative emotions. Therefore, the avoidant participants' tendency to smile when they consciously saw the angry faces suggests a defensive attempt to block cognitive access to and visible expression of negative emotions.

A subsequent study extended these findings to interpersonal interactions. Seedall and Wampler (2012) videotaped couples during a seminatural conversation and an interaction with a therapist, and assessed physiological signs of distress (skin conductance) and the type of affect they expressed to their partner during the interactions. More secure participants showed signs of adequate psychobiological coherence: They expressed more negative feelings toward their partners mainly when they showed increased levels of skin conductance. However, those higher in avoidance expressed more positive feelings toward their partner mainly when they showed increased skin conductance—another possible sign of lack of psychobiological coherence.

Insecure People's Problems in Identifying and Differentiating Emotions

Pursuing the hypothesis that avoidant people tend to exclude emotions from consciousness, several studies have found positive associations between avoidant attachment and scores on the Toronto Alexithymia Scale, indicating difficulties in identifying and describing emotions (e.g., Barbasio & Granieri, 2013; Hesse & Floyd, 2011; Keating, Tasca, & Hill, 2013). Avoidant attachment (assessed with either self-report scales or the AAI) is also related to inattention to feelings (e.g., Kim, 2005), less emotional awareness (e.g., Monti & Rudolph, 2014), and less recall and more dismissal of dreams (e.g., Contelmo, Hart, & Levine, 2013). More avoidant people are also less likely to use emotion words and reflect on emotional themes while speaking about their childhood experiences in the AAI (e.g., Borelli et al., 2013). In addition, they score lower on tests of emotional intelligence (e.g., Cherry, Fletcher, & O'Sullivan, 2013, Delhaye, Kempnaers, Stroobants, Goossens, & Linkowski, 2013; Lanciano, Curci, Kafetsios, Elia, & Zammuner, 2012; but see Kafetsios, 2004, for an unexpected positive association between avoidant attachment and emotion understanding).

Interestingly, most of the studies that have examined attachment-related differences in alexithymia indicate that attachment-anxious people may also have difficulty identifying and describing their feelings. According to Mallinckrodt and Wei (2005), higher alexithymia scores reflect not only lack of emotional awareness but also difficulties in differentiating between specific emotions and communicating specific feelings to others. It seems possible, therefore, that anxious strategies, which are associated with an undifferentiated, somewhat chaotic emotional architecture, create difficulties in differentiating and identifying specific feelings. In support of this view, Stevens (2014) found that, although attachment-anxious people reported having increased emotional awareness, they struggled to identify their feelings and manage emotion-related responses. Moreover, Hill and colleagues (2013) found that more anxious people (assessed with the ECR) were less likely to report dreams during psychodynamic psychotherapy.

Attachment-anxious individuals' problems in differentiating and identifying specific feelings may be a result of the intensity of their reactions to threatening events. Several studies have indicated that people who score high on attachment anxiety also score high on measures of emotional reactivity or intensity (e.g., Gratz et al., 2015; Wei, Russell, Mallinckrodt, & Vogel, 2007; Wei, Vogel, Ku, & Zakalik, 2005). Some of these studies also indicated that avoidant attachment is associated with lower emotional intensity and expression of both positive emotions (e.g., love, pride) and negative emotions (e.g., anger and sadness). This fits with our idea that even positive emotions play a role in strengthening attachment bonds—something that avoidant people generally do not wish to do. This conclusion was recently supported by Goodall (2015), who found that avoidant people have difficulty regulating positive emotions. Specifically, self-reports of avoidant attachment were associated with lower levels of *savoring strategies* (enhancing or prolonging a positive emotion in order to maximize its effect) and higher levels of *dampening strategies* (limiting or reducing the effect of a positive emotion through a variety of means, e.g., suppression or changing focus away from the positive emotion).

Anxious and avoidant individuals' problems in identifying their feelings are also evident in studies examining individual differences in *mindfulness*—the capacity to maintain mindful attention and awareness to “here and now” stimuli, sensations, feelings, and thoughts without

any judgmental attitude. In all of these studies, self-reports of attachment anxiety and avoidance have been inversely associated with self-reports of mindfulness (e.g., Bourne, Berry, & Jones, 2014; Pepping, Davis, & O'Donovan, 2013; Walsh, Balint, Smolira, Frederickson, & Madsen, 2009). Pepping and colleagues (2013) also found that difficulties in emotion regulation fully mediated the negative association between attachment insecurities and mindfulness.

Conclusions

An enormous body of research—larger than we can cover here—supports an attachment-theoretical approach to understanding emotion regulation in adults. Many creative hypotheses based on the theory have been formulated and tested since 1990, using a variety of research methods—including behavioral observations, interviews, questionnaires, physiological and neuroimaging assessments, subliminal priming, implicit measures of cognitive and emotional processes, and systematic manipulations of threatening contexts and social situations. The findings are coherent, mutually reinforcing, and compatible with the model of attachment system activation and functioning presented here.

When we compare the literature available when we wrote the 2008 version of this chapter with what has been published since, we see that the literature has more than doubled in size. In general it has supported both attachment theory and our model of attachment system functioning, while adding an enormous number of details based on new methods and hypotheses. Especially impressive is the use of experimental methods, including subliminal priming, to probe the mechanisms underlying previous observations and test causal, rather than merely correlational, hypotheses. Also impressive are the revolutionary developments in the study of physiological underpinnings of attachment-related processes, including the expanding use of fMRI, candidate gene methods, and both the assessment and administration of hormones. These new developments are useful for not only the additional light they shed on attachment processes but also the suggestions they offer concerning possible interventions to enhance security (e.g., through security “priming,” couple counseling, and therapeutic targeting of particular mediating processes, e.g., avoidant suppression of negative emotions and the use of effective cop-

ing skills). These gains in research make possible parallel gains in psychological interventions and, perhaps, in greater self-understanding.

Despite these substantial gains over the period of 8 years since the previous handbook, there are still important issues to be resolved. Most of the social-psychological studies of adults, including our own studies, have involved samples of normal college students and have relied on self-report measures of attachment style. As explained in this volume by Crowell, Fraley, and Roisman (Chapter 27) and by Hesse (Chapter 26), these measures often do not converge well with the AAI, which means that more research is needed to clarify the meaning of the various measures and their associations with emotion regulation. Interestingly, many of the connections between one kind of measure and an outcome or mediational processes are mirrored in studies using the other kind of measure, so the use of the two kinds of measures together might provide a more complete explanation of various outcomes and mediational processes. Additionally, many studies now suggest that some of the individual-difference variance in attachment anxiety (although perhaps not in avoidance) is attributable to genetic factors. If so, it will have implications for both theory and clinical applications. Equally important are epigenetic processes that are just barely beginning to be understood. Finally, we confess that social psychologists who study normal adults (often college students) take the substantial developmental literature on attachment more or less for granted, rarely studying actual links between attachment-related childhood experiences that can help us understand adult emotion regulation. This means that the actual childhood roots of some of the specific phenomena we have studied in adulthood remain to be fully identified. Fortunately, there are now several very long-term longitudinal studies that are beginning to shed a powerful light on these matters, as indicated in several chapters in this volume.

Whatever the final story turns out to be, attachment theory has already advanced the study of emotion regulation in adulthood. Most of the findings summarized here (and in our more comprehensive treatment in Mikulincer & Shaver, 2016) are highly replicable, and many have now been replicated in different countries, using stimulus materials and measures in different languages. Most of the findings are not likely to be challenged or revised in the future. Only their final, complete, and correct interpretation and integration remain to be established.

Chapter 25

Attachment in Middle and Later Life

Carol Magai
María Teresa Frías
Phillip R. Shaver

Bowlby's formulations about the origins and nature of human attachments (Bowlby, 1969/1982, 1973, 1980) have provided a rich corpus of theory about important aspects of close relationships and their development over time. The theory has stimulated an enormous body of research on attachment during infancy, childhood, and early adulthood, as demonstrated in this handbook. But research on relationships in later life, viewed from an attachment-theoretical perspective, has been relatively limited (Magai & Consedine, 2004). Moreover, there are no longitudinal studies of the stability of attachment styles from early adulthood to middle age and later life, nor is there any research on how attachment patterns established earlier in life influence attitudes and behaviors later in life. Nevertheless, longitudinal research on the relation between early family circumstances (broadly construed) and later-life functioning indicates that early familial conditions predict health and illness, psychological well-being, and even mortality (Duncan, Kalil, & Ziol-Guest, 2013; Preston, Hill, & Drevenstedt, 1998; Weisner, 2005; see Ehrlich, Miller, Jones, & Cassidy, Chapter 9, this volume). This research suggests that there may indeed be long-term consequences of attachment-related bonds formed earlier in life, and that their impact may be of great consequence.

In early life, attachment bonds ensure that the infant maintains proximity to the caregiver under conditions of uncertainty or threat and

develops internal working models of this figure's availability and sensitivity. As the child matures, the exploratory or exploration behavioral system, which provides the scaffolding for growth and development of various skills through exploration of the environment, becomes activated; the child ventures further and further away from the caregiver, although the caregiver retains the function of a "safe haven" if the child experiences distress. The process of exploration, development, and individuation evolves over time, and a sense of autonomy is normally achieved by early adulthood. However, it is assumed that because of internal working models, the attachment figure retains his or her power to serve as a real or virtual safe haven when the individual encounters challenges in adult life. The theory also predicts that the internal working models of caregivers generalize to other people in the adult's social networks and that attachment styles are relatively enduring, although they are also responsive to new inputs (Bowlby, 1973; Fraley & Brumbaugh, 2004; Mikulincer & Shaver, 2007). There is now a significant literature on younger adults to support these formulations. However, it is important to assess the viability of these formulations as applied to later life, given the age-graded and role-linked unique challenges that occur across the adult lifespan.

In this chapter, we consider the subject of attachments in middle adulthood and later life in the context of normative adult developmental transi-

tions and challenges. Themes that loom large for middle-aged adults include monitoring the health of aging parents; often taking responsibility for parents' care, sometimes while still providing care to adolescent or young adult offspring (Perrig-chiello & Hoepflinger, 2005); and eventually dealing with the loss of these primary attachment figures. Themes that loom large for later-life adults include increased social, emotional, physical, and financial dependency; dealing with bereavement of spouse and friends; facing issues of encroaching mortality; and finding personal meaning as the end of life approaches.

In the context of this literature review, we explore the questions of (1) whether attachment styles remain relatively stable in later life and (2) under what conditions they might be altered. We also examine how differences in attachment style may inform adult developmental issues. And we explore whether patterns of social exchange and identity of the most common attachment figures in late life are different from those in young adulthood.

Because the literature on affectional bonds in later life is so limited in terms of testing derivations from attachment theory, this review necessarily draws on other literatures that are not grounded in attachment theory but nevertheless speak to attachment issues, in particular, the literature on the nature and quality of affectional bonds in middle and later adulthood and the influence of these bonds on caring for elderly relationship partners. Finally, we focus on issues of loss and bereavement. We restrict our focus to reactions of adult children to the loss of their parent because of space limitations, and because this literature is better developed than the literature on other kinds of affectional bonds (e.g., those between siblings). (For a review of the broader literature on loss and bereavement, see Fraley and Shaver, Chapter 3, this volume.)

The Distribution and Stability of Attachment Styles in Later Life

One might expect the distribution of attachment styles to be different in later life than in childhood and young adulthood given that attachment bonds are forged not only in relational but also in cultural and historical contexts (Weisner, 2005). We also need to revisit the thesis that attachment styles are relatively stable, for it is conceivable

that the unique challenges of the latter part of the lifespan create differential instability.

Distribution of Attachment Styles in Older Adults

Studies of younger adults indicate a distribution of attachment styles that resembles the one found in studies of infants and children. About 55–65% of samples studied with self-report attachment measures have been found to be secure, 22–30% are avoidant (or dismissing), and 15–20% are anxious (or ambivalent or preoccupied; e.g., J. A. Feeney & Noller, 1990; Hazan & Shaver, 1987). Bakermans-Kranenburg and Van IJzendoorn (2009) conducted a meta-analysis of studies using the Adult Attachment Interview (AAI) in different countries and languages. They found that in a combined sample of 748 nonclinical North American mothers, 16% were classified as dismissing, 56% were secure-autonomous, 9% were insecure-preoccupied, and 18% were unresolved with respect to trauma or losses. Bakermans-Kranenburg and Van IJzendoorn found a similar distribution in a sample of nonclinical fathers: 24% were classified as dismissing, 50% were secure-autonomous, 11% were insecure-preoccupied, and 15% were unresolved.

These distributions have not been replicated in the few studies of older respondents. In brief, avoidant or dismissing attachment appears to increase or to become more common in older adults, and there are low base rates of ambivalent and/or preoccupied attachment (Van Assche et al., 2013). For example, one cross-sectional study of urban adults with a mean age of 63 years (Magai, Hunziker, Mesias, & Culver, 2000) found that security of attachment, as assessed by the AAI, was negatively correlated with age, and that dismissing attachment was positively correlated. Another study (Diehl, Elnick, Bourbeau, & Labouvie-Vief, 1998) assessed attachment styles in a sample of young (mean age = 30 years), middle-aged (50 years), and older adults (70 years) from a relatively affluent Midwestern suburb; the results indicated that whereas 18% of the young adults were dismissing, 22% of the middle-aged adults were dismissing, and the figure for the oldest sample was 40%. In a study of attachment style and the preparedness of middle-aged adults to provide care to older adults, 56% were classified as secure, 31% were dismissive, 4% were preoccupied, and 9% were fearful (Soerensen, Webster, & Roggman, 2002).

A study of patients with dementia (mean age = 76 years; Magai & Cohen, 1998), in which caregivers were asked to rate their family members' attachment style before the patients became ill, found that 56% were rated as secure, 37% as avoidant, and 6% as ambivalent. In a large, randomly drawn sample of urban elders living in an economically disadvantaged community, 78% were rated as avoidant, with most of the remainder being rated as secure (Magai et al., 2001). In a study of major life events in later life, 39% of participants were classified as secure, 42% as avoidant, and 19% as anxious (Hobdy et al., 2007). In a study of emotion regulation in older adults, 13% of participants were classified as secure, 83% were avoidant, and 4% were preoccupied (Consedine, Fiori, & Magai, 2012). Finally, in a study of emotional experience of adults 50–70 years of age, 12.8% were classified as secure, 77.6% were avoidant, and 9.6% were preoccupied (Consedine & Fiori, 2009).

Although the proportion of avoidant or dismissing and secure individuals varies across samples and appears to have something to do with participants' economic background, the data clearly show that the distribution of attachment styles in older adult samples is distinctly different from the distribution in samples of younger adults. Some authors (Diehl et al., 1998) have suggested that the higher proportion of avoidant older adults may be due to a greater number of losses experienced by older persons. For example, Cicirelli (2010) found that attachment styles in a group of older adult respondents varied as a function of marital status, with the widowed showing greater avoidance.

Magai and colleagues (2001) suggested that these differences may be due to cohort effects. In a test of this hypothesis, the authors subdivided their sample into a younger cohort born between 1922 and 1932, and an older cohort born between 1911 and 1921. The younger cohort had significantly lower numbers of persons with secure attachment than did the older cohort. However, there was no difference between the two age cohorts in terms of the number of close relatives or friends who had died within the past 5 years. Magai and colleagues suggested that the differential proportions of secure attachment in the two cohorts might represent the influence of Watsonian behaviorism, which advocated the withholding of affection from children and would have reached the height of its influence between the 1920s and 1930s, thus affecting the younger cohort.

Certain socialization practices that are thought to lead to the development of dismissive

attachment can also be particularly common in certain cultural groups. For example, Consedine, Magai, Horton, and Brown (2012) found that *socialization of repressive coping*, a style of affect regulation in which negative emotions are ignored, downplayed, or dissociated, is more common among African Americans. Alternatively, this effect might be due to intraindividual changes in levels of dismissing, secure, ambivalent, and fearful attachment in response to age-graded developmental challenges. Finally, it is possible that higher rates of avoidant attachment among older adults are due to the way in which avoidant attachment is measured. Studies with older populations typically employ self-report measures originally designed for use with young adults, in which attachment-related avoidance is operationalized as a preference for autonomy and independence. Given that loss of autonomy is a normative threat for older adults due to deteriorating health, it is possible that high rates of attachment-related avoidance reflect autonomy concerns that are normative among older adults rather than changes in the way they experience and behave in close relationships.

In any event, the apparent existence of high rates of avoidant or dismissing attachment in older adults is grounds for concern. Grossmann (1996) advanced the thesis that attachment relations maintained within the larger family system contribute to the survival of family members. His work, as well as that of his colleagues, suggests that particular attachment styles might confer adaptive advantage over other styles later in life. Wensauer and Grossmann (1995), for example, found that grandparents with a secure attachment orientation had larger social networks, named more supportive family members, and received and gave more help, whereas avoidant individuals were significantly more self-reliant. In a related prospective, 10-year longitudinal study of older Australians, Giles, Glonek, Luszcz, and Andrews (2005) found that social networks conferred an adaptive advantage over and above those provided by demographic, health, and lifestyle variables. In that study, better networks with friends (and, to a lesser extent, networks with confidants) were protective against mortality over the following decade. Somewhat surprisingly, the effects of social networks with children and relatives were not significant with respect to survival; however, it is important to note that this study did not assess *quality of attachment* to children and other relatives—an important dimension to consider from an attachment-theoretical perspective.

It is possible that the positive effects of attachment security on older adults' subjective well-being and survival are due in part to the fact that they are more skilled at managing and optimizing their social networks. Gillath, Johnson, Selcuk, and Teel (2011) compared a group of older adults who had recently become caregivers of their spouse with a group of college freshmen and examined their responses to their respective life transitions, assuming that both involved changes in social networks. The results showed that although the social network size of the older adults was significantly smaller, they did not differ in the number of close others. Although older adults reported less contact with their network members, maintaining social relationships was easier for secure older adults. Gillath and colleagues interpreted these results as evidence that secure older adults are more skilled at optimizing their social networks to buffer the negative consequences of late-life transitions (e.g., losses) than their less secure counterparts. It appears that by decreasing social contact with peripheral network members, secure older adults can focus on interacting with emotionally close members (Fung, Carstensen, & Lang, 2001).

Fiori, Consedine, and Merz (2011) suggested that attachment styles are also associated with types of social network and patterns of social exchange in later life. They found that greater attachment security was associated with larger kin and non-kin social networks, reciprocal exchange in both kinds of social networks, and fewer kind relationships that involved primarily giving support. In contrast, dismissing attachment was associated with smaller non-kin social networks and fewer non-kin relationships that involved primarily giving support. The authors interpreted the larger size of both kin and non-kin social networks among secure individuals as an indication that they had more people from whom to receive support and the ability to engage in behaviors that preserve social ties. Their ability to form reciprocal relationships may reflect their flexibility and ability to balance the complementary roles of caregiver and care seeker. Fiori and colleagues argued that the smaller size of non-kin networks that characterizes dismissing attachment can be explained by a tendency to distrust others, which decreases willingness to invest dwindling resources in relationships.

Older adults also differ in the identity of their attachment figures and the strength of their relationships with them (Cicirelli, 2010; Van Assche et al., 2013). In a study of a community-based sample of older adults, it was found that partici-

pants' attachment figures had changed from those of earlier adult life to adult children, as well as intangible figures, such as deceased loved ones and God. Moreover, participants reported having fewer full-blown attachments (ones in which the same person serves all the attachment functions: proximity, secure base, and safe haven) but a greater variety of attachment figures, including in-laws, caregivers, doctors, and animals (Van Assche et al., 2013). According to Carstensen (1995), the reduced number of full-blown attachments is explained by *socioemotional selectivity theory*, according to which, with age, people become increasingly selective in their relationships and reduce the number of people with whom they maintain closeness.

Stability and Change in Attachment Styles

Although attachment styles are thought to be relatively stable, with some research even indicating that attachment styles are trait-like (e.g., Banai, Weller, & Mikulincer, 1998), Bowlby's model of attachment patterns was quite accommodating of change (Bowlby, 1973; Fraley & Brumbaugh, 2004). A review of the child development literature by Campos, Barrett, Lamb, Goldsmith, and Stenberg (1983) indicated that, averaged over seven studies, 32% of infants and toddlers showed a change in classification over time. Similar rates have been reported in young adult samples (Baldwin & Fehr, 1995), and rates as high as 46% have been reported in studies of adults undergoing particularly acute stress (Cozzarelli, Karafa, Collins, & Tagler, 2003).

The literature on stability and change in later adulthood is far more limited. Indeed, at this point there are only two longitudinal studies that address this issue, both of which examined changes in attachment over a 6-year period. One study involved a sample of 370 relatively affluent, highly educated, predominantly European American men and women between ages 15 and 87 years (Zhang & Labouvie-Vief, 2004). The other involved 415 less affluent, less well-educated older adults (60% African American, 40% European American) who were 72 years old at the first time of measurement and 78 years old at the second (Consedine & Magai, 2006). The former study indicated that both secure and dismissing attachment increased over time; the latter study indicated that both decreased over time. The discrepancy in findings is probably related to the pronounced demographic

differences between the two samples, including the age ranges studied. It may also be due to the fact that the first study relied on simple paragraph measures of attachment style, whereas the latter used the 30-item Relationship Scales Questionnaire (Bartholomew & Horowitz, 1991). In the case of the exclusively later-life sample, Consedine and Magai (2006) suggested that the unexpected decrease in both security and dismissiveness (compared with previous cross-sectional studies) relates to sample-specific changes in the purposes served by attachment figures in later life and changes in patterns of social network engagement and composition. That is, the decrease in security may reflect the loss of key members of social networks due to mortality. Conversely, decreases in dismissiveness may reflect a tendency in this sample, or age group, to place increasing value on intimate, emotionally rewarding relationships when one's expected remaining time with them was limited.

Attachment and Well-Being in Later Life

As could be expected based on research involving young adults, attachment security in older adults is associated with physical and psychological health and well-being (Bodner & Cohen-Fridel, 2010; Consedine, Fiori, & Merz, 2013). Consedine and colleagues (2013) analyzed responses of 1,118 older adults to health and personality-related self-report measures and found that fearful attachment predicted greater physical impairment, presumably because fearful individuals' tendency to experience greater negative affect (another finding of their study) may contribute to experiencing physical symptoms more negatively.

Effects of adverse childhood experiences with caregivers also seem to affect older adults' sleep cycle. Poon and Knight (2011) found an association, in a sample of older adults, between self-reports of child abuse and neglect, on one hand, and sleep complaints on the other. The authors maintained that abusive or neglectful child-parent interactions may impair individuals' confidence in their ability to cope with stress. Those who experience child abuse are more likely to develop cognitive schemas involving harm, shame, and self-sacrifice (Wright, Crawford, & Castillo, 2009), all of which contribute to hypervigilance, which is physiologically incompatible with sleep. Similarly, Verdecias, Jean-Louis, Zizi, Casimir, and Browne (2009) found an association between a preoccupied attachment style and daytime napping, use of sleep-inducing

medications, and a tendency to sleep less, whereas a secure attachment style was associated with little difficulty initiating sleep.

A chronic sense of attachment insecurity could also cause changes in the functioning of the endocrine system. In adolescence and young adulthood, fearful attachment is associated with high activation of the hypothalamic-pituitary-adrenal (HPA) axis (Dewitte, De Houwer, Goubert, & Buysse, 2010), responsible for increases in cortisol. However, among older adults, cortisol levels of fearful individuals seem to be lower than the levels for other attachment styles (Kidd, Hamer, & Steptoe, 2013). Kidd and colleagues (2013) suggested that chronic activation of the HPA axis may occur in younger individuals who score high on fearful attachment, but over time, the HPA axis loses its resilience as a consequence of chronic dysfunctional activation.

In later life, some of the main causes of activation of the attachment system are losses of valued roles related to one's self-definition. Hobdy and colleagues (2007) studied two groups of older adults, one of individuals who had recently lost their jobs and the other of individuals whose last child had recently moved out of the family home. Perhaps because the job losses were generally unexpected, they were perceived as more threatening than having a grown child leave home. In both loss groups, secure individuals showed less of a drop in well-being than their insecure counterparts, but these results were qualified by gender. Among individuals scoring high on comfort with closeness (one dimension of secure attachment, as measured in this study), greater coping efforts were observed among men experiencing unemployment and among women experiencing an empty nest, each of which is a core aspect of the male or female gender role.

Attachments between Parents and Children in Later Life

Arguably, the most powerful affectional bonds are the bidirectional ones that develop between children and their parents. In this section, we examine what the literature has to say about the nature and quality of these bonds during later life.

As Ainsworth (1989) noted, there is no reason to think that a child's attachment to his or her parent wanes once adulthood is reached, or that a parent does not continue to offer a safe haven to

his or her adult offspring when needed. Although this proposition is intuitively reasonable, the attachment literature with respect to it is not well developed. Interestingly, there is much better-developed theory and research relevant to the parent–child relationship in the sociological literature. In the following paragraphs, we organize the findings about affectional bonds in later life into two categories: (1) attachment of older parents to their adult children, and (2) attachment of adult children to their aging parents. In each section, we attend first to the attachment literature, then to the sociological literature.

The Attachment of Aging Parents to Their Adult Children

Findings Based on an Attachment–Theoretical Perspective

In an interview-based assessment of attachment among older adult mothers (mean age = 72 years), Barnas, Pollina, and Cummings (1991) identified three general patterns of attachment to adult children: insecure-avoidant, insecure-mixed (secure–insecure), and secure. Interestingly, an anxious or preoccupied pattern did not appear in this older cohort—a pattern that mirrors research on the distribution of attachment styles in later adulthood (largely based on self-report measures) reviewed earlier. What is especially interesting about this study is that although the majority of women had secure attachments to at least one child, the quality of relationships varied across children for older adults who had more than one child. Half of the mothers had insecure attachments to at least one of their children, with 31% also having very insecure attachments to at least one child. Twenty percent had insecure-avoidant attachments to all of their children, 40% had insecure-mixed attachments to all of their children, and 40% had secure attachments to all their children.

There is a similarly sparse literature on the impact of early rearing experiences on adult patterns of attachment, although researchers suggest that relationship patterns forged early in life have a bearing on attachment relations in adulthood, at least as assessed by retrospective accounts. In a nationally representative sample of people between 15 and 54 years of age, Mickelson, Kessler, and Shaver (1997) found that an array of reported childhood experiences, including abuse and neglect, were associated with attachment in adulthood. Secure attachment was negatively associat-

ed with reports of physical abuse, serious neglect, and being threatened with a weapon; avoidant attachment was positively associated with serious assault, physical abuse, serious neglect, and being threatened with a weapon, rape, and sexual molestation. These interpersonal traumas, with the exception of serious assault, were also positively associated with anxious attachment.

Another study (Diehl et al., 1998) examined the reported early family climate of adults ranging in age from 20 to 87 years. A positive climate in the family of origin was indexed by the extent to which participants reported family members' supporting each other and being allowed to express their feelings freely; a negative family climate was one in which the family members emphasized rules and enforced rules with punishment. Higher ratings on secure attachment were associated with a more positive evaluation of the family of origin. Higher scores on fearful attachment were associated with lower scores on satisfaction with the family of origin and with the current family, and with higher scores on current negative family climate. Higher scores on preoccupied attachment were positively associated with current negative family climate and negatively associated with current positive family climate. Finally, there were no significant associations between dismissing attachment and any of the family-related variables. This research indicates that childhood maltreatment of various kinds, including physical abuse, negatively influences adult attachment representations and adult attachment organization (Cicchetti, Toth, & Lynch, 1995).

Insights from the Sociological Literature

INTERGENERATIONAL SOLIDARITY

Despite the limited literature on parent–child attachment in later life as viewed from an attachment perspective, there is a fair amount of sociological literature on *intergenerational solidarity* (Silverstein & Bengtson, 1997). The term *solidarity* denotes the cohesion among members of families and is defined by three dimensions: “opportunity” (frequency of contact and residential propinquity between generations), “function” (flows of instrumental assistance between generations), and “affinity” (emotional closeness and perceived agreement of opinions). Although there are generally affectional ties between parents and their adult children, the extent of these ties appears to be moderated by the gender of the parent

and the child (Rossi & Rossi, 1990). Affectional ties between mothers and their adult daughters appear to be among the strongest and most enduring of intergenerational bonds (Fingerman, 1996; Rossi & Rossi, 1990, 1991).

Using another index of relationship quality, Fingerman (1996) found that 75% of the mothers indicated that their daughters were among the three most important people in their lives; the corresponding percentage of daughters who nominated their mothers as such was 58%. A mother was also more likely to name a daughter as the person she got along with best, and the person with whom she was most likely to speak when upset, than a daughter was to name a mother. Fingerman speculated that this imbalance in relationship quality from the perspectives of mothers and daughters was probably a function of the older women's narrower social networks. As networks shrink in later life, the people who remain in the network tend to become more important as sources of emotional support and gratification (Carstensen, 1995).

Affectional ties between the generations conceivably have an impact on the nature of the social and instrumental support members provide each other in times of need. Two reviews of the literature on the factors that influence intergenerational support (Davey, Janke, & Savla, 2004; Swartz, 2009) indicate that the quality of relationship history is one of several dyadic characteristics that affect a parent's tendency to supply support to his or her adult children, but it is neither a necessary nor a sufficient condition. Support exchanges between the generations, particularly instrumental exchanges, are not entirely dependent on the quality of relations between parents and children. When both the parents and their adult children are healthy and self-sufficient, intergenerational support tends to remain dormant. However, when the child is in need of emotional, instrumental, or financial support, parents tend to provide it even if their relationship is insecure, suggesting that the strongest predictor of intergenerational support is need (Davey et al., 2004; Swartz, 2009).

INTERGENERATIONAL AMBIVALENCE

Although the theoretical interest in intergenerational ambivalence has increased in recent years, the empirical literature is not yet well developed. In one study based on a sample of mothers 60 years of age and older (Pillemer & Suito, 2002), about one-third of the mothers were "torn" in

their ties to their oldest child and felt conflicted about the relationship. One source of conflict was the tension between desires for autonomy and dependency. For example, mothers were concerned about encroachments on their autonomy when adult children failed to achieve and maintain normative adult statuses and financial independence. An analysis of the Iowa Youth and Families Project (Shuey, Wilson, & Elder, 2003), which also focused on mothers' experiences of ambivalence with respect to their children, found that a mother's own dependency increased her level of ambivalence.

In another study (Fingerman, 2001), older mothers were interviewed regarding both the pleasures and problems in their relationships, and one of the salient sources of tension was daughters' unsolicited advice or help. Interestingly, Fingerman also found that different mothers resolved the inherent tensions in their relationships in different ways. Three main styles were discerned: constructive, destructive, and avoidant. This distinction in styles of resolving tension finds a parallel in another study (Smith & Goodnow, 1999) of how adults responded to unasked-for support. Three styles were described: assertively ignoring or rejecting the help, active discounting, and accommodating. Although attachment styles were not measured in either study, the tripartite distinction among styles of resolving tensions and conflicts would seem to be compatible with attachment theory.

In another study of intergenerational ambivalence in a sample of 75 men and women above age 65 (Spitze & Gallant, 2004), participants were interviewed in focus groups. One salient theme was ambivalence about the extent to which children involved themselves in their parents' affairs and health. Parents expressed annoyance at children's overprotectiveness and controllingness; at the same time, they were appreciative of the concern these behaviors expressed. Parents tended to deal with their children's overprotectiveness in one of three ways: by withholding information and confiding in others, by ignoring the overprotectiveness, or by simply accepting it. The material also revealed a desire to be independent, coupled with a potentially conflicting desire for connection to children. This raises a particularly important issue with respect to the measurement of attachment in older samples. Dismissing attachment is often rated on the basis of emphasis on self-reliance and autonomy. If assertion of preference for autonomy is related to aging individuals' fears of becoming incapacitated and being burdensome to their chil-

dren, measures that rely too heavily on evidence of older adults' preference for autonomy and independence will confound attachment with developmentally normative trends. This is an issue to which we return later.

Intergenerational ambivalence has also been examined in a study in which participants of different ages indicated the quality of their relationships with a range of individuals in their social networks (Fingerman, Hay, & Birditt, 2004). Participants were asked to name social partners to whom they felt very close and people who bothered them. Participants could name any or all of their relationships in both circles. From the data, the researchers identified relationships that were solely close, solely problematic, and ambivalent. Fingerman and colleagues (2004) found that the young-old (60–69 years) and the old-old (>80 years) were more likely to describe both sets of relationships as solely close than were adolescents, young adults, and middle-aged adults. In fact, among the oldest-old, 92% rated their family relationships as close, 8% rated them as ambivalent, and none rated their relationships as solely problematic.

This apparent decline in conflicted relationships with age is consistent with *socioemotional selectivity theory* (Carstensen, 1995), which proposes that older adults deliberately shed their more peripheral and least emotionally gratifying social relationships in the service of regulating emotion and avoiding conflict. In terms of specific relations, the young-old—the oldest group who still had living parents—were more likely to rate the relationships with their parents as close (70%), with none rating parental relations as problematic. In the young adult sample, however, 43% rated their relationships with their parents as close, and 54% rated them as ambivalent. Sixty-three percent of the middle-aged adults rated their relationships with their parents as close, and 31% rated them as ambivalent. As in the case of the oldest-old adults, none of the parental relationships were rated as solely problematic.

Although the study was cross-sectional, the data could be taken as suggesting that people become less ambivalent about their parents as they age, perhaps reconciling differences as they confront the prospects of their own mortality. It should also be noted, however, that in some ways, the data from this study would seem to be at variance with the literature on attachment style distributions in later life; as reported earlier, this literature indicates that dismissiveness tends to increase with age. The difference between the two

sets of data may be attributable to the fact that in the Carstensen (1995) study, individuals were describing *specific* relationships rather than a general style of relating to others, which is tapped by self-report measures of adult attachment. It may simply be that when older adults think of peripheral relationships, they downplay their significance (thereby expressing dismissive attitudes); when they think of particular family relationships, they may focus on their positive nature, especially since close relations in later life are more fundamental to their survival and well-being (and thus less likely to be probed for negative content).

Alternatively, the less ambivalent ratings of the older adults in the Carstensen (1995) study may indicate their placing a premium on avoiding negative interactions. Indeed, several studies indicate that older adults tend to shun occasions where negative affect may be aroused, and that they report higher levels of positive emotion, less interpersonal friction, lower levels of negative emotion overall, and less conflict in their close relationships than younger family members do (e.g., Lefkowitz & Fingerman, 2003; Stimpson, Tyler, & Hoyt, 2005). Finally, another alternative explanation may be that children's behaviors toward their parents may become more positive as their parents become older because as parents enter late life, children may become more solicitous toward them and may protect their parents by not raising issues that upset them (Fingerman & Birditt, 2003).

The Attachment of Adult Children to Their Aging Parents

The Attachment Perspective

Early in development, the often fairly exclusive child–mother attachment broadens to include the father, siblings, grandparents, and other relatives. In a study involving a representative sample of Japanese and American individuals ranging in age from 8 to 93 years, Antonucci, Akiyama, and Takahashi (2004) examined social networks to determine how social ties are distributed at different ages. The findings were remarkably similar across the two cultures, with only slight variations. In the innermost ring (depicting closest relationships), 8- to 12-year-old children named their mothers first, followed by fathers and siblings. Adults ages 21–39 still mentioned their mothers first, but the next most frequently mentioned persons were spouses. Among 40- to 59-year-olds, spouses were the most frequently nominated as the closest relationships,

with children mentioned next, and only then were mothers likely to be named. Among 60- to 79-year-olds, the closest relationships were spouses and children, with mothers no longer being nominated. Finally, among 80- to 93-year-olds, the pattern seen in 60- to 79-year-olds continued, but with the addition of grandchildren. In Japan, grandchildren were sometimes even nominated as being very close.

We note from this study the prominence of the mother as the main attachment figure in early life. Although she is often displaced by a spouse later in adulthood, the mother persists as a close attachment figure through middle age. Her disappearance from the circle of closest relations later in life is likely to be due to her death.

Insights from the Sociological Literature

INTERGENERATIONAL SOLIDARITY

There is a fairly sizable literature on solidarity with respect to adult children and their parents, and this literature supplies much evidence of mutual support and value consensus (Bengtson, Rosenthal, & Burton, 1996; Davey et al., 2004). One of the most methodologically sound studies, a nationally representative survey of cross-generational relationships as reported by adult children (Silverstein & Bengtson, 1997), found that 73% of the sample described themselves as very close to their mothers (vs. somewhat close or not close at all) and 57% described themselves as being very close to their fathers. However, feelings of emotional closeness, while common, did not fully capture the range of intergenerational patterns. The same researchers (Bengtson et al., 1996) also applied a latent class analysis to six dimensions of intergenerational solidarity derived from the broader dimensions of opportunity, function, and affinity. The six dimensions were emotional closeness, similarity of opinions, geographic distance, frequency of contact, providing instrumental assistance, and receiving instrumental assistance. Five types of intergenerational relations emerged. The “tight-knit” type was indicated by relations in which adult children reported being engaged with their parents on all six indicators of solidarity. The “sociable” type was characterized by a high degree of emotional closeness and similarity of opinion, close geographic proximity, and frequent contact, but low levels of instrumental exchange. Adult children characterized as “intimate but distant” were engaged with their parents in terms of emotional closeness

and similarity, but not geographic proximity, frequency of contact, or instrumental exchange. The “obligatory” type was characterized by geographical proximity and frequent contact but was low on emotional closeness, similarity, and instrumental exchange. Finally, adult children characterized as “detached” were not engaged with their parents on any of the six indicators of solidarity.

INTERGENERATIONAL AMBIVALENCE

Earlier we described a study of close, ambivalent, and problematic relationships (Fingerman et al., 2004) based on the ratings of older adults. That same study also gathered data on how young and middle-aged adults rated their relationships with their parents, among other family members and nonfamily individuals. In this case, there was more evidence for ambivalence. Whereas for the oldest group of adults the proportion of relationships with children characterized as ambivalent was quite low (only 6%), 56% of the young adults and 31% of the middle-aged adults rated their relationships with their parents as ambivalent. The corresponding proportions of “close” relationships were 43 and 63%, respectively. Another study (Wilson, Shuey, & Elder, 2003), using data from the Iowa Youth and Families Project, focused on adult children’s ambivalent feelings toward their parents and in-laws. The authors found that children were more ambivalent in female dyads, in relations with in-laws, in relations with parents in poor health, and in cases where a daughter was serving as a caregiver to a parent.

Continuity of Relations over Time

Based on what we know about the intergenerational transmission of attachment styles between mothers and their young infants (e.g., Benoit & Parker, 1994; Fonagy, Steele, & Steele, 1991), one would expect differential patterns of solidarity both to be linked to individuals’ relational histories and to affect current functioning. Indeed, there is much evidence to support these expectations. The bulk of literature on intergenerational solidarity and intergenerational ambivalence suggests that the history of early parent–child relationships, such as experiences with rejection (Stimpson et al., 2005; Whitbeck, Hoyt, & Huck, 1994), divorce, and other family problems (Webster & Herzog, 1995), may affect current solidarity in various ways. These include exchanges of help and sup-

port (Parrott & Bengtson, 1999), conflict (Clarke, Preston, Raskin, & Bengtson, 1999; Whitbeck et al., 1994), strain (Whitbeck et al., 1994), depression (Stimpson et al., 2005; Whitbeck, Hoyt, & Tyler, 2001), and reciprocity (Silverstein, Conroy, Wang, Giarrusso, & Bengtson, 2002).

Giving and Seeking Care: Relations to Attachment

Changes in family structure and economics have contributed to generations of a family being more interdependent in many cases, which can both challenge and strengthen family ties. Due to increases in the time devoted to education and the complexity of young families (e.g., involving divorce and children born outside of marriage), middle-aged parents in contemporary families may continue to provide financial support to their young adult children more than parents did in previous decades. Moreover, due to demographic shifts in the population of most Western countries related to reduced mortality and longer lifespans, there is an unprecedented lengthening of the overlap between the lifespans of adult children and their parents (Perrig-chiello & Hoepflinger, 2005). Because of this overlap, elderly parents are nowadays providing child care for their grown children's children (Swartz, 2009). This has become especially important given the increased rates of divorce and single parenting (Bengtson, 2001).

An occasion for conflict resides in the changing nature of relationships over developmental time, due to differential engagement of two different behavioral systems—attachment (care seeking) and caregiving. We typically think of the child as the care seeker and the parent as the caregiver, but these roles often change in later life. Despite the extension of disability-free life expectancies within the older adult population, the last phase of the lifespan is often accompanied by physical infirmity and the resulting assumption of substantial burdens of care by middle-aged children. It has been estimated (Perrig-chiello & Hoepflinger, 2005) that approximately 50% of all women (who tend to be the caregivers in families) will need to deal with dependent parents during middle age, and men and women both will need to reengage psychologically with their parents in ways that activate attachment-related feelings and motivations.

Given these demographic changes, both children and parents are faced with adding new roles to their lives. As the parent becomes infirm or incapacitated and becomes a care seeker, the middle-aged adult may need to step in and provide care—generally a new role for the child. These role accretions in the parent–offspring relationship would seem to engender one of the most common sources of intergenerational ambivalence: the role reversal entailed in the transition from adult child to adult caregiver, and in the gradual, unhappy relinquishment of autonomy by the aged parent (Diehl et al., 1998).

Caregiver: A New Role for the Child

Caring for an elderly parent seems to be a nearly normative task for today's middle-aged adults, which may have negative consequences for both parties of the relationship. Merz, Consedine, Schulze, and Schuengel (2009) examined questionnaire responses of 1,456 Dutch dyads and found that, on the adult child's side, providing support to a parent was associated with feelings of burden that were not affected by relationship quality.

Although the quality of the child–parent bond does not seem to affect the sense of burden of caring for an elderly parent, it may well affect the kind of care aged parents receive from their children (Diehl et al., 1998). The researchers found that empathy and social responsibility—traits associated with the inclination to help others—were positively associated with attachment security and negatively associated with fearful avoidance. Dismissing attachment was negatively associated with empathy, and preoccupied attachment was negatively associated with responsibility. Compatible experimental work (Mikulincer, Shaver, Gillath, & Nitzberg, 2005) has shown that increasing individuals' felt security through both implicit and explicit security priming fosters compassion and altruistic behavior.

Research indicates that concern for aging parents' health is highly salient in the minds of adult children, and that dealing with this concern is a pervasive aspect of relationships with parents (Cicirelli, 2000). Theoretical sociologists provided some of the earliest formulations concerning the motives and means by which adult children provide help to aging parents. From a sociological standpoint, helping behavior is seen as one aspect of intergenerational solidarity, and

helping behavior itself is viewed as a function of a particular elderly person's dependency needs, residential propinquity to an adult child, filial obligations, and gender roles. The Longitudinal Study of Generations (Silverstein, Parrott, & Bengtson, 1995) assessed parent-child dyads participating in three waves of data collection. The results indicated that intergenerational affection was the factor that most motivated daughters to provide support, whereas for sons the predominant factors were filial obligation, legitimization of inheritance, and frequency of contact. Data from the same study indicated that a history of affection was also associated with equitable and reciprocal exchange of support, as well as with a greater likelihood of giving and receiving various forms of support and help (Parrott & Bengtson, 1999).

Operating within an attachment perspective, Cicirelli (1983, 1993) proposed that caregiving by adult children is motivated by enduring affectional ties between children and their parents, and by protective motives on the part of children. That is, an adult child, who may still come to an elderly parent for instrumental or emotional support during times of stress (e.g., childrearing, job difficulties, divorce), is motivated to preserve and/or restore the threatened existence of the attachment figure as long as possible, and this may involve becoming a caregiver when the parent is ill. However, the quality of the child's attachment to the parent may influence the quality of his or her caregiving.

In the literature on caregiving in dating and marital relationships (i.e., in young adult samples), secure individuals have been found to report and display more sensitive and responsive care and less controlling caregiving than avoidant and ambivalent individuals (Collins, Guichard, Ford, & Feeney, 2006; B. C. Feeney & Collins, 2001). Attachment-oriented studies of caregiving in the context of adult children providing care to elderly parents are quite limited in number, but the findings are consistent in showing that secure attachment can ameliorate anticipated or experienced caregiver burden. In one of the first studies of its kind, Cicirelli (1983) proposed that affectional ties between children and their parents might be a better predictor of helping than filial obligation. He studied a sample of middle-aged adults with mothers age 60 and above. Attachment was measured by an index of feelings of closeness and perceived similarity through identification; attachment behaviors were assessed by a composite of residential proximity, frequency of visits, and

frequency of telephone contacts. Path analysis revealed that caregiving behaviors were predicted by feelings of attachment, maternal dependency, and filial obligation. Current helping behaviors were a direct effect of only two variables, attachment feelings and greater dependency on the part of the parent, whereas feelings of attachment and filial obligation had indirect effects, acting through their effect on what Cicirelli described as "attachment behavior" (defined as communication over distance to maintain psychological closeness). Future help was predicted by attachment behavior, feelings of attachment, low conflict, and parental dependency; filial obligation had no direct effect on commitment to provide future help.

A more recent study assessed the degree to which middle-aged children were prepared to face the challenge of future caregiving responsibilities as a function of attachment style (Soerensen et al., 2002). This study found that security of attachment was a significant and positive predictor of feeling prepared to provide care, whereas both anxious-ambivalent and avoidant attachment predicted lower levels of feeling prepared. Three other studies have examined the actual caregiving experience and its impact on *caregiver burden* (defined as subjective experiences of stress and strain). One study assessed attachment and obligation in daughters caring for elderly mothers (Cicirelli, 1993). The data indicated that although both variables were related to the help provided by the daughters, stronger (or more secure) attachment was associated with less subjective burden, whereas stronger obligation was associated with greater burden. In another study, Crispi, Schiaffino, and Berman (1997) found that secure (vs. insecure) attachment of middle-aged children to a parent diagnosed with dementia was associated with lower "caregiving difficulty" (a measure of subjective and objective burden) and with lower psychological distress.

Another study hinted at the possibility that the attachment style of the older parent and his or her behavior may influence the experience of caregiver burden in the child (Magai & Cohen, 1998). In this study, patients with dementia who were rated as having an anxious attachment style before they became ill displayed more anxious and depressed symptoms than did patients with secure or avoidant attachment styles. Patients with the avoidant style displayed more activity disturbance than patients with the anxious style, and more paranoid symptoms than those with a secure style. Relatedly, caregivers of patients with a secure style

reported lower caregiver burden than those caring for patients with avoidant or anxious attachment styles. Thus, there are likely to be reciprocal and dynamic aspects of the care experience at the level of the dyad; this feature is alluded to in a recently published multicomponent conceptual model, with both caregivers' and care recipients' characteristics and behaviors affecting the relationship dynamic (B. C. Feeney & Collins, 2004).

There is evidence of intergenerational transmission of attachment and caregiving patterns. Longitudinal data from a Swiss study, *Transitions and Life Perspectives in Middle Age* (Perrig-chiello & Hoepflinger, 2005), indicate that *filial autonomy* (a measure of successful coping with normative developmental tasks in adulthood) was negatively correlated with filial helpfulness and with secure relations with the adults' own children. These findings suggest that a strong sense of separateness between middle-aged individuals and their parents was mirrored in a less secure relationship with their own children. Moreover, the strength (or security) of attachment to parents was positively associated with the strength of relationships with the middle-aged participants' own children. Another set of investigators (Wilson et al., 2003), using data from the Iowa Youth and Families Project and focusing on adult children's ambivalent feelings toward their parents and in-laws, found that there is greater ambivalence when there were poor relations during childhood.

Compatible results were found by Klaus (2009), who analyzed the effect of secure attachment and history of supportive interactions on social support provision of German adult children to an elderly parent. In this study, secure attachment was assumed to be expressed by the child's propensity to feel close to the parent. The results showed that children tended to provide more support if they had received more support from the parent in the past and if they were securely attached. Similarly, Swartz (2009) reported that children whose parents had invested more time and emotional and financial support in them tended to provide more support 27 years later. Klaus interpreted the tendency of more securely attached children to be supportive as a result of early parental caregiving behavior and as an effort to keep the parent alive and preserve the emotional bond.

Chen and colleagues (2013) examined adults' attachment representations and the task of caring for elderly parents with dementia. They found that individuals who indicated having a secure base script for caring for an elderly parent also

reported less criticism, hostility, and emotional overinvolvement in their relationships with their elderly parents. Moreover, their results showed that such script knowledge has a stronger effect when the caregiving task is perceived as more difficult. Based on these findings, Chen and colleagues argued that the value of knowledge from a secure base script lies more in providing a motivational framework and a goal structure (to be a good, secure base) than in specific skills. Chen and colleagues' results also suggest that a certain amount of stress is required for script knowledge to have an impact on caregiver behavior. It may be that in the context of caring for a parent with dementia, stress represents a signal that allows adult children to recognize the need, then shift into their role as caregivers.

Help Seeking in Later Life: A New Role for the Parent

Despite older adults' clear preference for retaining their autonomy in later life, most people cannot realistically hope to avoid an increase in dependency if they live long enough. Among the potential elicitors of care seeking are (1) the various forms of chronic illness with which persons are afflicted in late life that require constant monitoring and/or care (e.g., diabetes, poor vision, and kidney disease); (2) growing limitation of activities and greater physical dependency caused by illnesses such as arthritis and circulatory disease; and (3) anxiety and depression resulting from bereavements of various kinds and the individual's own looming death.

Threats and illness are innate elicitors of attachment behavior in early life. In later life, after decades of successful autonomy, encroaching dependency can seem a cruel denouement; as already noted, this newly emerging threat appears to elicit an internal approach-avoidance struggle between autonomy and dependence. Conceivably, this struggle is more difficult for insecurely attached individuals. Anxiously attached people are sometimes too eager to seek care and reassurance from attachment figures in general, which may cause the caregivers to distance themselves, generating even more insecurity in their needy older adult dependents. Avoidant individuals, who are likely to deny their distress, are therefore unlikely to seek help. In both kinds of cases, the insecure elderly parents may perceive less social support, as has been found in studies of younger adults (Vogel & Wei, 2005).

Merz and colleagues (2009) analyzed data from 1,456 dyads data from the Netherlands Kinship Panel Study to investigate emotional experiences in older adults receiving support from and adult children. They found that older adult parents tend to experience negative emotions related to their loss of autonomy, but such reactions are buffered by good relationship quality. As mentioned earlier, secure individuals seem to be better able to deal with the growing dependency that arises in late life.

Grieving the Death of a Parent

One of the most common attachment-related challenges of adulthood is coming to terms with the death of one's parents. According to the National Survey of Family Households (2003), among 9,230 adults age 45 or older who were interviewed, 58.3% had lost their mother and 75.7% had lost their father. Around 12 million American adults, 5% of the population, lose a parent each year. Demographic data indicate that maternal and paternal deaths are most likely to occur when children are between 45 and 64 years of age and between 35 and 54 years of age, respectively (Winsborough, Bumpass, & Aquilino, 1991). Attachment theory suggests that these losses elicit profound feelings. Yet the literature on this subject is somewhat limited. This seems especially odd given that all of us—if we live long enough—will experience the loss of first one parent and then the other. Once both parents are deceased, feelings of being an “orphan” are common (Stroebe, Schut, & Stroebe, 2005).

What limited literature exists indicates that the death of an aged parent can cause changes in an adult child's marital relationship, sibling relationships, and relationship with the surviving parent. Although the marital relationship can be a source of support when the spouse's parent dies, and can strengthen the relationship (Moss & Moss, 1983–1984), a parent's death may also have deleterious effects. In one prospective study, Umberson (1995) found that recent maternal death was associated with a decline in reported social support from the adult child's marital partner, a reduction in marital harmony, and an increase in the partner's negative behaviors and relationship strain and conflict. Barner and Rosenblatt (2008) also examined how couple relationships are affected by the death of a parent. They found that

death of a parent led to changes in both frequency and content of communications between partners and seemed to foster discussion, negotiation, and role transition.

The death of a parent in middle adulthood also has an impact on sibling relationships. Khodyakov and Carr (2009) tested this hypothesis using data from the Wisconsin Longitudinal Survey (WLS) and found a modest negative effect of parental death on adult siblings' perceived relationship closeness, suggesting that living parents unite their children. The authors also found a further negative effect on sibling relationships of having a remaining, widowed parent to care for. One sibling may feel resentment toward the other, if the latter is perceived as not having contributed a fair share to caring for either parent (Cicirelli, 1993) or if they disagree about how well they performed their caregiving roles (Brody, 1990). Finally, in another study, Lee, Dwyer, and Coward (1993) found that father–daughter relationships deteriorated significantly after the mother's death, but that this effect was much weaker for the father–son relationship.

It appears that there are only two attachment-oriented studies of parental bereavement in later life, although in neither case were standard measures of attachment employed. One of the studies (Scharlach, 1991) tested the thesis that resolution of grief depends on the bereaved adult's attachment status relative to the parent who has died. Scharlach considered both initial and residual grief reactions in 35- to 60-year-olds. Results of the study indicated that two of the strongest predictors of initial and residual grief were the expectedness of the parent's death and the level of the adult child's personal autonomy. The latter effect was interpreted as indexing a secure attachment, inasmuch as successful functioning as an autonomous adult is thought to be the result of a healthy separation from one's parents.

In the other study, Popek and Scharlach (1991) used interview and questionnaire data to examine the responses of adult daughters to the deaths of their elderly mothers. The authors found that a daughter's ability to resolve her grief 1–5 years after the mother's death was significantly affected by the kind of relationship they had when the mother was still alive. Coders assessed the nature of each relationship (close or distant) and whether each participant's feelings regarding the mother's death were relatively resolved or unresolved. Thirty-seven percent were classified as close and resolved, 35% were close and unre-

solved, and 26% were distant and unresolved; one participant's relationship (0.02%) was classified as distant and resolved. Based on the authors' descriptions of other key characteristics of the groupings, the first category probably reflected a secure daughter–mother relationship, the second a pre-occupied and/or fearful-avoidant relationship, and the third a dismissing relationship.

Despite the physical departure of the parents from adult children's lives, there is evidence of their continued influence. In fact, one study suggests that internalized representations of parents function as "silent" attachment partners even after the parents' deaths, at least as studied within the context of dementia research (see also Fraley & Shaver, Chapter 3, this volume). The belief among many elderly patients with dementia that one or both of their parents is still alive—called *parent fixation*—has been reported as fairly common (Miesen, 1992).

In a study of the relation between level of cognitive functioning and the expression of various forms of attachment behavior in a psychogeriatric nursing home in the Netherlands, observations of attachment behavior were made with the Standard Visiting Procedure, akin to Ainsworth's Strange Situation, in which the person with dementia was first alone in a room, then with the researcher, and finally with a family member. A critical point in this procedure occurred when the family member suddenly announced that he or she had to leave, thus creating a potentially threatening moment that should activate the attachment system. Individuals who were more cognitively intact exhibited less parent fixation and more overt forms of attachment behavior directed at a family member, such as turning toward or calling after the person. Those who were functioning at a lower level displayed more parent fixation and fewer overt attachment behaviors of any other kind.

Miesen (1992) hypothesized that the invocation of deceased parents by patients with dementia represents an attempt to regulate the fear and uncertainty that accompanies loss of cognitive function. In this view, parent fixation is an attachment behavior expressing the need for safety and security. In the early stages of dementia, he theorized, parent fixation is not observed because other, more organized forms of attachment behavior are still possible, and because of the security provided by available living attachment figures. As the illness progresses, however, the "strange situation" that is dementia becomes a more permanent condition, with the now pervasive experience of feeling un-

safe being increasingly managed internally, as reflected in parent fixation.

Similar conclusions were drawn by Osborne, Stokes, and Simpson (2010), who studied parent fixation in a group of 51 older adults with dementia living in the community or in a nursing home. They interviewed target participants and had one relative of each complete measures of the participant's cognitive impairment and executive functioning, behavioral consequences of parent fixation, premorbid personality, and attachment style. Surprisingly, parent fixation was negatively associated with attachment anxiety, especially among participants living in a nursing home. Osborne and colleagues suggested that "parent fixation may therefore act as a process by which individuals seek symbolic representation of a good, consistent attachment figure" (p. 934).

What Is New Since 2008? And Where Might Research Go from Here?

One requirement is that authors of this volume say briefly how the literature in a given area has changed since the previous edition of this handbook was published in 2008. In general, the new publications largely converge with and add to the ones that existed before 2008. There is more evidence for the relative frequency of the different attachment patterns later in life, confirming that attachment-related avoidance seems more prevalent in older adults than in younger adults. There is also more evidence for the smaller size of older adults' social networks, a phenomenon that occurs without noticeably reducing the number of very close relationships. There is more evidence for the normative changes in attachment hierarchies, with parents (especially mothers) being important through childhood and peers becoming more important in adolescence and beyond, and with romantic or marital partners being especially important in adulthood. In late life, many adults begin to view one or more of their adult children as attachment figures, causing substantial adjustments in relationship patterns. Many older adults also maintain psychological relationships with deceased members of their attachment hierarchies, and with religious personages, such as God. There is more evidence concerning physiological and health factors in late life, with fearfully avoidant individuals seeming to have more symptom com-

plaints. There is evidence that child abuse, experienced decades before the later years, continues to affect people in numerous ways—a topic that deserves more research attention. Also important is the influence of changing family structures and economics in relations between adult children and their parents. New research indicates that “secure-base scripts” are important in later adulthood, as they were already known to be in childhood and early adulthood. Finally, there is new evidence, although still sparse, for the effects of caring for an elderly parent on the caregivers’ marital and sibling relationships.

As the lifespans of older adults in developed societies continue to grow longer, the issues discussed in this chapter will become more important. The proportion of the population that comprises older adults in many of these societies has grown and will continue to grow, placing a greater burden of care on adult children. The gradual erosion of the expectations for marriage is likely to continue, creating new needs for care of children and grandchildren, as well as declining older adults. There will be many opportunities for attachment researchers to examine these social developments.

One issue that was important in the 2008 version of this chapter, and which continues to be important today, is measurement. In particular, researchers should explore alternative measures of attachment patterns in older adults. The existing literature suggests that attachment-related avoidance increases later in life, but no one knows whether this is actually happening or the measures created originally to assess young adults with respect to romantic relationships are less appropriate for older adults. Similarly, the measures of caregiving that have been developed for research on couple relationships need to be reconsidered for extension to the study of other kinds of caregiving—for example, in relation to older adult parents.

In future research, it will be important to differentiate among forms of dependency based on a social environment that elicits and/or reinforces dependent behavior; insecurity-based dependency (similar to anxious, preoccupied attachment); and reasonable, self-accepted dependency, which may be a beneficial stance used to conserve energy and resources in late life (Parks & Pilisuk, 1991). The field would be well served if future research on caregiving and attachment in later adulthood were directed at assessing types of caregiving, types of dependency, and their interactions and long-term consequences.

Little is known about which child in the family becomes the caregiver and what might motivate acceptance of the role. If, as Cicirelli (1983, 1993) proposes, caregiving is motivated in part by children wanting to protect their attachment figures so as to assuage their own “fear of abandonment,” we might expect more anxiously attached adult children to rise to the occasion.

We know that innate tendencies to provide care to others in need can be overridden or suppressed by attachment insecurity (B. C. Feeney & Collins, 2001; Mikulincer et al., 2005). At such times, anxiously attached individuals are likely to be focused on their own needs rather than those of their distressed relationship partners. We also know that avoidantly attached individuals tend to be disapproving of other people’s vulnerabilities, weaknesses, and needs (Collins & Read, 1994), and therefore cannot be expected to be sensitive to others’ distress. This raises questions about the quality of care that insecure adult children will provide, perhaps especially in the presence of the original cause of attachment insecurity (i.e., a parent’s insecurity-arousing behavior).

Finally, our review of the literature has brought to the fore the continuing neglect of bereavement following the loss of one or both parents as a midlife experience with potentially profound personal and family significance. Writing about the passing of his own parents, Levy (1999) suggested that when one parent dies, there may be changes in the relationship with the remaining parent; that when either parent or both parents die, there may be changes in other interpersonal relationships or changes in identity that provoke identity reorganization; and that the death of a parent refocuses an adult’s sense of time.

An important paper by Stroebe and colleagues (2005) offers a conceptual model—the *dual-process model of coping with bereavement*—that integrates coping theory and attachment theory in a very promising way. The model suggests that there is an array of successful and unsuccessful coping styles, as well as attachment styles, some of which are loss-oriented and others of which are restoration-oriented. Furthermore, Stroebe and colleagues suggest that these coping orientations, when considered jointly with attachment styles, may enable researchers to understand when and for whom the process of continuing or loosening the attachment bonds with a lost loved one are likely to be adaptive or maladaptive. There is a great deal of interesting and important research to be done in this area.

Chapter 26

The Adult Attachment Interview

Protocol, Method of Analysis, and Selected Empirical Studies: 1985–2015

Erik Hesse

Beginnings

Thirty years ago, in an article entitled “Security in Infancy, Childhood, and Adulthood: A Move to the Level of Representation,” Main, Kaplan, and Cassidy (1985) reported the results of a 6th-year follow-up study of 40 San Francisco Bay Area children who had been seen with each parent in the Ainsworth Strange Situation (Ainsworth, Blehar, Waters, & Wall, 1978) at 12 (or 18) months of age. In this study, special emphasis was given to verbatim transcriptions taken from a structured interview protocol used with the parents—namely, the Adult Attachment Interview (AAI), developed by Main and her students in the early 1980s (George, Kaplan, & Main, 1984, 1985, 1996). This hour-long interview was unusual in that the *coherence* and *clarity* with which the speaker described early relationships and their effects were examined across the conversation with the interviewer and ultimately became the chief focus of analysis (Main & Goldwyn, 1984a; Main, Goldwyn, & Hesse, 2003). This emphasis on conversational properties stood in sharp contrast to interview formats in which the speaker’s direct report and evaluation of various family experiences were simply being recorded as stated (e.g., positive vs. negative), and taken as the target of study.

The protocol for the AAI emerged in conjunction with the Berkeley Social Development Project’s longitudinal study of families. Two of Main’s graduate students, Carol George and Nancy Kaplan, had asked whether something “further” might be added to their (doctoral and master’s) theses (see Hesse, 1999). In response, Main had suggested that each parent be interviewed about his or her family background, and an initial set of queries was assembled, with a particularly well-known question being Kaplan’s “Could you give me five adjectives to describe your relationship with each parent in childhood—and then tell me why you chose each adjective?” As the Berkeley studies progressed, the initial brief and somewhat casual (originally half-page) series of questions was extended and elaborated into what ultimately became the formal “Adult Attachment Interview” protocol (George et al., 1994, 1995, 1996; see Table 26.1 below). And, from the first, the AAI protocol was transcribed verbatim for both speakers.

A formal scoring and classification system for the AAI was not originally intended or anticipated, but rather was serendipitously initiated when Main became intrigued by a particular interview in which the speaker’s responses to the AAI queries appeared to her to be surprisingly reminiscent of the behavior

TABLE 26.1. Brief Précis of the Adult Attachment Interview (AAI) Protocol Excerpted from George, Kaplan, and Main (1996)

-
1. To begin with, could you just help me to get a little bit oriented to your family—for example, who was in your immediate family, and where you lived?
 2. Now I'd like you to try to describe your relationship with your parents as a young child, starting as far back as you can remember.
 5. To which parent did you feel closer, and why?
 7. Could you describe your first separation from your parents?
 10. How do you think your overall early experiences have affected your adult personality? Are there any aspects you consider a setback to your development?
 11. Why do you think your parents behaved as they did during your childhood?
 15. What is your relationship with your parents like for you currently?
-

Note. The AAI cannot be conducted on the basis of this brief, modified précis of the protocol, which omits a number of questions, as well as the critical follow-up probes. The most recent AAI protocol (George, Kaplan, & Main, 1996; 72 manuscript pages) is available from Naomi Gribneau Bahm (ngbrelibility@gmail.com). Copyright 1996 by the authors. Adapted by permission.

of B4 infants. B4 is a subcategory of infant secure (B) Strange Situation responses to parental leaving and return in which—as compared to Ainsworth's prototypical B3 babies—expressions of distress upon separation are somewhat exaggerated, as is proximity seeking and contact maintaining on reunion (Ainsworth et al., 1978).

But how was it that Main was able to “tell” from a speaker's verbatim AAI text that he would have been the parent of a B4 infant? Although the speaker was clearly essentially coherent and collaborative, Main noted that he went to slightly unusual lengths in describing tender, emotionally affecting aspects of his life, lingering in somewhat lengthy descriptions of his loss of a beloved family member. Thus, like a B4 infant, this speaker to a slightly unusual degree seemed to be attempting to draw and maintain the interviewer's attention, and (not untowardly) to evoke a sympathetic response (see Hesse, 1999, p. 400).

As first reported in 1985, it was soon discovered that differences among transcribed verbatim responses regarding relationships with parents, as discussed within the AAI, could be systematically placed into one of three adult attachment categories—secure, dismissing, or preoccupied (Main, 1985, 2001; Main & Goldwyn, 1984a, 1989; Main et al., 1985, 2003). The fourth (“unresolved for loss or abuse experiences”) and fifth (“cannot classify”) categories were added later (see Hesse, 1996; Hesse & Main, 2000). Remarkably, both of these latter categories were also found to be systematically associated with offspring who had been classified as *disorganized* in the Strange Situation 5 years previously.

In this current contribution to the third edi-

tion of the *Handbook of Attachment*, I focus once more on a brief description of the queries used in the AAI, as well as the associated coding scales and classification system. Although the methods of analyzing AAI transcripts have grown increasingly sophisticated over the years (e.g., Main & Goldwyn, 1984a; Main et al., 2003), from the outset, the scoring procedure focused on the overall coherence of the text. Potential indices of insecure states of mind, are observed via any major contradictions and inconsistencies in the narrative, as well as passages that are exceptionally short, long, irrelevant, or difficult to follow. Thus, once systematized, differences in speakers' language use while responding to queries regarding their attachment history and its effects have consistently been the basis of AAI analysis, and the source of its predictive power.

Over time, the AAI has been increasingly applied in conjunction with clinical, developmental and, most recently, psychophysiological, genetic, and neuroscience research. In “The First 10,000 Adult Attachment Interviews: Distributions of Adult Attachment Representations in Clinical and Non-Clinical Groups,” Marian Bakermans-Kranenburg and Marinus Van IJzendoorn (2009) reported that at least 200 adult attachment representation studies, comprising more than 10,500 AAI classifications, had been conducted in the preceding 25 years (1984–2009). In that analysis, Bakermans-Kranenburg and Van IJzendoorn had employed the Web of Science and PsycLIT search engines to locate AAI studies utilizing the system of analysis that ultimately emerged as the Main, Goldwyn, and Hesse classification and scoring system (2003; see Main & Goldwyn, [1984a] for the first version of this system).

Critically, in conjunction with their 2009 analysis, Bakermans-Kranenburg and Van IJzendoorn reported that AAI interviews administered to clinical participants, compared to nonclinical participants, were more frequently classified as insecure (dismissing, preoccupied, or unresolved). Disorders with an internalizing dimension (e.g., borderline personality disorders) were found to be associated with more preoccupied and unresolved AAI classifications, whereas disorders with an externalizing dimension (e.g., antisocial personality disorders) were associated with dismissing and preoccupied classifications. Depressive symptomatology was associated with organized insecurity (e.g., dismissing or preoccupied) but not with the category identifying unresolved loss or abuse. In contrast, adults with identifiable abuse experiences or posttraumatic stress disorder (PTSD) were mostly unresolved. Finally, these authors suggested that use of the AAI coding scales, in addition to the categories, might lead to more reliable associations with clinical symptoms and disorders.

For the purposes of this chapter, a comparable report has been compiled by Sarah Foster at Northumbria University, similarly utilizing Web of Science and PsycLIT search engines. Foster's search has revealed that between 2008 and 2015, more than 130 additional adult attachment representation studies were published, comprised of ~7,800 AAIs. This means that, on average, approximately eight attachment representation studies were published each year between 1985 and 2008, while approximately 16 studies each year were published between 2008 and 2015.

Thus, there has been more than a twofold increase in the last 7 years in empirical AAI representation studies. Relatedly, a notable number of case studies, reviews, and theoretical papers have been published as well.

Given the volume of this literature, space limitations necessarily preclude the same type of extensive review of AAI research contained in the 1999 and 2008 editions of this chapter. I therefore mention some studies only by brief references to topic and author. An emerging empirical literature on the AAI as utilized in conjunction with studies in psychophysiology, genetics, and neuroscience is presented in somewhat more detail. This topical area is selected for somewhat greater elaboration because it is largely new and, I believe, will be of special interest to the majority of readers. A paper devoted to a comprehensive review of empirical AAI studies from 1984 to 2016 is being planned

by Robbie Duschinsky, Sarah Foster, Mary Main, and myself.

The remainder of this chapter is organized into four sections, and is followed by Appendix 26.1, which provides a description of, and the means to accessing, training in AAI analysis. The first section, "The AAI Protocol and The Original Three "Organized" AAI Categories" describes the protocol, and then the secure (F), dismissing (Ds) and preoccupied (E) response patterns first identified by Main and Goldwyn (1984). Thereafter, I discuss the ways in which the organized classifications can be understood in terms of both *attentional* and—separately, albeit relatedly—*linguistic (conversational or discourse)* mechanisms. I conclude this first section by presenting some prototypical responses to an AAI query that are common among the three classifications of "organized" speakers. The unresolved (U) and cannot classify (CC) categories are not discussed until the end of the second section because, by nature, they involve speech characteristics and attentional processes not directly comparable to the organized categories.

In the second section, "The AAI Scoring and Classification System," I describe how trained coders systematically approach the analysis of an AAI transcript. I note that beyond placement into the five major classifications there are two additional means of analyzing the AAI (i.e., via scales and 12 subclassifications). These latter two approaches have drawn less attention in the literature, despite the fact that, in some contexts, they may reveal information not captured by examining results for the F, Ds, E, U, and CC categories alone.

In the third section, "Earned or Evolved Security," I provide a historical and theoretical overview of this topic, especially as it relates to central issues involving conceptualizations of AAI coherence.

In the fourth section, "Selected Empirical Studies Involving the AAI," I review a group of studies based on the AAI, beginning with Main's original investigation of a San Francisco Bay Area sample (Main & Goldwyn, 1984b, 1988, 2008). Here I discuss the best-replicated findings regarding the AAI (including investigations of its psychometric properties), as well as a necessarily select group of studies (with apologies to many excellent investigators whose work is not reviewed) in a variety of other salient domains, such as intervention and longitudinal studies. I conclude with a section on studies—almost exclusively conducted since 2008—involving use of the AAI in conjunction with studies in psychophysiology, genetics, and neuroscience.

Before beginning the descriptive portion of this chapter, I underscore that although self-reported measures of romantic attachment produce many exciting and intriguing results (see, in this volume, Crowell, Fraley, & Roisman, Chapter 27, and J. A. Feeney, Chapter 21; Mikulincer & Shaver, 2016), they show little relation to attachment status as assessed in the AAI (e.g., Roisman et al., 2007).

The AAI Protocol and the Original Three “Organized” AAI Categories

The AAI protocol, devised as noted by Mary Main and her graduate students at Berkeley (George et al., 1984, 1985, 1996) utilizes a prespecified format, with questions asked in a set order, accompanied by specific follow-up probes. The protocol is deliberately arranged to bring forward structural variations in the presentation of a life history, and interviewers must make certain that their own part of the conversation serves only to highlight, not to alter, participants' usual tendencies to respond in particular ways.

The AAI normally takes approximately an hour to administer and currently (George et al., 1996) consists of 20 questions. The entire interview, including all spoken contributions by both the interviewer and the interviewee, is transcribed verbatim, including (timed) pauses, dysfluencies, and restarts. Cues to intonation, prosody, and non-verbal behavior are omitted.

The AAI opens with a call for a general description of relationships with parents during the speaker's childhood, followed by a request for five adjectives that best represent the relationship with each parent. After the adjectives describing each parent are requested (first for the mother), the speaker is probed for specific episodic memories that illustrate why each descriptor was chosen. This process is then repeated for the father and, when applicable, for any other significant attachment figure (e.g., stepfather or nanny). The interviewer asks which parent the speaker felt closer to and why; what the speaker did when emotionally upset, physically hurt, or ill; and how the parents responded at such times. The participant is then asked about salient separations, possible experiences of rejection, and any threats regarding discipline. Next, the speaker is queried regarding the effects of these experiences on his

or her adult personality; whether any of these experiences constituted a setback in development; why parents are believed to have behaved as they did during childhood; and whether there were any persons who did not serve as parenting figures, yet were thought of as parent-like during childhood. The latter might, for example, include a special teacher or uncle.

An especially important feature of the AAI protocol is the section addressing experiences of loss of significant persons through death. Here, significant losses occurring at any point in the speaker's lifetime are addressed. Speakers are asked to describe how the death occurred, their reactions to the loss at the time, any funeral or memorial service attended, changes in feelings over time, effects on adult personality, and (where relevant) effects on their behavior with their own children. In the case of persons with multiple losses, interviewers restrict their queries to those three or four that seem most significant. Descriptions of any abuse experiences (and, indeed, any overwhelmingly frightening experiences throughout a speaker's lifetime) are also sought.

Toward the close of the interview, participants are queried regarding the nature of current relationships with any living parents. In addition, they are questioned as to how they feel about being separated from their child (or imagined child), and if they are ever worried about their child (or think they would worry about an imagined child). Finally, participants are invited to speculate regarding wishes for their real or imagined child in 20 years, as well as to reflect on anything they feel they have learned or gained from their own experiences growing up. Last, participants are asked what they hope their child (or imagined child) will have learned from experiences of being parented by them.

Table 26.1 offers examples of some of the questions taken from the AAI protocol (George et al., 1985, 1986, 1996) but omits their follow-up probes. The current 72-page protocol is available (see Appendix 26.1), and administering the AAI requires practice with feedback from experienced interviewers.

The central task the interview presents to participants is that of (1) producing and reflecting on memories related to attachment, while *simultaneously* (2) maintaining coherent, collaborative discourse with the interviewer (Hesse, 1996). This is not as easy as it might appear, and George et al. (1985, 1986, 1996) have remarked on the potential of the protocol to “surprise the unconscious.”

As indicated earlier, the interview requires the speaker to reflect on and answer a multitude of complex questions regarding his or her life history, the great majority of which the speaker will never have been asked before. In contrast to the pace and content of ordinary conversations, in which each speaker has time for planning what to say, the AAI moves at a relatively rapid pace, so that usually all questions and probes have been presented within an hour's time. However, ample opportunities are provided for speakers to contradict themselves, to find themselves unable to answer clearly, and/or to be drawn into excessively lengthy or digressive discussions of particular topics.

To maintain a consistent and collaborative narrative, a speaker must not only address the question at hand but also be able to remember (and potentially reflect on) what he or she has already said, in order to integrate the overall presentation as it unfurls. It is striking that although the interviewee is always informed in some detail regarding the overall topic of the interview prior to its administration, actually engaging in the process often appears to be a far more powerful experience than anticipated. For some speakers, this leads to notable (and often ultimately systematic and repeated) incoherencies in linguistic aspects of the presentation in that at times the interviewee may not be able to maintain his or her usual degree of control over how the spoken story unfolds.

Given these possibilities, one can readily note that the AAI protocol is structured to bring into relief individual differences in what are presumed to be deeply internalized strategies for regulating emotion and attention when speakers are discussing attachment-related experiences. This is achieved despite the fact that although the interview transcripts contain the full verbatim exchange, including silences and dysfluencies, they are devoid of references to body movement, facial expression, or intonation. It is remarkable, then, that on the basis of language use alone, trained AAI coders are able to score and classify AAI texts such that they predict significantly how speakers will behave with others, including offspring, partners, friends, and even those to whom they have been newly introduced.

Finally, I should emphasize that the claim that for most speakers the interview is able to elicit a particular (usually singular; i.e., "classifiable" as opposed to "unclassifiable") state of mind with respect to attachment is based on the assumption that, by adulthood, what were originally independent attachments to mother and to father (e.g.,

in infant Strange Situation behavior; see Main & Weston, 1981) will have coalesced.

An initial exploration of this assumption was undertaken by Furman and Simon (2004), who administered the AAI twice to 56 young adults. One interview focused only on the mother, and the other, only on the father. As would be expected if a single attachment-related state of mind does eventually predominate in most individuals, despite the independence of Strange Situation classifications observed in infancy, Furman and Simon found that state of mind with respect to the father was significantly related to state of mind with respect to the mother.

Attentional and Linguistic Processes Involved in Distinguishing among the Organized AAI Categories

This section introduces two ways in which some of the underlying mechanisms that may be responsible for the individual differences in discourse forms characteristic of secure, dismissing, and preoccupied speakers as elicited by the AAI protocol have been conceptualized. I begin with Main's (1990) consideration of attentional flexibility versus inflexibility, and then turn to a discussion of Grice's (1975, 1989) maxims for adherence to, versus violations of, the requirements of conversational coherence and collaboration. The dovetailing of Grice's conversational maxims and the state-of-mind scales that Main and Goldwyn had devised—several years prior to Main's first reading of Grice—has been, and remains, striking. Grice's work has been highly useful heuristically, and references to Grice's maxims have appeared in all but the earliest versions of the AAI scoring and classification system.

The Organized Categories of the AAI Considered in Terms of Attentional Flexibility

The AAI scoring and classification system was initially grounded in the relation between the three central or organized forms of parental responses to the AAI queries (*secure-autonomous*, *dismissing*, or *preoccupied*) and the three central or organized forms of infant response to that same parent in the Strange Situation (respectively, *secure*, *avoidant*, *ambivalent/resistant*), as first uncovered in Main's San Francisco Bay Area study (Main & Goldwyn, 1984b, 1988, 2008; Main et al., 1985). The term

organized is rooted in Main's (1990) contention that infants in the original three Strange Situation categories differ in flexibility versus inflexibility of attention to (1) the parent and (2) the inanimate environment—differences that are revealed in the Ainsworth separation-and-reunion procedure. Main has ascribed the capacity for attentional flexibility to secure babies because they readily alternate between attachment and exploratory behavior as the Strange Situation procedure unfolds, exploring in their mothers' presence, and exhibiting attachment behavior (e.g., crying, calling) in the mothers' absence and again upon reunion (this time in the form of seeking proximity and contact), most often followed by return to exploration. Correspondingly, differing forms of attentional inflexibility have been ascribed to avoidant and resistant/ambivalent infants.

Main later proposed that the organized AAI categories can also be viewed in terms of attentional flexibility (Main, 1993, 2000; Main, Hesse, & Kaplan, 2005). Thus, attentional flexibility is seen in secure-autonomous parents as they fluidly shift between presenting their attachment-related experiences and responding to the request to evaluate the influences of these experiences (Hesse, 1996). In contrast, differing forms of attentional inflexibility are observed in dismissing and preoccupied AAI texts.

The Organized Categories of the AAI Considered in Terms of Grice's Maxims

Before I discuss further the current methods of analyzing AAI transcripts, I provide a brief review of Grice's (1975, 1989) work. My aim in this section is to facilitate an understanding of differing "organized" language usages within the AAI, and to thereby convey what is actually being assessed when coherence versus incoherence of a given text is considered.

Although the AAI interviewer adheres to the interview questions and their probes as faithfully as possible, there are, of course, two speakers involved in the exchange. This means that, at heart, the interview is a conversation, as well as a response to a request for a spoken autobiography, permitting its analysis in terms of the extent to which the participant's responses approach the "Gricean" requirements for an ideally rational, coherent, and cooperative conversation. Grice (1975, 1989) proposed that these requirements are met insofar as speakers adhere to four specific

"maxims" or principles. To the degree that these maxims are "violated," the conversation strays from the cooperative, rational ideal, but, in fact—as Grice stressed in his later work (1989)—complete and continual adherence is not expected. For a text to be classified as *secure-autonomous*, coherent, cooperative discourse must simply be *relatively* well maintained, as compared to that of insecure conversationalists (defined below) observed in this context.¹ The four maxims are as follows:

1. *Quality*: "Be truthful, and have evidence for what you say." This maxim is violated when, for example, a speaker's parent is described in highly favorable, general terms (e.g., highly positive adjectives), but the specific biographical episodes recounted subsequently contradict (or simply fail to support) the interviewee's adjectival choices. An interview of this kind can also be considered internally inconsistent. Internal inconsistency of the kind just described appears most frequently in the texts of individuals classified as *dismissing*.

2. *Quantity*: "Be succinct, and yet complete." This maxim demands conversational turns of reasonable length—neither too short nor too long. By requiring speakers to be sufficiently "complete," Grice was articulating that incomplete, excessively short answers are not acceptable. This occurs when, for example, "I don't remember" becomes the response to several queries in sequence, cutting off further inquiry. Excessively terse responses occur most frequently in the texts of individuals classified as *dismissing*.

In terms of quantity, Grice also requires that so long as they are complete, responses should be reasonably succinct; consequently, the maxim of (appropriate) quantity can also be violated when a speaker takes excessively long conversational turns. Here, the interviewee may hold the floor for several minutes, perhaps providing increasingly unnecessary (and not infrequently pejorative) details. Excessively lengthy responses occur most frequently in the texts of individuals classified as *preoccupied*.

3. *Relation*: "Be relevant to the topic as presented." The maxim of relation or relevance is violated when, for example, queries regarding the childhood relationship with the speaker's mother are irrelevantly addressed with discussions of current interactions with the mother or descriptions of the speaker's relationship with his or her own children. As might be expected, violations of relevance occur most frequently in the texts of individuals classified as *preoccupied*.

4. *Manner*: “Be clear and orderly.” This maxim is violated when, for example, speech becomes grammatically entangled, psychological “jargon” is used, vague terms appear repeatedly, or the speaker does not finish sentences that have been fully started. Violations of manner appear most often in *preoccupied* texts.

Having concluded this discussion of Grice’s conversational maxims,² I present one representative interview query and provide examples of responses that would be typically associated with each of the three organized AAI classifications. Where relevant, I discuss violations of specific maxims.

Examining Differing Interview Query Responses as They Relate to the Organized AAI Categories

One question that is especially useful for characterizing individual differences in response to AAI queries, and perhaps also the best-known of all the AAI protocol questions, is question 3, in which the participant is addressed as follows:

“Now what I’d like you to do is to think of five adjectives, words, or phrases that would best describe your relationship with your mother during childhood—say, between the ages of 5 and 12, but even earlier if you can remember. Take a minute to think, and then I’m going to ask you why you chose them.”

Notice that this question includes two parts that operate at different “mental levels”: a *semantic* level (the descriptors, or adjectives themselves, devoid of space–time particulars) and an *episodic* level (what happened and, if possible, roughly when), which suggests that there will be a rationale for the adjectival choice. By implication, of course, the interviewer is requesting that any particular adjective selected will be accompanied by an illustrative account.

In essence, the adjectival constellation that the speaker is asked to provide for his or her relationship with a given parent during childhood requires the person (whether consciously or unconsciously, accurately or inaccurately) to produce “on the spot” a fairly complex and incisive synopsis of the general nature of the childhood relationship. Once the adjectival constellation has been provided, the speaker has in effect “taken a stance” as to the kind of relationship he or she had with

this particular parent. The adjectival constellation can vary from a set of extremely negative to a set of extremely positive descriptors, but, of course, it can include mixed assessments as well. For example, with respect to the mother, if the choice of adjectives include “loving, caring, supportive, trustworthy, and warm,” the speaker is obviously attempting to convey that he or she had a highly positive experience with mother during childhood. However, an adjectival constellation such as “caring, interfering, warm, sort of unpredictable, and rule maker” conveys a more mixed impression.

Next, the participant is systematically probed for a specific memory that would illustrate why each particular word or adjective was selected. This is the portion of the “adjectival” question in which the participant is implicitly asked to begin drawing on episodic memory. Note that even if the adjectives provided by two different speakers were identical, the narrative that emerged in the two cases could have entirely different forms.

Let us consider the “loving . . .” constellation noted earlier. The interviewer is now required to probe as follows:

“OK, the first word you gave to describe your relationship with your mother during childhood was *loving*. Can you think of a memory or incident that would illustrate why you chose that word?”

The range of potential responses to this request is virtually infinite, yet it will yield information that can be approached with a view toward assigning scores and ultimately a state-of-mind classification. Thus, it is likely that the speaker’s response bears deeply on the degree of his or her own self-awareness, and in some cases—whether or not the person is conscious of it—on the motivation to convey a particular impression to the interviewer. Consider as an example the following, and not at all uncommon, response to the interviewer’s probe for any memories or incidents that could illustrate why the speaker chose *loving*.

INTERVIEWEE: I don’t remember . . . (5-second pause).

Well, because she was caring and supportive.³

[Notice that here the speaker is simply using similar words to describe the previous words. In essence, the speaker is repeating the word rather than answering the question.]

INTERVIEWER: Well, this can be difficult because a lot of people haven’t thought about these

things for a long time, but take a minute and see if you can think of an incident or example.

INTERVIEWEE: (10-second pause) Well . . . (5-second pause), I guess like, well, you know, she drove me to school, and I was always really proud of her, I mean, she was really pretty, and she took a lot of care with her appearance.

Here it is impossible, of course, to know whether the speaker is aware that she has not answered the question. What can be readily inferred, however, is that (a) an attempt is being made to convey a positive impression of her childhood that (b) in fact does not provide believable support for the adjectives chosen. Clearly, something psychologically quite complex is taking place here, despite the brevity of the response. Although convincingly loving interactions may be recounted later in the interview, at this point, we can say that if the speaker continues along these lines—that is, seeming to attempt to create a positive (but unsupported) picture of her childhood experiences with her mother—it is likely that the transcript as a whole will be classified as dismissing.

Thus, dismissing speakers (dismissing would be the best-fitting classification for the previous speaker if only this interview extract was available) violate Grice's quality/truthfulness maxim by failing to provide evidence for what they have claimed. The responses are frequently also excessively succinct, violating of quantity and perhaps involving (whether deliberate or unconscious) restrictions in attention that lead *away from* rather than participating in a discussion of the topic of childhood experiences with the mother.

I now turn to a second speaker who also describes the mother as "loving."

INTERVIEWEE: Loving . . . (5-second pause). My mom would stick up for me to the teacher, or to a kid's parents, or . . . anybody, really. I could put it another way, too. I just knew where I stood with her, and that she'd be comforting if I was upset or crying or something.

INTERVIEWER: Thank you (interrupted).

INTERVIEWEE: (interrupting and continuing) Oh, maybe you wanted a specific example. Um, that time I set fire to the garage, using my brother's chemistry set, I absolutely positively wasn't supposed to use . . . came running when the neighbors phoned the fire department about the smoke. I expected to get the life lectured out of me, but she just ran straight for me and picked me up and hugged me real hard. Guess

she was so scared and so glad to see me, she just forgot the lecture.

If the discussion of childhood parenting continues steadily in this vein, with well-supported (whether positive or negative) statements regarding parenting and clear responses similar to this one,⁴ the trained coder will begin to suspect that the transcript is likely to be classified secure-autonomous.⁵ In terms of the Gricean maxims, the speaker I presented here had kept to the maxim of *quality* or truthfulness providing evidence for "loving," which Grice at times called the "overriding principle" for cooperative, rational discourse. There are no violations of manner or relevance (the speaker is easy to follow and stays on topic). The passage is too brief to illustrate attentional flexibility, but no inflexibility is evident.

Finally, here is an example of a third participant, who has also chosen "loving" to describe his mother:

INTERVIEWEE: Uh, yeah, sort of very loving at times, like people were in the old days—uh, my youth, lot of changes since then. I remember home, and home was good and that. And uh, loving, my wife is loving with [child]—taking him out to the movies tonight, special thing he's been wanting to see all week, dadadada. Actually, it's more like a month, that turtle movie, don't like it too much myself. Too many turtles—where are they from, outer space? Saw it, though, now, when was it, um, maybe 6 months ago. Yeah, she's very loving with [child].

INTERVIEWER: Mm-hm. OK, well, what things come to mind when you describe your childhood relationship with your mother as "very loving at times"?

INTERVIEWEE: Really great things, felt really special, really grateful to her for that. My childhood, I remember just sitting on the porch, rocking, rocking back and forth, watching my parents, or maybe having some lemonade—or, you know, this, that, and the other. Special sorts of things, just me and her. I wasn't easy, my temperament was hard on her, kind of hard. Me and my cousins from [Town 1] going down soon—really big birthday, she's gonna be 80, gives my age away. (Continues.)

Although speech of this kind is not common, it provides a good example of one of the subclassifications of the preoccupied category ("passively preoccupied," subcategory E1). The speaker is un-

able to stay with the question, which was about his childhood relationship with his mother, and veers to the relationship his wife has with their child. Other than drinking lemonade together, examples of how the mother was loving during childhood are not provided, since, for whatever reason, the speaker moves into topics irrelevant to the request to support “loving” (e.g., his mother’s upcoming birthday). In addition, vague and/or incomprehensible speech is inserted into a number of sentences (e.g., dadadada).

Notice, then, that as in the earlier case of the dismissing (first) speaker, the question asked of this preoccupied speaker is not answered. However, this failure to answer appears in a very different form. These are violations of Grice’s maxim of relevance (e.g., moving into topics irrelevant to the question, and lack of clarity).

Thus, while the AAI asks the same questions of each participant, as shown here, very different responses appear not only regarding the same questions but also in illustrating the same adjectives. The essence of the AAI scoring and classification system (Main et al., 2003) amounts to a systematization of the different language uses seen in response to the set questions of the protocol. Unfortunately, space limitations preclude reviewing examples involving a negative adjectival descriptor (see Hesse, 2008).

The AAI Scoring and Classification System

As noted earlier, the AAI scoring and classification system initially focused only on the original three “organized” classifications and their 12 subclassifications, together with an accompanying set of continuous rating scales (Main & Goldwyn, 1984a). The earliest rules for classifying and scoring AAI transcripts were based on interviews with parents (both mothers and fathers) who were visiting Main’s Social Development Project laboratory at the University of California at Berkeley, together with their 6-year-old children. Five years earlier, when the children were between 12 and 18 months of age, each had been seen in the Strange Situation conducted separately with each parent. Scores for reunion behavior (e.g., avoidance or resistance), as well as major classifications and their associated subclassifications (Ainsworth et al., 1978), had been assigned at that time.

Out of the available sample of 103 dyads, Main and Goldwyn had selected a development sample of 36⁶ for intensive study. Within this ini-

tial sample, they searched for differences and commonalities in the ways the parents of infants who had been judged secure, avoidant, or ambivalent/resistant with them in the Strange Situation 5 years earlier conversed about and described their own attachment histories and their effects. (The U and CC categories were developed later.)

The most notable characteristics of each transcript were recorded, including and especially regarding the speaker’s probable experiences with each parent during childhood, together with the speaker’s state of mind with respect to his or her attachment history. A speaker’s “state of mind” was captured by gradually developed continuous rating scales used to assign secure-autonomous, dismissing, or preoccupied classifications. Both coders used their knowledge of attachment to “guess” the status of each transcript, before “de-blinding” themselves to the Strange Situation classification and subclassification of the speaker’s infant. The development sample of 36 texts was subsequently discarded, and—with no further feedback from Main—Goldwyn then continued alone through the remaining 67 texts. The results of this study are described later in this chapter (see also Main & Goldwyn, 1988, 2008).

Later, the scoring and classification system came to include a chapter concerning the identification of speech and reasoning irregularities in the parents of infants judged as disorganized (Main, DeMoss, & Hesse, 1989). The 1989 guidelines were used by Ainsworth and Eichberg (1991) and Fonagy, Steele, and Steele (1991) in the initial parent–infant replication studies.

Over the ensuing years, feedback from studies of parent–infant dyads in other samples (including high-risk and clinical samples) has allowed the system to continue to evolve. Consequently (see Main et al., 2003), the system now includes several means of identifying texts that cannot be classified within the original three-part system (leading to U, CC, or both; e.g., when characteristics of both preoccupied and dismissing texts are present and/or speech patterns are anomalous in themselves).

The Organized Categories of the AAI

The organized categories of the AAI—secure-autonomous, insecure-dismissing, and insecure-preoccupied—are those in which the speaker shows a definitive, essentially singular “strategy” for getting through the interview, whether by “simply answering the questions” (as secure-au-

tonomous speakers have been informally said to do); by untowardly cutting the discourse short (e.g., “I don’t remember”) whether within or outside of awareness, together with blocking discussion of potentially distressing aspects of experiences (as speakers whose transcripts are assigned to the insecure-dismissing category tend to do); or by manifesting a confused, unrelenting focus on varying incidents, feelings, and relationships aroused by the interview questions (as insecure-preoccupied speakers tend to do). So long as a single one of these strategies seems to be at work throughout the interview, uninterrupted by a collapse of discourse or reasoning during the discussion of potentially frightening experiences, the transcript is considered organized.

As first noted in my discussion of the AAI protocol, each of the organized states of mind with respect to attachment stand—albeit at the discourse level—in parallel to the secure, avoidant, and resistant forms of attachment behavior seen in the Strange Situation conducted with infants (first termed the *organized* infant attachment strategies by Main, 1990).⁷ It is intriguing, then, that parents producing inflexible, insecure-dismissing AAI texts, in which queries are often avoided, tend to have infants who avoid them, essentially “dismissing” the fact of their comings and goings during the Strange Situation. Parents who produce insecure-preoccupied AAI texts, remaining on topics to excessive lengths—often particularly in describing failings of the parents—tend to have infants who are seen as ambivalently (angrily or passively) preoccupied with them rather than attending to the available toys or other aspects of the surroundings. Finally, parents who are flexible in their responses to the AAI queries, neither attempting to bypass them or becoming entangled with or by them, produce secure-autonomous AAI transcripts (“valuing of attachment, but seemingly able to objectively evaluate any particular attachment relationship or experience”), tend to have infants whose attention in the Strange Situation is also flexible, alternating between attachment and exploratory behavior as the parents remain within the room (exploration predominates), leave (attachment behavior eventually predominates) and then return to the room (attachment behavior followed by return to exploration).

AAI coders begin their work with the “experience scales” by deriving scores for central aspects of inferred loving versus unloving behavior of each parenting figure during the interviewee’s childhood. Next, continuous scores on the scales for “overall state of mind with respect to attach-

ment” are assigned, including the scale eventually recognized to be of primary importance (i.e., the scale for “coherence of transcript”). Finally, using a “feature” analysis, the coder assigns a best-fitting organized classification and associated subclassification, even if later the text will additionally be found to be primarily unresolved or even unclassifiable (in this latter case, two disparate classifications may have been assigned).

Scales Estimating a Speaker’s Probable Experiences with Each Parent during Childhood

A 9-point continuous scale is provided for the coder’s estimation of the degree of “loving behavior” exhibited by each parent during childhood, supported by examples and not to be confused with the speaker’s love for the parent or unsupported statements that the parent was loving. Evidence of four kinds of unloving behavior is also assessed (rejecting of the child’s attachment; role-inverting/heightening of attachment—or, at the high end, demanding of care; neglecting; and pressuring to achieve). Every other point of each scale (i.e., 1, 3, 5, 7, and 9) is well defined, and each scale includes a lengthy introduction explaining what is meant by the construct. Behavioral examples that may be found in the transcript are offered as well. As is evident, the higher the scores for inferred negative experiences, the necessarily lower the score for loving. Finally, it should be noted that the coder selecting the score may assign a score far different from that which the speaker might have assigned—a fact most obvious when the speaker has provided extremely positive adjectives for the relationship with the mother during childhood, but when asked what the speaker did when hurt or upset during childhood has responded, “I hid. Once I had a broken arm that hurt a lot, but I didn’t tell my mother; she would have been real angry.” The form taken by the five scales resembles that of Ainsworth and colleagues’ (1978) four “sensitivity” scales (available on the Everett Waters website at www.john-bowlby.com): a long, well-worked-out introduction followed by alternating point definitions that allow for interpolation by the coder.

Scales Delineating a Speaker’s State of Mind with Respect to Attachment

Once a coder has scored the five scales for loving and unloving behavior, he or she moves to scoring the speaker on eight scales describing state of mind

with respect to attachment. Correct scores on the state-of-mind scales cannot be assigned without careful prior assignment of scores for experience. For example, the extent to which the childhood relationship with the mother is “idealized” in the speaker’s descriptions and evaluations cannot be determined until the coder has decided how “loving” she probably was. Thus, the eventual assignment to an “overall organized state of mind with respect to attachment” usually depends on the speaker’s probable experiences with the parents during childhood only to the extent that experiences are needed to determine state of mind score. This should be clear from the fact that speakers with unfavorable childhoods can be readily assigned to the secure-autonomous category, based on the coherence of their text. (Note, however, that some category placements do not require experience scores for derivation).

In summary, the assignment of a speaker to any given organized category depends on scores on the continuous scales identifying states of mind with respect to attachment, and a feature analysis—not described here—that follows upon it, rather than on the scales for inferred childhood experiences of parenting. The general criteria for assignment to the state-of-mind scales are displayed in Table 26.2.

Although I will soon attend to the striking associations between the original state-of-mind scales and Grice’s (1975, 1989) maxims, here I briefly take a historical approach and consider our early definitions and findings. As is clear from Table 26.2, the scale most closely identified with adult (and infant) security from our first efforts onward has been the scale for “coherence of transcript.” In *Webster’s New International Dictionary* (1959, p. 520), the term *coherence* is derived from the Latin, meaning approximately “a sticking together or uniting of parts.” Further regarding this definition, Main and Goldwyn (1988, p. 42) noted that *coherence* may be identified as “a connection or congruity arising from some common principle or relationship; consistency; [or] connectedness of thought, such that the parts of the discourse are clearly related, form a logical whole, or are suitable or suited and adapted to context.”

From this point of view, coherence involves more than simply internal consistency. In other words, even if an individual speaks in a manner that is plausible and internally consistent, thereby adhering to the first aspect of the criterion, he or she may still discuss a topic at excessive length or make obscure analogies, thus failing to shape speech in a manner suitable to the discourse ex-

change. Thus, conversational cooperation, as well as internal consistency, was an important component in Main and Goldwyn’s (1984a, 1984b) original conceptualization of coherence.

Recognizing Relations between the State-of-Mind Scales and Grice’s Maxims

As noted earlier, in general, discourse is judged to be coherent when a speaker appears able to access and evaluate memories while *simultaneously* remaining plausible (consistent or implicitly truthful) and collaborative (Hesse, 1996). When the discussion and evaluation of attachment-related experiences are in fact reasonably consistent, clear, relevant, and succinct, this leads to relatively high AAI coherence scores and placement in the secure-autonomous category. Notably, from the inception of the AAI onward, scores for overall coherence of AAI transcripts have proven vital to analyses of the text and have been associated with infant security of attachment (see the description of the original San Francisco Bay Area study, below).

As shown in Table 26.2, dismissing speakers had already been identified in the early Main and Goldwyn (1984a) scoring system as having high scores on “idealization of the parent(s),” which pointed to a violation of Grice’s maxim of quality (“Be truthful, and have evidence for what you say”). Many dismissing speakers had also been described as excessively succinct, violating the quantity maxim by cutting short the conversational exchange with statements such as “I don’t remember.” These latter speech habits had been quantified as “insistence on lack of memory.” Preoccupied speakers had been identified primarily as violating Grice’s maxims of relevance, quantity, and manner, which can be termed the *maxims of collaboration*. Violation of each of these maxims is taken into consideration in the scales for “angrily preoccupied discourse,” as well as “passive/vague discourse.” For example, with respect to relevance, and as seen in these scales, some preoccupied speakers wander from topic to topic or move away from the context of the query (e.g., discussing current relations with parents when asked about childhood experiences), whereas others become embroiled in excessively lengthy descriptions of past or current problems with parents. Still others do both. Violations of manner also typify preoccupied speakers, as seen especially in vague speech (“sort of, sort of . . . and that”), excessive use of psychological jargon (“My mother had a lot of

TABLE 26.2. “State-of-Mind” Scales Used in the AAI, Related to the Three Major Categories

Scales associated with the secure-autonomous adult attachment category

Coherence of transcript. For the highest rating, the speaker exhibits a “steady and developing flow of ideas regarding attachment.” The person may be reflective and slow to speak, with some pauses and hesitations, or speak quickly, with a rapid flow of ideas; overall, however, the speaker seems at ease with the topic, and his or her thinking has a quality of freshness. Although verbatim transcripts never look like written narratives, there are few significant violations of Grice’s maxims of quantity, quality, relation, and manner. The reader has the impression that, on the whole, this text provides a “singular” as opposed to a “multiple” model of the speaker’s experiences and their effects (see Main, 1991).

Metacognitive monitoring (scale presently under development). For the highest rating, evidence of active monitoring of thinking and recall is evident in several places within the interview. Thus, the speaker may comment on logical or factual contradictions in the account of his or her history, possible erroneous biases, and/or the fallibility of personal memory. Underlying metacognitive monitoring (Forguson & Gopnik, 1988) is active recognition of an appearance–reality distinction (the speaker acknowledges that experiences may not have been as they are being presented), representational diversity (e.g., a sibling may not share the same view of the parents), and representational change (e.g., the speaker remarks that what is said today might not have been said yesterday). This scale is included here because it does identify one of the principal aspects of speech found in secure-autonomous speakers; however, the scale needs further work at present, since criteria for high scores are overly stringent, leading to insufficient range.

Scales associated with the dismissing adult attachment category

Idealization of the speaker’s primary attachment figure(s). This scale assesses the discrepancy between the overall view of the parent taken from the subject’s speech at the abstract or semantic level and the reader’s inferences regarding the probable behavior of the parent. Since the reader has no knowledge of the speaker’s actual history, any discrepancies come from within the transcript itself. For the highest rating, there is an extreme lack of unity between the reader’s estimate of the speaker’s probable experience with the primary attachment figure(s) and the speaker’s positive to highly positive generalized or “semantic” description. Despite inferred experiences of, for example, extreme rejection or even abuse, the portrait of the parent is consistently positive, and gratuitous praise of the parents may be offered (e.g., references to “wonderful” or “excellent” parents).

Insistence on lack of memory for childhood. This scale assesses the speaker’s insistence upon the inability to recall his or her childhood, especially as this insistence is used to block further queries or discourse. The scale focuses on the subject’s direct references to lack of memory (“I don’t remember”). High ratings are given to speakers whose first response to numerous interview queries is “I don’t remember,” especially when this reply is repeated or remains firmly unelaborated. Low scores are assigned when speakers begin a response with a reference to lack of memory, then actively and successfully appear to recapture access to the experience they have been asked to describe.

Active, derogating dismissal of attachment-related experiences and/or relationships. This scale deals with the cool, contemptuous dismissal of attachment relationships or experiences and their import, giving the impression that attention to attachment-related experiences (e.g., a friend’s loss of a parent) or relationships (those with close family members) is foolish, laughable, or not worth the time. High ratings are assigned when a speaker makes no effort to soften or disguise his or her dislike of the individual or of the topic, so that—in keeping with the apparent intent of casting the individual (or topic) aside (“My mother? A nobody. No relationship. Next question?”)—the sentences used are often brief, and the topic is quickly dropped. However, only low scores are given for “gallows” humor: “Oh hell, I didn’t mind another separation, I guess that one was #13.” (Note. Speakers receiving high scores on this scale are assigned to a relatively rare adult attachment subcategory, Ds2, in which attachment figures are derogated rather than idealized.)

Scales associated with the preoccupied adult attachment category

Involved/involving anger expressed toward the primary attachment figure(s). Accurate ratings on this scale depend on close attention to the form of the discourse in which anger toward a particular attachment figure is implied or expressed. Direct descriptions of angry episodes involving past behavior (“I got so angry I picked up the soup bowl and threw it at her”) or direct descriptions of current feelings of anger (“I’ll try to discuss my current relationship with my mother, but I should let you know I’m really angry at her right now”) do not receive a rating on the scale. High ratings are assigned to speech that includes, for example, run-on, grammatically entangled sentences describing situations involving the offending parent; subtle efforts to enlist interviewer agreement; unlicensed, extensive discussion of surprisingly small recent parental offenses; extensive use of psychological jargon (e.g., “My mother had a lot of material around that issue”); angrily addressing the parent as though the parent were present; and, in an angry context, slipping into unmarked quotations from the parent.

Passivity or vagueness in discourse. High scores are assigned when, throughout the transcript, the speaker seems unable to find words, seize on a meaning, or focus on a topic. The speaker may, for example, repeatedly use vague expressions or even nonsense words; add a vague ending to an already completed sentence (“I sat on his lap, and that”); wander to irrelevant topics; or slip into pronoun confusion between the self and the parent. In addition, as though absorbed into early childhood states or memories, the subject may inadvertently (not through quotation) speak as a very young child (“I runned very fast”) or describe experiences as they are described to a young child (“My mother washed my little feet”). Vague discourse should not be confused with restarts, hesitations, or dysfluency.

material around that issue”), and use of nonsense words (“dadadada”). Phenomena conforming to these violations (hence, pointing to the preoccupied classification) have been quantified in continuous scales identifying passivity or vagueness of discourse (manner) and involved/involving anger (relevance, quantity, and manner). (Brief examples of speech typical of secure, dismissing, and preoccupied speakers were provided earlier.)

Table 26.2 provides an overview of the present continuous scoring systems for states of mind (Main & Goldwyn, 1998; Main et al., 2003). I now return, however, to the remaining work of the AAI coder as he or she reviews the text.

As a close look at Table 26.2 indicates, *an AAI coder's first estimate of category placement is based entirely on the configuration of the continuous scores for the state-of-mind scales.* “Expectable configurations” are given in the AAI scoring and classification manual, where, for example (ignoring the still-under-development metacognition scale), high scores on coherence and low scores on idealization, derogation, involved/involving anger, passivity of discourse, and insistence on lack of memory point to a secure-autonomous transcript, whereas low scores on coherence and high scores on (either or both) involved/involving anger or passivity of discourse point to a preoccupied speaker. An acceptable range for the configuration of scores is given for each AAI classification, and coders record their first estimate of classification from these scores. Where scores point to conflicting major classifications, the coder may begin to consider the likelihood that the text is unorganized (unclassifiable). However, importantly, it is only after recording the classification(s) emerging from the configuration of state-of-mind scores (which is termed the “bottom-up” or “score-to-classification” analysis) that the coder will turn to the “top-down” or (classificatory) feature analysis of the text, as delineated below.

The Application of a Feature Analysis to Classify, and Subclassify a Respondent's State of Mind

First, it should be underscored that the three organized categories of the AAI are ultimately divided into 12 subclassifications. This is in keeping with Ainsworth's division of her three organized infant Strange Situation classifications into eight subclassifications, which she predicted would “in time prove even more useful than classification into the

three major groups themselves” (Ainsworth et al., 1978, p. 251). Parents' AAI subclassifications and their infants' Strange Situation subclassifications have now been found to be significantly related in four different investigations (as noted in and including Behrens, Hesse, & Main, 2007) but nonetheless remain underutilized.

Second, from its inception, the AAI scoring system has included a set of (9-point) continuous rating scales that assess the speaker's current “state of mind with respect to attachment,” whether with respect to a given parent (e.g., idealizing the father) or with respect to discourse patterning in general (e.g., overall coherence of transcript, overall passivity). As researchers from several laboratories have correctly emphasized, use of these scales releases the restriction of range imposed by the presentation of findings only in terms of classifications, hence substantially increasing statistical power (Fyffe & Waters, 1997; Roisman, Fraley, & Belsky, 2007). This section brings together all three current methods of AAI text analysis.

In the final step of interview analysis, a coder determines the applicability of all *features* associated with each major classification (and subclassification) to the transcript in hand. Insofar as possible, this step is carried forward independently of the continuous scores assigned to the scales for states of mind. Table 26.3 elaborates (1) scale score configurations; (2) Gricean discourse characteristics; (3) some of the features that point to particular AAI classifications; and (4) the associated infant Strange Situation classifications.

For reasons of space, I do not elaborate on the particular features pointing to each of the three organized classifications here. Instead, examples of these features are placed in Table 26.3.

The 12 Subclassifications of the AAI Briefly Noted

As the scales and features developed for the analysis of the AAI were being created, Main and Goldwyn (1984b) began to note what at times were striking differences between transcripts that had been placed in a given major classification category. Thus, for example, within the dismissing classification as a whole (which was associated with the infant avoidant classification devised by Ainsworth et al., 1978), there were four distinct subtypes of transcripts. This indicates at once that the AAI system differs from Ainsworth's in important ways because her infant system contained

TABLE 26.3. Scale Score Configurations, Feature Analyses, and Their Relations to the Organized Categories of Infant Strange Situation Behavior

Adult states of mind with respect to attachment
<u>Secure-autonomous (F): Predictive of secure (B) Strange Situation behavior</u>
<p><i>Scale score configuration.</i> Moderate to high scores for coherence. Low to low-moderate scores on scales indicative of insecure states of mind.</p> <p><i>Discourse characteristics.</i> Coherent, collaborative discourse. Descriptions and evaluations of attachment-related experiences and their effects are reasonably consistent, whether the experiences appear to have been favorable or unfavorable. Discourse does not notably violate any of Grice's maxims.</p> <p><i>Features predominating with respect to attitudes toward attachment.</i> Avows missing, needing, and depending on others. Seems open and "free to explore" interview topic, indicating a ready flexibility of attention. States that attachment-related experiences have affected his or her development and functioning. Seems at ease with imperfections in the self. Explicit or implicit forgiveness of or compassion for parents. Can flexibly change view of person or event, even while interview is in progress, suggesting autonomy and ultimate objectivity. Sense of balance, proportion, or humor. Ruefully cites untoward flawed behavior of self as appearing at times despite conscious intentions or efforts.</p>
<u>Dismissing (Ds): Predictive of avoidant (A) Strange Situation behavior</u>
<p><i>Scale score configuration.</i> Low scores on coherence; high scores on idealization or derogation of one or both parents, often accompanied by high scores on insistence on lack of memory for childhood.</p> <p><i>Discourse characteristics.</i> Not coherent. Violates the maxim of quality (consistency/truthfulness), in that positive generalized representations of history are unsupported or actively contradicted by episodes recounted. Violates the maxim of quantity—either via repeated insistence on absence of memory; or via brief contemptuous derogation of, or active contemptuous refusal to discuss, a particular event or figure.</p> <p><i>Features predominating with respect to attitudes toward attachment.</i> Self positively described as being strong, independent, or normal. Little or no articulation of hurt, distress, or feelings of needing or depending on others. Minimizes or downplays descriptions of negative experiences; may interpret such experiences positively, in that they have made the self stronger. May emphasize fun or activities with parents, or presents and other material objects. Attention is inflexibly focused away from discussion of attachment history and/or its implications: Responses are abstract and/or seem remote from present or remembered feelings or memories, and topic of interview seems foreign. May express contempt for other person(s), or, relatedly, for events usually considered sorrowful (e.g., loss or funerals).</p>
<u>Preoccupied (E): Predictive of resistant/ambivalent Strange Situation behavior</u>
<p><i>Scale score configuration.</i> Low scores for coherence; high scores for either passive or angry preoccupation with experiences of being parented (rarely, preoccupied with frightening experiences).</p> <p><i>Discourse characteristics.</i> Violates manner, quantity, and/or relevance, while quality/truthfulness may not be violated. In regard to quantity, sentences or conversational turns taken are often excessively long. In regard to manner, responses may be grammatically entangled or filled with vague usages ("dadadada," "and that"). In regard to relevance, the present may be brought into responses to queries regarding the past (or vice versa), or persons or events not the objects of inquiry may be brought into the discussion.</p> <p><i>Features predominating with respect to attitudes toward attachment.</i> Responses to interview are persistently closely and inflexibly tied to experiences with and influences of the parents, even when these are not the objects of inquiry. May attempt to involve the interviewer in agreement regarding parents' faults; may seem to weakly, confusedly praise parents, but with oscillations suggestive of ambivalence; and/or (rare) may relate frightening experiences involving them. Topic of interview is addressed, but seems inflexible and closed so that interview responses may seem memorized or unconsciously guided, as if the attachment-related history is "an old story." Unbalanced, excessive blaming of either parents or self. Indecisive—for example, evaluative oscillations ("Great mother. Well, not really, actually pretty awful. No, I mean actually, really good mother, except when she ..?."). May be unusually psychologically oriented, offering authoritative "insights" into motives of self or others. The lexicon of "pop" psychology may appear with excessive frequency.</p>
Infant Strange Situation behavior

(continued)

Secure (B)

Flexibility of attention: Explores or plays in parent's presence, changes attentional focus to parent on at least one separation, and seeks parent during at least one reunion. In preseparation episodes, explores room and toys with interest, with occasional returns to or checks with parent ("secure-base phenomenon"). Shows signs of missing parent during separation, often crying by the second separation. Greet parent actively, usually initiating physical contact. Usually some contact maintaining by second reunion, but then settles and returns to play.

Avoidant (A)

Little flexibility of attention: Focuses on toys or environment, and away from parent, whether present, departing, or returning. Explores toys, objects, and room throughout the procedure. Fails to cry on separation from parent. Actively avoids and ignores parent on reunion (i.e., by moving away, turning away, or leaning out of arms when picked up). Little or no proximity or contact seeking, distress, or expression of anger. Response to parent appears unemotional. Focuses on toys or environment throughout procedure.

Resistant or ambivalent (C)

Little flexibility of attention: Focuses on parent throughout much or all of procedure; little or no focus on toys or environment. May be wary or distressed even prior to separation. Preoccupied with parent throughout procedure; may seem angry or passive. Fails to settle and take comfort in parent on reunion, and usually continues to focus on parent and cry. Signs of anger toward parent are mixed with efforts to make contact, or are markedly weak. Fails to return to exploration after reunion, as well as during separation, and often preseparation as well (i.e., preoccupied by parent, does not explore).

Note. Descriptions of the adult attachment classification system are summarized from Main et al. (1985, 2003). Descriptions of infant A, B, and C categories are summarized from Ainsworth et al. (1978).

only two subclassifications for avoidant infants (A1 and A2).

As an example, two types of transcripts of speakers who were highly dismissing of attachment—and most frequently having highly avoidant babies (A1)—differed sharply in their characteristics. In the first (Ds1), speakers were remarkably *idealizing* of one or both parents, whereas in the second (rare) subtype (Ds2), speakers were contemptuously *derogating* of one or both parents (or of attachment-related experiences; e.g., making fun of displays of grief following a loss). In a prison population, the Ds2 subclassification has been found with unusual frequency among murderers and prisoners who are otherwise violent toward persons (Hobson et al., 2016). Among mothers, it has been found to be associated with frightening behavior toward offspring (Evans, 2008).

Likewise, five subclassifications of the AAI were developed for secure-autonomous parents, of which four corresponded directly to Ainsworth's four secure infant subclassifications. A fifth subclassification was created for parents who seemed somewhat conflicted or resentful and/or mildly angrily preoccupied regarding their parents (F5). These speakers, however, often somewhat humorously indicated acceptance of the anger and involvement, which had characterized their relationship with their parents and, they concluded,

would probably continue to do so. Interestingly, this subclassification of security was inductively found to predict a prototypically secure (B3) Strange Situation response in offspring.

Finally, three AAI subclassifications were found to predict resistant/ambivalent infant Strange Situation behavior, parallel to two of Ainsworth's Strange Situation subclassifications. Thus, angrily and passively preoccupied speakers were found to have angrily and passively ambivalent babies, respectively. In addition, a third subclassification, E3, *fearfully* preoccupied, was developed for AAI texts. Interestingly, it was developed in order to characterize just one of the 103 Bay Area transcripts. However, this subclassification was later found to be predominant in a study of patients with borderline personality disorder (Patrick, Hobson, Castle, Howard, & Maughan, 1994).

For an extensive description of the AAI and Strange Situation subclassifications, which in several studies have shown a significant parent-to-infant match, see Hesse (2008).

The Unresolved/Disorganized and Cannot Classify Categories: Breakdowns in Discourse Strategy

The unresolved/disorganized (unresolved, U) and cannot classify (,CC) categories (see Table 26.4)

were delineated only some years following the inception of the AAI, most likely because their subtlety and complexity could not be recognized until a firm grounding in the three organized categories had been established. Thus it seems likely that, as is generally true with taxonomic endeavors, an awareness of these “exceptions to the rule” was revealed in systematic ways only after much experience with the more basic entity under consideration had been acquired.

Delineating and Refining the Unresolved Attachment Category

As early as 1984, Main and Goldwyn had informally noted that the parents of unclassifiable infants, many of whom would later become classified as disorganized/disoriented, sometimes spoke in unusual ways about loss experiences. Unresolved or “disordered” mourning had most commonly been understood as falling into two general categories: (1) “chronic mourning,” a continuing strong grief reaction that does not abate over an extended period of time (see Fraley & Shaver, Chapter 3, this volume); or (2) “failed mourning,” in which expectable grief is substantially minimized or does not occur (see Bowlby, 1980). As the analysis of discussions of loss experiences within the AAI development sample proceeded, however, it became evident that the linguistic indicators of “unresolved” attachment status in adults that predicted disorganized attachment in infants did not appear as explicit manifestations of either chronic or failed mourning.

Over time, it became increasingly clear that what the parents of disorganized infants had in common were various indications of what was ultimately termed “lapses in the monitoring of reasoning or discourse” during discussions of potentially traumatic experiences (Hesse & Main, 1999, 2000). More specifically, the AAI transcripts of these individuals were distinguished by the appearance of (ordinarily) brief slips in the apparent monitoring of reasoning or of the discourse context during the discussion of loss or (discovered later) other potentially traumatic events (see Table 26.4). Such discourse/reasoning lapses were considered to be suggestive of temporary alterations in consciousness or working memory and are believed to represent either interference from normally dissociated memory or belief systems or unusual absorptions involving memories triggered by the discussion of traumatic events (Hesse & Main, 1999, 2006; Hesse & Van IJzendoorn, 1998, 1999).

Lapses in the monitoring of *reasoning* are manifested in statements that suggest the speaker is temporarily expressing ideas that violate our usual understanding of physical causality or time-space relations. Marked examples of reasoning lapses are seen when speakers make statements indicating that a deceased person is believed simultaneously dead and not dead in the physical sense—for example, “It was almost better when she died because then *she could get on with being dead* and I could get on with raising my family” (Main & Goldwyn, 1998, p. 118, emphasis added). This statement implies a belief, operative at least in that moment, that the deceased remains alive in the physical sense. Statements of this kind may indicate the existence of incompatible belief and memory systems, which, normally dissociated, have intruded into consciousness simultaneously as a result of queries regarding the nature of the loss experience and its effects. Lapses in the monitoring of *discourse* would seem to suggest that the topic has triggered a “state shift” indicative of considerable absorption, appearing to involve entrance into peculiar, compartmentalized, states of mind in which discourse is not appropriately regulated (Hesse, 1996; Hesse & Main, 2006; Hesse & Van IJzendoorn, 1999). Thus, for example, an abrupt alteration or shift in speech register inappropriate to the discourse context occurs when a subject moves from his or her ordinary conversational style into a eulogistic or funereal manner of speaking, or provides excessive detail. (In addition, albeit rarely, individuals experiencing major trauma can also be assigned to the unresolved category on the basis of reports of extreme responses to traumatic events, such as suicide attempts.)

Both sudden state shifts and the abrupt appearance of incompatible ideas suggest momentary but qualitative changes in consciousness. Thus, they appear to represent temporary/local as opposed to global breakdowns in the speaker’s discourse strategy. Discourse/reasoning lapses of the kinds just described often occur in high-functioning individuals and are normally not representative of such a speaker’s overall conversational style. For this reason, among others, transcripts assigned to the unresolved category are given a best-fitting alternate classification (e.g., unresolved/dismissing [U/Ds]).

Early discoveries regarding the relation between secure, dismissing, and preoccupied parental AAI status and secure, avoidant, and resistant/ambivalent attachment status have already been

TABLE 26.4. Scale Scores, Discourse Characteristics, and Features Associated with the Disorganized and Unorganized/“Cannot Classify” Categories of the AAI, and Corresponding Infant Strange Situation Categories

Adult states of mind with respect to attachment
<u>Unresolved/disorganized (U)</u>
<p><i>Scale scores.</i> Scores above 5 on either unresolved loss or unresolved abuse (the distinctions between these are retained) lead to category placement. At scale point 5, the coder must decide whether the transcript fits the unresolved/disorganized classification.</p> <p><i>Discourse characteristics.</i> During discussions of loss or abuse, individual shows striking lapse in the monitoring of reasoning or discourse. For example, individual may briefly indicate a belief that a dead person is still alive in the physical sense, or that this person was killed by a childhood thought. Individual may lapse into prolonged silence or eulogistic speech. The speaker will ordinarily otherwise fit Ds, E, or F categories.</p> <p><i>Features predominating with respect to attitudes toward attachment.</i> No particular features beyond lapse. May fit the descriptors for Ds, E, or F.</p>
<u>Unorganized/“cannot classify” (CC)</u>
<p><i>Scale score configuration.</i> Scale scores may point to contradictory insecure classifications (e.g., strong idealizing and strong involved/involving anger are seen within the same transcript) as in the “original” form of CC. Alternatively, all state-of-mind scores are low, none moving fully to midlevel (e.g., below midpoint for all scores indicative of insecure states of mind, as well as for coherence; see Hesse, 1996). Finally, some CC texts cannot be determined by scale scores and rely on the use of feature analysis (Main et al., 2003).</p> <p><i>Discourse characteristics.</i> The early “contradictory strategies” discourse forms seen in CC texts are described below. In newer forms of CC, violations of Grice’s maxims do not necessarily take the forms ordinarily seen in insecure speakers. Coherence violations are not necessarily limited to particular locations in the text, or particular persons or events. In rare and extreme cases, the transcript as a whole may be so incoherent as to be difficult to follow.</p> <p><i>Features.</i> In the “original” form of CC, features sufficient to fit the text to two directly contrasting classifications (e.g., dismissing and preoccupied) are observable. In one newer form of CC (Main et al., 2003), the transcript is incoherent without elevated scores for insecure states of mind. Transcripts may also now be considered unclassifiable if (1) the speaker seems to attempt to frighten the listener (e.g., with the sudden, unintroduced, detailed discussion of a murder) or (2) refuses to speak during the interview, without responding that memories are unavailable or are too painful to discuss. Finally, transcripts are considered unclassifiable if they seem to fit equally well to both a secure and insecure classification (e.g., CC/Ds/F or CC/F/E).</p>
Infant Strange Situation behaviors
<u>Disorganized/disoriented (D)</u>
<p>The infant displays disorganized and/or disoriented behaviors in the parent’s presence, suggesting a temporary collapse of behavioral strategy. For example, the infant may freeze with a trance-like expression, hands in air; may rise at parent’s entrance, then fall prone and huddled on the floor; or may cling while crying hard and leaning away with gaze averted. Infant will ordinarily otherwise fit A, B, or C categories. At 6 years of age, previously disorganized infants in several samples have been found to be role-inverting or “disorganized/controlling” with the parent, being either punitive or caregiving/sollicitous.</p>
<u>Cannot classify (CC)</u>
<p>The infant displays aspects of more than one classification, without necessarily being primarily or even notably otherwise disorganized/disoriented. For example, the infant may fit well to the avoidant category on the first reunion, and to the resistant category on the second. Alternatively, the infant’s Strange Situation behavior may be so diffuse throughout the procedure that it cannot via any single reunion or separation response be found to fit to any single category.</p>
<p><i>Note.</i> Descriptions of the U and CC categories of the adult attachment classification system are summarized from Hesse and Main (2000) and from Main et al. (2003). The description of the infant D category is summarized from Main and Solomon (1990); the description of the child D category is based on Main and Cassidy (1988); and the still new infant/child CC category has been utilized in publications by Abrams et al. (2006) and Behrens et al. (2007).</p>

described. The next discovery regarding the AAI (Main & Hesse, 1990) was based on the identification of a fourth infant Strange Situation classification: disorganized/disoriented (hereafter, disorganized or D; Main & Solomon, 1990). Infants were placed in this fourth category when they failed to maintain the behavioral organization characteristic of those classified as secure, avoidant, or ambivalent-resistant. Although this failure to maintain organization had previously been described as “unclassifiable” Strange Situation behavior by Main and Weston (1981), a review of unclassifiable babies in the large Bay Area sample had indicated that most displayed disorganized and/or disoriented behaviors in the Strange Situation (Main & Solomon, 1986, 1990). Thus, the “unclassifiable” babies were observed engaging in unusual displays such as approaching the parent with head averted, putting hand to mouth in a gesture indicative of apprehension immediately upon reunion with the parent, or rising to approach the parent and then falling prone to the floor. Infants were also labeled disorganized if they froze all movement with arms elevated, or if they held still for many seconds with a trance-like expression.

A follow-up review of Strange Situation videotapes taken from several samples of somewhat to markedly troubled parent–infant dyads led to expansion of this infant system, which was finalized (above) in 1990. Disorganized attachment has now been observed in the majority of infants in maltreatment samples (e.g., Carlson, Cicchetti, Barnett, & Braunwald, 1989; Lyons-Ruth, Connell, Zoll, & Stahl, 1987), whereas in low-risk samples, it has been found associated with both externalizing and internalizing disorders (Fearon, Bakermans-Kranenburg, Van IJzendoorn, Lapsley, & Roisman, 2010; Groh et al., 2012; Van IJzendoorn, Schuengel, & Bakermans-Kranenburg, 1999; see Solomon, George, & De Jong, 1995, for initial findings).

By 1990, it had been shown that unresolved AAI status in a parent predicted disorganized attachment in the infant (Main & Hesse, 1990; see Table 26.4). Specifically, in conjunction with a 6th-year follow-up study, Mary Main and I found that 5 years earlier, 91% (11 of 12) of mothers with unresolved loss or trauma, as identified in the AAI, had had babies who were disorganized with them in the Strange Situation, while only 16% of mothers who were not considered unresolved had had disorganized infants 5 years earlier. Thus, there was now an AAI category corresponding to and predictive of

each of the four Strange Situation categories in use at the time. Since this original study, 9-point scales for both indices of unresolved loss and abuse (e.g., Main et al., 2003) were developed, while as noted similar 9-point scales for scoring infant disorganized behavior had already been developed (Main & Solomon, 1990). Finally, by 2006 an analysis of a subset ($n = 36$) of parents and infants drawn from the Bay Area sample had confirmed a significant correlation between parental lapses of monitoring in the AAI surrounding loss or other trauma and infant disorganized/disoriented behavior in Strange Situations conducted with the parent ($\phi = .56$, $p < .001$; Abrams, Rifkin, & Hesse, 2006).

Emergence of the Cannot Classify Adult Attachment Category

A fifth interview category, “cannot classify” (CC), emerged in the early 1990s as Mary Main and I began noticing a small percentage of transcripts that failed to meet criteria for placement in any of the three central or organized attachment categories, and additionally did not fit to placement as Unresolved. This was first observed in transcripts in which, for example, an unsupported positive description of one or both of the parents led to a relatively high idealization score, whereas, in direct contradiction to the expected global patterning for dismissing speakers, highly angrily preoccupied speech was also found. Thus, the high idealization score called for placement in the dismissing category, whereas other portions of the transcript called for preoccupied category placement. Main and I (see Hesse, 1996) therefore concluded that these transcripts were unclassifiable and should be placed in a separate group. Because both this “contradictory strategies CC” and other CC subtypes involve low coherence, they are necessarily defined as insecure.

Earned or Evolved Security

In 1989, “earned” security was suggested as a new (sub)classification of security within the AAI manual, including instructions to coders that this taxonomic placement should be applied to transcripts in which the participant, *although speaking coherently and collaboratively*, either “(a) appeared to have had difficult childhood relationships with parents, and/or (b) another untoward experience such as loss or separation” (Main & Goldwyn,

1989, p. 119). This additional subcategory of security placed greater emphasis on the overriding import of coherence than had appeared in previous coding manuals. Thus, it was now formally proposed that (1) coders should stipulate when a transcript indicated that an individual's experiences had been notably unfavorable, while (2) the individual simultaneously maintained his or her "secure" status via the coherence of his or her narrative. Emphasizing the similarity between "earned" and what was to be called "continuous" security, "earned-secure" speakers have recently been found as likely to have secure infants as those secure speakers who described favorable early experiences (Saunders, Jacobvitz, Zaccagnino, Beverung, & Hazen, 2011).

For clinicians, the concept of "earned" security has had special relevance because it clearly bears directly on the nature of their work. The fact that AAI texts could be found coherent and collaborative even when the speaker's childhood experiences appeared to have been highly unfavorable underscored long-held views that a secure state of mind can be achieved despite early adversity. It was reasoned, then, that so long as clients could be successfully assisted in becoming coherent regarding their experiences via favorable new relationships with a therapist, they might expectably be enabled to attain a secure state of mind. This had already been, of course, the position taken by Bowlby (1988) and many others working in the field of mental health.

Early on, then, Bowlby had suggested that "working models" of the self, relationships, and the self within relationships formed in early childhood—although resistant to change—nonetheless most likely retain the potential for change within the context of new experiences with other persons (see, e.g., Bowlby, 1988). Of course, these changes could be for better or worse, but as a therapist Bowlby's emphasis was on the enduring possibility of positive reorganization within an individual's working models of the self and interpersonal relationships. And, in the same year, Egeland, Jacobvitz, and Sroufe (1988) had reported that within a sample of mothers who had experienced abuse in childhood, those who had received emotional support from a nonabusive adult, participated in therapy, or had an emotionally satisfying supportive partner were markedly less likely to become abusive than those abused mothers who had not had the advantage of such experiences. Other evidence for the possibility of such change was pro-

vided shortly thereafter by Rutter, Quinton, and Hill (1990), who, in their longitudinal study of institutionally reared children, found that many became competent parents following warm and confiding marital experiences. Finally, the success of therapists in assisting clients classified insecure on the AAI to attain a secure state of mind with respect to attachment has been empirically documented in two longitudinal studies, as I note below (Buchheim et al., 2016; Levy et al., 2006).

Before going further, I should note that despite my own interest and that of others in retrospectively identified "earned security" I had stated earlier that

we must leave open the possibility that because the AAI does not necessarily provide valid information about an individual's actual experiences, we do not know whether those who appear to be "earned-secure" have in fact—and, of course, in contradiction to what they "remember" during the AAI—had substantially positive early experiences that are now, ironically, coherently misrepresented. (Hesse, 1999, p. 426)

Thus, it seemed conceivable that *some* individuals considered earned-secure on the basis of their coherent recounting of a harsh childhood may have been secure with at least one parent specifically during the early years of life—a fact that, depending on child age, might well not be readily consciously accessible (Hesse, 1999, p. 426; Hesse, 2008, p. 588). Indeed, early loving experiences with at least one parent could somehow be aiding the speaker in a coherent reconstruction of experiences, despite the fact that later experiences had in fact been unfavorable. These and other important questions regarding the role of early experiences can be addressed only via longitudinal studies (Hesse, 1999). Fortunately, two such studies have been undertaken by Glen Roisman and his colleagues, both in Minnesota: one by Roisman, Padron, Sroufe, and Egeland (2002), and (more recently) the other in conjunction with the National Institute of Child Health and Human Development (NICHD) study of families and children (Roisman, Haltigan, Haydon, & Booth-LaForce, 2014), as discussed below.

I should note here that with increasing time, it has become clear that the term *earned-secure* is not an ideal taxonomic label for this fairly unusual form of AAI security. First, the term implies that the coherence and collaboration of such texts

should be seen as a product of a (conscious or unconscious) *effort* to reorganize attachment-related representational states constructively. Of course, some individuals could have reorganized their state of mind *sans* any conscious personal effort; hence, the term *discontinuous secure* might initially seem preferable. Unfortunately, the term *discontinuous secure* still leaves a problem, since it might reference either lost or gained security.

Consequently, given the aforementioned difficulties, I now suggest that both the terms *discontinuous secure* and *earned secure* be replaced with the term *evolved secure*, which implies a forward and positive directional shift, without implying a necessarily conscious and/or active process. And fortuitously, the frequently used initials, ES, can be retained.

I now discuss the unfortunate complications that initially arose because no precise cutoff criteria for scoring earned security were provided before 1998, when Main and Goldwyn set earned-secure criteria: The text must include loving scores of 2.5 or below on the 9-point scale for *both* parents (Main & Goldwyn, 1998). Note that given this restricted guideline, the coder may still have judged the parents to have provided some attention and instrumental assistance during childhood. But, even so, parenting would still have been absent indices of actively loving behavior (e.g., reliable physical affection, the forgiving of the child's misbehavior, or [when appropriate] defending the child to others, such as teachers or overly strict relatives).

Prior to 1998, however, many researchers had of course been eager to explore the topic of earned security and in doing so created early criteria that were markedly less stringent (i.e., earned security was identified in texts in which at least *one* parent scored less than 5 on the 9-point Loving scale, and *either* of the parents also scored 5 or higher on rejecting, neglecting, pressure to achieve and/or role reversal [commonly referred to as the Pearson criteria; see Pearson, Cohn, Cowan, & Cowan, 1994]).

Recently, Roisman and colleagues (2014) attempted to address this issue by examining data using both the less stringent pre-1998 Pearson criteria informally employed by most researchers at that time, as well as the more stringent 1998 Main and Goldwyn criteria for earned secure. Additionally, where comparisons to continuous secure were to be made, Roisman and colleagues have offered analyses additional to the Pearson criteria (i.e.,

analyses that follow Main and Goldwyn's stipulation that only those texts where the average parental Loving scale score was 6.5 or above should be utilized for the "continuous secure" assignment, and each parent scoring 2.5 or below on the Loving scale for "earned secure").

Although these criteria are likely to be met by some individuals interviewed in adulthood, the current criteria for earned-secure AAI status (again, a coherent transcript, despite both parents scoring at 2.5 or below for loving) was not met by any of the 19-year-old participants in the Bay Area follow-up study (Main, Hesse, & Kaplan, 2005), and it was met only infrequently in two other studies of participants averaging 19 years of age (Roisman, Fortuna, & Holland, 2006; Roisman et al., 2002). The fact that so few adolescents are judged to be earned secure is probably not surprising, given that increased potential for introspection normally develops in adulthood. Furthermore, this suggests that future studies of retrospectively identified "earned security" (i.e., identified via apparent remembrances of AAI participants) will be most productive if undertaken within samples of postcollege-age adults.

A number of investigations of earned security within postadolescent samples have now been completed, each utilizing a cross-sectional design. For example, Caspers, Yucuis, Troutman, and Spinks (2006) have reported that continuous secure adults (identified through Loving scores of 5 or above for both parents) were less likely than *both* insecure and earned-secure adults to abuse alcohol or other substances. However, earned-secure adults ($N = 25$, identified as both parents scoring at 2.5 or below on loving) were more likely to have entered psychotherapy than either dismissing or continuous secure participants. Strikingly, like Caspers and her colleagues, Jacobvitz (2008; Jacobvitz, Booher, & Hazen, 2001; see also Saunders et al., 2011) also found that earned-secure adults (both parents scoring at 3 or below on loving) had spent more time in therapy than either continuous secure or insecure participants.

As discussed earlier, before the implementation of the Main and Goldwyn guidelines, most investigators studying earned security had essentially divided their secure participants into two groups: those inferred to have had "more" versus "less" loving parents, with the latter usually being identified by one of the parents having received a loving score either below the sample median or below a score of 5 on the 9-point scale.

In the majority of these studies, mean scores for the mothers' loving behavior during childhood for participants termed *earned secure* have been above 5, with many scores falling well above 5. Although, ideally, these might therefore best have been termed studies of participants with parents inferred to have been "more" versus "less" loving, rather than studies examining continuous secure versus earned-secure participants, they have yielded interesting results.

For example, in a pioneering study in 1994, Pearson and colleagues found that although earned-secure participants scored higher on a depression inventory than did their continuous-secure counterparts, they were equally warm toward their 42-month-old offspring and equally providing of structure. A few years later, Phelps, Belsky, and Crnic (1998) found that self-reported "daily hassles" were not higher for earned-secure than for other mothers, helping to rule out a possible "depressogenic" hypothesis that earned-secure mothers tended simply to report their experiences as being worse than did others. In addition, they found that earned-secure mothers' sensitivity to offspring held up even under high-stress conditions. And perhaps surprisingly, Paley, Cox, Burchinal, and Payne (1999) found that earned-secure wives were no less positive and no more negative than continuous-secure wives during marital interactions.

Beginning on a series investigating the "earned-secure" subclassification, Roisman and colleagues (2002) inspected longitudinal data from 19-year-olds in a Minnesota high-risk sample ($N = 170$). In this study utilizing the pre-1998 criteria, transcripts in which either parent (usually the father) fell below 5 on the 9-point loving scale were defined as earned-secure. The mean loving scores for mothers of participants identified as earned-secure was 5.46, whereas for continuous-secure participants the mean loving score for mothers was one point higher, 6.50. In sharp contrast, mean *fathers'* loving scores for the two groups differed substantially, being 2.56 for earned-secure and 5.73 for continuous-secure participants. Thus identified (i.e., given the obviously average loving scores of "earned-secure" participants' mothers) it does not seem surprising that earned-secure status in this study was not significantly associated with either (1) having been insecure with mother in the Strange Situation at either 12 or 18 months or (2) significantly less positive observed interactions with mother at 24 months, 42 months, or 13

years of age. Since earned-secure mothers' loving scores *averaged* 5.46 in this study, neither significantly less positive nor significantly less negative outcomes should have been expected.

It would, then, clearly be premature to conclude from this study that AAI scores for parental loving are unrelated to childhood experiences, thereby making retrospective earned/evolved-secure assignments invalid. This is because (1) security or insecurity in infancy was identified on the basis of Strange Situation classification with *mother*, yet (2) retrospective insecurity appears to have been determined mainly on the basis of inferred early insecurity with *father*. For the same reason, observations of father-child interactions would have been necessary to decide whether earned-secure status did or did not correspond significantly with observed early experience.

In a further study aimed at untangling the "meaning" (and reality basis of) the earned-secure classification, Roisman and colleagues (2006) attempted to induce sad or happy moods just before administering the AAI, with a view toward ascertaining whether context could alter reports regarding experience with the parents. In this study, participants were asked to focus for 10 minutes on an autobiographical memory relevant to achieving a sad (or happy) state, although whether the memory needed to relate to interpersonal relationships was not specified. Sad (or happy) music was played during this period, and participants were urged to achieve a mood state as intense and as real as possible. The participants were identified as earned-secure in keeping with the "early" and less stringent earned-secure criteria described above (i.e., if they were coherent during the AAI, and if one of the two parents had received a loving score below 5, as well as a score above 5 for rejecting or neglecting behavior). The remaining coherent participants were regarded as continuous-secure.

With the earned- versus continuous-secure categories defined via the less strict criteria, placement in the earned- versus continuous-secure categories was impressively related to induced mood. Thus, a cross-tabulation of experimental condition among secure participants revealed that participants were overrepresented as earned-secures in the sad condition, and as continuous-secures in the happy condition. The mood induction procedures did not, however, affect insecure speakers, and in interpreting this finding, Roisman and colleagues (2006, p. 61; see also Sroufe & Waters, 1977) sug-

gested that perhaps only secure speakers have the ability to “tune behavior and emotion properly to contextual demands.” Importantly, however, and as the investigators emphasize, coherence scores—the heart of the AAI scoring procedure—were *not* affected by induced mood.

It is crucial to note, however, that induced sad moods in this study did not in fact lead to placement in the earned-secure group using Main and Goldwyn’s (1988) criteria (i.e., Loving scale scores of 2.5 or below for *both* parents). In the sad condition, fathers’ mean loving scores for secure participants were at 4.45 ($SD = 1.74$) and mothers’ mean loving scores were 5.52 (which is, again, considered adequate parenting [see Main et al., 2003], and ranged to above 7 ($SD = 1.66$). Thus, even in the sad condition, mothers’ loving scores for secure participants remained at the average for most samples, with many secure participants’ mothers scoring well above average. As such, the findings of this study cannot be taken to indicate that concurrent sad mood can lead to placement in the earned-secure group.

Roisman and colleagues’ (2014) more recent efforts to address the topic of earned security were via longitudinal observations of adolescents participating in the Study of Early Child Care and Youth Development (SECCYD). Contrary to my expectations, even using the strict Main and colleagues (2003) criteria, earned/evolved secure individuals did not appear to have suffered the degree of adversity in parenting relationships throughout as much of their youth as I would have anticipated. Roisman and colleagues found that overall, “earned secures” in the NICHD sample appeared to have had better experiences of parenting during childhood and adolescence than those classified as insecure.

There is a notable exception, however: Using the Main and Goldwyn definition, “earned secures” were observed to have had *below*-average sensitivity from the mother between the early period of 5–64 months (Roisman et al., 2014, p.105), indeed, insensitivity comparable to insecure (earned-secure = $-.16$, insecure = $-.29$) existed during this period. In striking contrast, maternal sensitivity scores for continuous-secures during the same period was $.56$. Thus, impressive differences were observed between 6 months and 5.3 years. This is an intriguing finding, and it warrants further investigation. It is not unreasonable to speculate, as I had in 1999 and 2008, that early insensitivity may be especially influential.

In addition to reduced early maternal sensi-

tivity, using either the earlier or the more stringent criteria, “earned secures” were found to have lower family income relative to needs than “continuous secures,” as well as parents who had more depressive symptoms. Finally, in keeping with speculations that earned security could be associated with parental loss or abandonment, and in striking contrast to 5% father absence for continuous secures, father absence was recorded for 28% of earned-secures (31% for those judged insecure). While untoward parental absence is, of course, a potential stressor in its own right, it was specifically noted by Main and Goldwyn (1989, p.119) as one of the experiential factors stipulated as a difficulty which, noted in a coherent transcript, could lead to the assignment of earned-secure. Later versions of the AAI scoring and classification system rely on scores and features devoid of emphasis on specific unfavorable experiences (see Main et al., 2003). Although the other stressors identified among earned-secures in this 2014 study—greater financial difficulties, higher parental depressive symptoms—are not directly related to parental insensitivity (and are also not quantifiable on the existing AAI scales), it is indeed possible that these stressors did in fact lead some “earned-secure” speakers to experience important aspects of parenting as adverse. Put another way, these particular kinds of negative experience may not have been expressed overtly but rather “showed up” in ways that were somehow quantifiable on the existing AAI inferred experience scales. This would, of course, lead to a mismatch between these scales and the negative variables that Roisman and colleagues (2014) were investigating. Thus, some “earned secures” could have had difficult childhoods involving depression or parental absence that are not incisively quantified within the current AAI system. In addition, as in the case of the stability analysis of this sample (Groh et al., 2014), it would be premature to make generalizations regarding evolved security from this study alone.

Thus, whereas in 2008 the degree to which earned-secure status reflected actual (observable) adverse experiences in childhood remained, as previously (Hesse, 1999), an open question, more recent studies have nonetheless failed to provide conclusive evidence to counter the proposition that, strictly defined, earned/evolved-secure status will be found to represent a coherent AAI description of what may ultimately be confirmed as an insecure childhood. Another currently unanswered question is whether the induction of sad moods in persons with secure-autonomous status can reduce

parental loving scores sufficiently to ensure that loving behavior on the part of both of the participant's parents would appear inadequate.

The first of these issues will ultimately be resolved by prospective or longitudinal studies of normative samples (including assessments of security with each parent at multiple time points) that follow participants *beyond late adolescence*, so that individuals who are insecure in adolescence will have had the opportunity to form a coherent representation of their lives despite early adverse experiences with parents. The second might be addressed by new mood induction studies, perhaps optimally by asking adult participants to focus on sad versus happy (nonautobiographical) prospective events rather than elements from their autobiographies. However, many other approaches to the investigation of earned security (using the Main and Goldwyn guidelines) should be undertaken as well, and will likely continue to provide interesting outcomes, as demonstrated in several recent cross-sectional studies of adult populations described earlier (e.g., Caspers et al., 2006; Jacobvitz, 2008).

It should also be noted that pre- to posttherapy studies that show moves from insecure to secure-autonomous attachment status (see Levy et al., 2006; see also Buchheim et al., 2016)—both utilizing Kernberg's transference-based therapy (e.g., Yeomans, Clarkin, & Kernberg, 2015)—may eventually allow us to trace one developmental pathway to earned security within adulthood, and therefore may also make an important contribution to our understanding of this intriguing topic. Case studies carefully documenting representational change in states of mind with respect to attachment across the course of therapy may also be useful, and some especially well-described studies are available (see Ammaniti, Dazzi, & Muscetta, 2008; see also Muscetta, Dazzi, DeCoro, Ortu, & Speranza, 1999).

In closing, although Roisman and colleagues' (2014) important study raises critical questions about retrospective accounts of earned security, it nonetheless leaves a significant need for further investigation. Because the 2014 NICHD study utilizes an adolescent sample with an overrepresentation of white and higher-educated families, the distribution is skewed toward security (59%) and, relatedly, both the preoccupied (3%) and unresolved (3%) classifications are significantly underrepresented with respect to global norms (Van IJzendoorn & Bakermans-Kranenberg, 2014). First, more studies utilizing more extensive and carefully implemented measures of parental sensi-

tivity are urgently needed. In addition, the Saunders and colleagues (2011) study suggests that by following Bowlby (1988) theoretically and Rutter and colleagues (1990) empirically, tapping into real experiences may in some cases have indeed led to actual change in the reorganization and coherence of representational processes, which in turn would increase the likelihood of internal consistency in an AAI narrative. Roisman and colleagues' ambitious and admirable report leads me to conclude that until further studies are conducted, utilizing samples with more *normative distributions*, and *at later ages*, caution is warranted in the interpretation of retrospective accounts of earned or evolved security.

Selected Empirical Studies Involving the AAI

This section opens with a discussion of Main and Goldwyn's original parent–infant study,⁹ which differed from most succeeding studies (except Fonagy et al., 1991) in its emphasis on AAI state-of-mind scale scores, as well as its report of a significant AAI to Strange Situation match in subclassifications (replicated by Behrens et al., 2007). The just-mentioned emphasis on subclassification can be seen as comparable to the emphasis on scales or “dimensions” emphasized elsewhere (e.g., Groh et al., 2014; Roisman et al., 2007) in that it tests the ability of the instrument at fine-grained levels. Additional reviewed AAI studies include topics such as psychometric properties, parent-to-offspring matches, clinical populations, and, as noted earlier, psychophysiology, genetics, and neuroscience.

The Bay Area Study: Linking Parental AAI Responses to Infant Attachment Status

The initial Bay Area study establishing relations between parental AAIs and infant Strange Situation responses to the speaker 5 years earlier involved 32 mothers and 35 fathers, and was conducted by Main and Goldwyn (1988, 2008 [see Note 9]; see also Main et al., 1985; Main & Goldwyn, 1984b; Main et al., 2005). In this randomly selected sample of 67 dyads (sample sizes varied slightly across analyses), 48% of parents were classified as secure, 39% as dismissing, and 13% as preoccupied. The central findings were

not only the remarkable correspondence between the three then-existing organized states of mind with respect to attachment based on a parent's AAI and the infant's response to that parent in the Strange Situation, but also the significant match between adult and infant *subclassifications* (briefly mentioned earlier), and finally, significant matches between parental state-of-mind scores and continuous dimensions of the infant's Strange Situation behaviors. As mentioned earlier, at the time the AAI texts were analyzed (Main & Goldwyn, 1982), the infant disorganized attachment category (Main & Solomon, 1986, 1990) had yet to be developed, and anomalous Strange Situation behavior was simply termed "unclassifiable" (Main & Weston, 1981). All unclassifiable infants were moved to their best-fitting organized classification for purposes of analysis, and a single coder, unaware of infant Strange Situation behavior (R. Goldwyn), worked through all interviews. Interjudge agreement with two undergraduate coders was high.

- *Transcripts of interviews with the parents of children who had been secure with them in the Strange Situation 5 years before.* Infant Strange Situation security was assessed with a 3-point scale, in which very secure (B3) infants scored a 3, and insecure infants a 1. With respect to scores for the then-existing state-of-mind scales (later elaborated), the strongest correlate of infant security of attachment for both mothers and fathers was the coherence observed in the AAI text overall ($r = .48$ for mothers, $r = .53$ for fathers). Finally, a majority of parents of both sexes were matched to their infants in terms of secure versus insecure attachment status. The effect size was $d = 1.50$ for mother–infant dyads and $d = 0.78$ for fathers ($d = 0.80$ marks a strong effect). Interestingly, three of the 18 secure infants (17%) had mothers—also judged secure on the AAI—whose own parents had both scored below a 3 on the Loving scale. Moreover, for fathers, there was no significant relation between infant security and either of the parents' loving scores on the AAI, and both parents of one father whose infant was judged secure with him had loving scores of 1. Thus a "grandchild's" security with a parent appeared not to be solely a function of the parent's security with his or her own parents. This finding is pertinent, of course, to the topic of "earned/evolved" security, described earlier.

- *Transcripts of interviews with the parents of children who had been avoidant of them in the Strange*

Situation 5 years before. To explore relations between infant avoidance and parental state-of-mind characteristics, Ainsworth and colleagues' (1978) 7-point scales for infant avoidance of proximity to the parent during the two 3-minute reunion episodes of the Strange Situation 5 years previously were used. For both mothers and fathers, their infants' avoidance under stress was significantly correlated with their own insistence on lack of memory for childhood ($r = .41$ for mothers, $r = .47$ for fathers). For mothers, idealization of their own mothers ($r = .47$) and fathers ($r = .43$) were also significantly related to infant avoidance. For fathers, relations between infant avoidance and idealization of their mothers ($r = .53$) and their fathers ($r = .64$) were even stronger.⁸ At the level of classifications, the effect sizes for the relation between parental dismissing classification and infant avoidant classifications in this sample were $d = 1.22$ for mothers and $d = 0.68$ for fathers.

- *Transcripts of interviews with the parents of children who had been resistant with them in the Strange Situation 5 years before.* Scores for infant resistance to the parent on reunion were expected to be correlated with the parent's preoccupied anger toward his or her own parents. For the mother–infant sample (six infants were classified as resistant), preoccupied anger expressed in the AAI regarding both the mother's mother ($r = .56$) and the mother's father ($r = .47$) were significantly related to infant angry resistance 5 years earlier. Only two infants were resistant with their fathers.

Transcripts taken from the parents of resistant infants had most commonly been judged preoccupied. Two of the infants of the three preoccupied fathers had been resistant, as were five of the infants of the six preoccupied mothers. The effect size linking maternal preoccupied attachment status to the infant resistant/ambivalent classification was $d = 1.75$, whereas the link between paternal preoccupied status and infant resistant attachment was $d = 1.08$.

The observed three-way agreement between AAI status and infant Strange Situation behavior for mother–infant dyads was 75%, whereas the agreement expected by chance was 37% ($\kappa = .61, p < .001$). The three-way agreement for fathers was 69%, whereas the agreement expected by chance was 46% ($\kappa = .41, p < .01$). The match between the 12 AAI "organized" subclassifications and the eight infant Strange Situation subclassifications was 46%, with a 17% match

having been expected by chance (see Hesse, 2008, for elaboration).

Properties of the AAI

In 1996, Van IJzendoorn and Bakermans-Kranenburg reported that in a combined (meta-analytic) sample of 584 nonclinical mothers, 24% were classified as dismissing, 58% as secure-autonomous, and 18% as preoccupied. With the unresolved category considered, a four-way analysis of the available 487 nonclinical mothers showed the following distribution: 16% dismissing, 55% secure-autonomous, 9% preoccupied, and 19% unresolved. The combined distribution of non-clinical fathers was highly similar. A meta-analysis published 12 years later by these same authors (Van IJzendoorn & Bakermans-Kranenburg, 2008) yielded very similar proportions, although the combined sample size was much larger (1,012 nonclinical mothers).

AAI distributions in adolescent samples did not differ significantly from distributions in the nonclinical adult samples. However, combined samples from very low-socioeconomic-status (SES) samples ($N = 995$) did differ significantly from nonclinical mother samples, with the unresolved and dismissing categories being over-represented, and the secure-autonomous category correspondingly underrepresented in these samples. The AAI was found to be unrelated to social desirability (Bakermans-Kranenburg & Van IJzendoorn, 1993; Crowell et al., 1996; Sagi et al., 1994), and showed only a modest association with social adjustment (Crowell et al., 1996). Although the AAI in general has been found only weakly related to content-based retrospective parenting style measures and appears to be independent of general personality measures (Van IJzendoorn, 1995), persons classified as preoccupied have been found to report more symptoms on the Minnesota Multiphasic Personality Inventory, whereas dismissing individuals report fewer (Pianta, Egeland, & Adam, 1996).

By 1996 the AAI had been subjected to a series of rigorous psychometric tests of stability and discriminant validity (Van IJzendoorn, 1995). Stability studies typically employ different interviewers across the time period in question, with coders unaware of one another's classifications. With interviews conducted two months apart ($N = 83$), Bakermans-Kranenburg and Van IJzendoorn (1993) found 78% stability ($\kappa = .63$) across the three organized attachment categories (the

unresolved category was less stable), and an Israeli study of 59 college students in which AAIs were conducted 3 months apart yielded 90% test-retest stability ($\kappa = .79$; Sagi et al., 1994). The mean interjudge agreement for this latter study was 95%. Both studies indicated that category placement could not be attributed to the influence of a particular interviewer.

Benoit and Parker (1994) found 90% three-category stability between a prebirth interview and interviews conducted at 11 months of infant age ($n = 84$). Stability has also been tested across 18 months in New York (86% three-category stability, $\kappa = .73$; Crowell et al., 1996) and 4 years in Rome (95% secure-insecure correspondence, 70% three-category correspondence; Ammaniti, Speranza, & Candelori, 1996). Steele and Steele (2007) reported striking 5-year stability in a group of 51 mothers interviewed during pregnancy and again when their children were 5 years of age. The interviews were classified by independent teams of coders, and no individuals were considered "cannot classify" at either time period. Remarkably, 86% stability was found within the remaining four major classifications (F/Ds/E/U), across the 5-year period.⁹

Because of the weight given to coherence scores when AAI transcripts are being assigned to secure versus insecure attachment status, it has been important to establish that in five out of six studies conducted by 2008, secure versus insecure adult attachment status had been found to be unrelated to intelligence, including assessments specific to verbal fluency (Van IJzendoorn, 1995). Moreover, because insistence on lack of memory for childhood is associated with the dismissing category, it has been necessary to assess individuals' general abilities involving memory. Thus, if persons assigned to the dismissing category suffer from overall difficulties with childhood memories, their insistence on lack of recall for early relationships and interactions might not pertain to state of mind specific to attachment history. This question was first examined by Bakermans-Kranenburg and Van IJzendoorn (1993), who found the AAI categories to be independent of non-attachment-related memory. In an Israeli study, Sagi and colleagues (1994) used an even broader range of memory tests. Here the accuracy of memories for childhood events was ingeniously assessed, and subjects were also examined for "immediate" memory skills in a test of (non-attachment-related) paired associates. No differences were found across the categories.

One of the most important questions pertaining to the discriminant validity of the AAI stems from its reliance on individual differences in discourse characteristics. If these characteristics were found to generalize to non-attachment-related topics, the inability of the parents of insecure infants to produce coherent and collaborative AAI narratives could not readily be attributed to an (insecure) state of mind arising specifically from a request for a review and evaluation of their attachment history.

This question was addressed by Crowell, Waters and colleagues (1996), using an Employment Experience Interview, which followed the form of the AAI protocol but focused instead on technical aspects of the speaker's work history. Although transcripts of the Employment Experience Interview could be reliably classified as secure-autonomous, dismissing, or preoccupied, these classifications were orthogonal to the secure-autonomous, dismissing, and preoccupied classifications assigned to the same 53 mothers based on the AAI. Thus, it appears that the attachment-related queries within the AAI protocol do in fact have a direct influence on the linguistic form manifested in the interview transcript.

Further Establishing the Link between Adult (AAI) and Child Attachment Status

Within approximately a decade following the publication of Main and colleagues (1985), the remarkable relation between a parent's AAI classification and his or her infant's Strange Situation classification uncovered in Berkeley had been well replicated, and the association between a parent's discussion of his or her own attachment history and infant Strange Situation behavior was found to be robust. In succeeding years, AAI-Strange Situation matches were found in both high-risk samples (e.g., based on an inner-city Hispanic and African American sample; Ward & Carlson, 1995) and in other languages (German: Grossmann, Fremmer-Bombik, Rudolph, & Grossmann, 1988; Hebrew: Sagi et al., 1997, and Japanese: Behrens et al., 2007; Kazui, Endo, Tanaka, Sakagami, & Suganuma, 2000).

In 1995, Van IJzendoorn used meta-analytic techniques to examine a total of 18 AAI samples, including 854 parent-infant pairs from six different countries. This overview revealed that when the three-way analysis was used, there was a 75%

secure-insecure correspondence between parental and offspring security—a finding that held even when the interview was conducted prior to the birth of the first child (in Toronto: Benoit & Parker, 1994; in London: Fonagy et al., 1991; Steele, Steele, & Fonagy, 1996; in inner-city New York: Ward & Carlson, 1995). The combined effect size of the secure-insecure parent-to-infant match across samples (inclusive of mother-infant and father-infant dyads) was $d = 1.06$ ($r = .47$, biserial $r = .59$), which is considered very large ($d = .80$ is considered large). The explained variation on the basis of r was 22%, and for biserial r , it was 35%. Using a statistic devised by Rosenthal (1991), Van IJzendoorn calculated that it would take 1,087 studies with null results to diminish the combined one-tailed p level to insignificance.

Turning to more specific parent-to-infant matches in Van IJzendoorn's (1995) meta-analysis, the combined effect size for the match between the dismissing adult and infant avoidant classifications was $d = 1.02$ (equivalent to $r = .45$), and the match between the preoccupied adult and infant resistant/ambivalent classifications was $d = 0.92$ ($r = .42$). Correspondence for the three-way infant and AAI classifications across the 13 samples for which it could be calculated was 70%. It is interesting as well (Van IJzendoorn's [1995] Table 2, p. 393), however, that in this analysis, 82% (304/369) of secure-autonomous mothers had secure offspring, and 64% of dismissing mothers had insecure-avoidant offspring; however, only 35% of preoccupied mothers had insecure-resistant/ambivalent infants.

As noted earlier, with respect to parent-child dyads, both cannot classify and unresolved interviews are associated with the "disorganized infant" Strange Situation classification (Main & Solomon, 1986, 1990). Both of these AAI categories have been found to predominate in clinical samples (Van IJzendoorn & Bakermans-Kranenburg, 1996, 2008), and infants' disorganized attachment with their mothers has been associated with psychopathology assessed in the same individuals in young adulthood (Carlson, 1998), especially when intervening trauma was present (Ogawa, Sroufe, Weinfield, Carlson, & Egeland, 1997).

In his 1995 meta-analysis, of the nine studies that included unresolved AAI status (548 dyads), Van IJzendoorn calculated $d = 0.65$ (equivalent to $r = .31$) for the relation between normally very brief lapses in speech surrounding traumatic experiences during the AAI and similarly minimal disorganized disruptions in Strange Situation behav-

ior. The fleeting and difficult-to-identify nature of *both* phenomena suggests that the association between adult unresolved status and infant disorganized status may have been attenuated in this calculation—and not only by instability in the appearance of the phenomena but also by the need for extensive training in identifying them.

Consistent with the above, Van IJzendoorn (1995) found that *amount of training* was very strongly related to differences in effect sizes ($z = 5.59$, $p = 1.30E-08$), especially when researchers attempt to link unresolved and/or unclassifiable AAI texts to infant disorganization, with less training being associated with markedly smaller effects. For example, the effect size relating unresolved AAI status in 45 mothers to infant disorganized attachment status for Ainsworth and Eichberg's (1991) study (with AAIs coded by Ainsworth following her establishment of reliability across 50 [as opposed to the usual 30] AAI transcripts, and Strange Situations coded by N. Kaplan and D. Weston following training across 75 Strange Situations) was extremely large, or $d = 2.32$.

As another example of a study in which unresolved parental status was compared to offspring disorganized/controlling behavior (D-controlling is the midchildhood equivalent of infant disorganized attachment), Behrens and colleagues (2007) studied 43 mother–child dyads in Sapporo, Japan. Two experts (E. Hesse and M. Main) in the sixth-year system of coding mother–child reunion classifications (see Main & Cassidy, 1988) coded the reunion behavior of the Japanese children, and Behrens coded the mothers' AAIs. Overall AAI to 6-year reunion matches were strong, and the effect size for mother's unresolved/cannot classify AAI status and her child's status as controlling or cannot classify reunion behavior was $d = 1.50$ (equivalent to $r = .60$).

Hughes, Turton, Hopper, McGauley, and Fonagy (2001) provided another illustration of the relation between maternal unresolved AAI status and infant disorganized attachment. This study focused on the effects of stillbirth of a first infant when mothers ($N = 53$) were seen in the Strange Situation with their next-born infant. The overall association between maternal unresolved status with respect to the stillbirth loss and disorganized attachment as identified in the succeeding offspring was $r = .50$ ($p < .0001$). Importantly, the association between stillbirth experience and disorganization in the next infant was not significant once unresolved maternal attachment was excluded from the model.

Twenty years after Van IJzendoorn's 1995 meta-analysis revealing a remarkably strong relation between parental AAI classification and offspring Strange Situation behavior, a new meta-analysis addressing the same issues ("Narrowing the Transmission Gap: A Synthesis of three decades of research on Intergenerational Transmission of Attachment") was published by eight authors from four countries (Verhage et al., 2015). Here, space limitations preclude the article's report of advances made toward narrowing the "transmission gap" that Van IJzendoorn had identified in 1995. I therefore confine myself to summarizing parent–infant concordance from 95 samples ($N = 4,819$), based on studies conducted "all over the globe" (Verhage et al., 2015, p. 1). To begin with, according to Verhage and colleagues' (2015) conclusion, and somewhat astonishingly, all analyses confirmed the intergenerational transmission of attachment.

A first point made by the authors is that the evidence fails to support a "genetic" account of cross-generational continuity on the basis of either behavioral or molecular genetic studies. Rather, "attachment theory provides a psychological and environmental account of intergenerational transmission" (Verhage et al., 2015, p. 1). Studies were intended to be included only if the AAI coders had received training from a certified AAI trainer (see attachment-training.com for a list of certified trainers), and only a few investigators did not provide this information (responding "no information" or "not applicable"). However, investigators were not queried as to whether their coders had successfully completed the available 30-case AAI reliability check (see Appendix 26.1). Studies reporting extreme results (specifically, Ainsworth & Eichberg, 1991, for the remarkable strength reported for the unresolved AAI-disorganized–Strange Situation link, and Solomon & George, 2011, for the absence of any significant AAI–Strange-Situation associations in all four categories) were "winsorized" [transformed to the next largest or smallest value in the distribution] as extreme outliers.

Verhage and colleagues' (2015) study is extraordinarily thorough; I regret that I can mention only a few additional results here. Using the four-way analysis of the AAI, the autonomous parent to secure infant classification ($k = 59$, $N = 3,226$) yielded a significant combined effect size of $r = .31$. However, there was a significant difference in effect size between published data ($k = 32$, $r = .40$) and unpublished data ($k = 27$, $r = .21$). Unresolved status on the AAI also showed an overall signifi-

cant combined effect size of $r = .21$ ($r = .31$ in the 1995 report), while again, effect sizes for published data were larger and closer to the 1995 report ($r = .28$).

The report by Verhage and colleagues (2015) is monolithic and, indeed, magnificent, covering many more analyses than can be touched on in this chapter. In closing, the authors state: “The association between caregiver attachment representations and child–caregiver attachment has been confirmed as a robust and universal effect by this new series of meta-analyses, albeit smaller than in the initial studies” (p. 23). The authors noted that the smaller “effect sizes were moderated by risk status of the sample, biological relatedness of child–caregiver dyads, and age of the children” (p. 1). Additionally, the effect sizes in this study were no doubt influenced by the fact that AAI coder certification was not available and hence was not a prerequisite for study inclusion.

Unresolved States of Mind and Frightening/Disruptive Behavior toward Offspring

In 1990, Mary Main and I first put forward the hypothesis that parents judged to be unresolved on the AAI would exhibit frightened (from facial expressions of fright to direct apprehensive flight from the infant), frightening (and surprisingly, not infrequently predator-like), and/or dissociative behavior toward or in the presence of their offspring. Consequently, by 1991 we had developed an initial coding system for identifying frightened/frightening/dissociative (FR) parental behavior from videotapes. Our thinking was that if, as we believed, lapses in the monitoring of reasoning or discourse surrounding the discussion of potentially traumatic events during the AAI occurred in conjunction with intrusions from the speaker’s partially dissociated frightening experiences (Hesse & Main, 1999, 2006), such intrusions might also occur in the presence of and/or during the parent’s interactions with the infant.

The classic manifestations of primitive fear include attack, flight, fainting (e.g., falling to the floor as though “playing dead”), and freezing. Such indices of parental fear, we reasoned, could expectably alarm an infant and place it in a disorganizing paradox similar to that created by direct maltreatment. Thus, as in the case of maltreatment, the haven of safety and the source of alarm would be in the same location, placing the infant in an inherently disorganizing position. Our coding

system identifying FR behavior (Main & Hesse, 1991, 1998) was forwarded to Karlen Lyons-Ruth, to assist in her development of “AMBIANCE,” a system identifying parental disruptive behaviors more generally (see Lyons-Ruth, Bronfman, & Parsons, 1999). Unresolved status on the AAI has now been found to predict both frightening and atypical parental behavior in several independent samples (e.g., Abrams et al., 2006; Hesse, 1999; Jacobvitz, Leon, & Hazen, 2006; Lyons-Ruth et al., 1999; Madigan, Moran, & Pederson, 2006; see also Madigan, Bakermans-Kranenburg, et al., 2006).

It should be noted, however, that in a pioneering study of 80 dyads in the Netherlands (Schuengel, Bakermans-Kranenburg, & Van IJzendoorn, 1999), substantially frightening parental behavior was linked to infant disorganization, but—interestingly—only if the unresolved mother had a secondary classification as insecure. Citing the work of Stevenson-Hinde, who had emphasized that sensitive caregiving requires an outward-directed attention, Schuengel et al. suggested that an underlying secure-autonomous state of mind—quite likely via an ability to maintain focus on the immediate surround while overriding intrusions from untoward memories—might be protective in the context of unresolved/*secure* as opposed to unresolved/*insecure* status.

Jacobvitz and colleagues (2006) partially replicated the “protective effect” of underlying security uncovered in Schuengel and colleagues’ 1999 study, as would Heinicke and colleagues (2006) in an intervention study. In Jacobvitz and colleagues’ (2006) study, 116 prospective first-time mothers were administered the AAI during pregnancy and were videotaped at 8 months of infant age in their homes. As expected, women classified as unresolved with respect to loss and/or abuse displayed substantially higher levels of FR behavior during interactions with their infant than did other mothers, including extended trance-like stilling and anomalous aggressive actions. However, in keeping with Schuengel and colleagues’ findings, levels of FR behavior in the Jacobvitz and colleagues study were lower if an unresolved mother’s underlying AAI classification was secure. In addition, unresolved responses to loss in the AAI were found in this latter study to fully mediate the association between loss of an attachment figure other than the parent and FR behavior.

Thus, as discussed above, in 1990, Main and Hesse suggested that parental FR behavior would mediate the relation between unresolved lapses in speech in the AAI and infant disorganized behav-

ior in the Strange Situation. Given the fleeting nature of all three of the phenomena under examination—(1) lapses in the monitoring of speech or reasoning during the AAI (Main & Hesse, 1990); (2) FR behavior in parents (Abrams et al., 2006; Hesse & Main, 2006; Main & Hesse, 1990) or, similarly, atypical parental behaviors (Lyons-Ruth et al., 1999); and (3) disorganized infant behavior (Main & Solomon, 1986, 1990)—it is striking that a first meta-analysis of five samples testing the Main–Hesse hypothesis and using investigators at differing levels of training found even a partial (although still incomplete) mediation that accounted for 42% of the variance between parental FR behavior and infant disorganization (Madigan, Bakermans-Kranenburg, et al., 2006). By 2008, Canadian coders highly trained in the Main–Hesse system for assessing parental FR behavior found that maternal FR behavior accounted for over 50% of the variance in the association between maternal unresolved attachment status on the AAI and infant disorganized Strange Situation behavior (Evans, 2008). Still more recently, Jacobvitz, Hazen, Zaccagnino, Messina, and Beverung (2011) reported full mediation between unresolved AAI status and disorganized Strange Situation behavior in offspring via a coding of maternal FR behavior extended to include verbal FR behavior.

Studies Comparing AAI Classifications in Clinical and Nonclinical Populations

As already noted, the central categories of the AAI were developed and refined in the mid-1980s with respect to a 1-year-old's (secure vs. insecure) response to the speaker in a stressful situation, using a middle- to upper-middle-class sample from the San Francisco Bay Area. It was therefore initially surprising that—without adjustment—this system for assessing adult attachment status was later shown to discriminate between clinical and nonclinical populations (Van IJzendoorn & Bakermans-Kranenburg, 1996, 2008; see also Bakermans-Kranenburg & Van IJzendoorn, 2009). Moreover, in 1996 Van IJzendoorn and Bakermans-Kranenburg showed that the effect size discriminating clinical from nonclinical populations ($d = 1.03$) was virtually identical to that discriminating the parents of secure infants from the parents of insecure infants ($d = 1.06$). Ultimately, in a four-way analysis (secure-autonomous, dismissing,

preoccupied, unresolved/cannot classify), only 8% of members of clinical samples were judged secure. (I note that *clinical samples* as used here indicates persons with specific diagnoses, not those simply electing to enter psychotherapy.)

By the mid-1990s, many studies of clinically distressed adolescents and adults were conducted, and the predominance of the unresolved (as well as the preoccupied) classification was striking. For example, a study of 24 closely comparable female subjects (12 with borderline personality disorder and 12 with dysthymia, none comorbid) was conducted at the Tavistock Clinic, using a coder who was unaware of either the participants' diagnoses or the aims of the investigation (Patrick et al., 1994). Patients with borderline personality disorder were selected for having met at least seven of the eight criteria in the third, revised edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III-R; American Psychiatric Association, 1987). All of the 12 borderline patients—but only four of the dysthymic patients—were classified as preoccupied (Fisher's exact test, two-tailed; $p = .001$). Moreover, 10 of the 12 patients with borderline personality disorder were classified specifically as fitting to a rare subcategory of preoccupation, termed E3 “fearfully preoccupied with traumatic events and experiences.” Importantly, however, whereas the overall rates of experiences of loss (and trauma, as defined in AAI manuals) did not differ between the patients with borderline personality disorder and dysthymia, all nine of the borderline subjects reporting loss or trauma were classified as primarily unresolved (e.g., U/E3), as compared with only two of the 10 patients with dysthymia reporting loss or trauma (Fisher's exact test, two-tailed; $p = .0007$). This suggestion of greater sensitivity to loss or trauma in patients with borderline personality disorder as opposed to dysthymia is an important finding, although it likely has more than one possible interpretation.

Two years after Patrick and colleagues' (1994) report, Fonagy and his colleagues (1996) undertook a large study of 82 clinically distressed young adults at a national center for the inpatient treatment of severe personality disorders in London, comparing interviews to those of 85 well-matched controls. The category most strongly differentiating the groups was unresolved (76% inpatients vs. 7% controls) and—as in an earlier study of subjects with anxiety disorders conducted by Manassis, Bradley, Goldberg, Hood, and Swinson (1994; 14 of 18, or 78% unresolved)—subjects with anxiety disorders were found to be especially

likely to be unresolved (38 of 44, or 86%). Among the subclassifications, the E3 subcategory of preoccupation was again found to be unexpectedly common in the psychiatric group (28 vs. 1%). Replicating the earlier outcomes of Patrick and colleagues, 47% of the patients with borderline personality disorder had also been classified E3.

A different and highly informative investigation was conducted by administering the AAI to 66 young adults (mean age = 26 years) who had been hospitalized 11 years earlier in adolescence, together with 76 matched (nonhospitalized) controls (Allen, Hauser, & Borman-Spurrell, 1996). Both groups came from upper-middle-class families, and individuals suffering from psychosis or organic impairment were excluded from the hospitalized sample. Any information that could provide evidence of previous hospitalization was carefully removed from the transcripts, so that the coder (Hesse) successfully remained unaware of group status. The proportion of secure-autonomous transcripts among individuals hospitalized 11 years earlier (7.6%) was exceptionally low. Moreover, the interview transcripts of 25.8% of the hospitalized group were judged as “cannot classify,” as compared with 6.6% of the comparison group. Speakers who had been hospitalized were more likely to express contempt or derogation for attachment-related experiences and attachment figures, and received higher scores for unresolved responses to abuse experiences. The state-of-mind scale for derogation was also found to be related to criminal behavior and to hard drug use. Given the success of this original study, it is perhaps not surprising that Hauser, Golden, and Allen (2006) concluded that with the development of the AAI, narrative studies have begun to come (or, one might add, to come again) into their own in psychiatry and psychoanalysis.

As explained earlier, speakers are assigned to the “cannot classify” category whenever contradictory discourse strategies (e.g., both elevated indices of dismissal and preoccupation) appear within the AAI. With this in mind, two early case studies are of special interest. In the first, a mother described as “cannot classify” (Minde & Hesse, 1996; the coder was unaware that the transcript was taken from a patient in therapy) successfully demanded to have her child removed by cesarean section 1 month early, and then insisted on staying with the infant in intensive care for periods that far exceeded usual hospital practices. At later times, she was observed to alternate between periods of overinvolvement and periods of neglect.

In the second case study, home observations of a mother judged “cannot classify” by Hughes and McGauley (1997) indicated marked neglect and carelessness to a degree inviting external injury, alternating with sudden trips to the hospital occasioned by (an apparently unsubstantiated) fear of germs. In keeping with the hypothesis that discourse usage in the AAI should be predictive of caregiving, then, these two case studies of unclassifiable (CC), contradictory discourse were reflected in contradictory behavior toward the offspring.

In 2008, the AAI status of adolescents living in the streets of Mexico City with their infants were studied by Gojman de Millán and Millán. These included two individuals coded as “cannot classify,” and one—whose behavior and outcome appeared far more promising—coded as “unresolved/secure.” Another case study describes a patient classified as “unresolved/preoccupied” on the AAI who suffered from both narcissistic and borderline personality disorders; this case is discussed in terms of both her AAI and her therapist’s reflections (Buchheim & Kachele, 2003). Finally, a particularly impressive set of case studies has traced change over the course of psychoanalysis, considering especially the movement from “unresolved/cannot classify” status to organized insecurity over time (Ammaniti et al., 2008).

Ward, Lee, and Polan (2006) investigated a *nonclinical* New York sample of 60 adult women, who were administered the AAI and seen in a diagnostic setting. Using the organized (F/Ds/E) attachment categories in the analysis, the researchers found that a majority of women with insecure attachment classifications were diagnosed with some psychopathology. However, when the unresolved category was included, unresolved participants whose alternative placement was secure-autonomous—while experiencing some difficulties with daily functioning, such as marital discord or physical symptoms—were significantly less likely to be diagnosed with psychopathology than were participants with unresolved/insecure classifications.

In a review of 61 clinical samples, Van IJzendoorn and Bakermans-Kranenburg (2008) used a correspondence analysis to ascertain possible patterning of AAI classifications in relation to clinical diagnoses. All clinical groups with psychiatric diagnoses tended toward insecurity, although clinical status in general was not related to a specific organized insecure AAI category. However, when the three-way analysis was used, individuals with borderline personality disorder and those experi-

encing more internalizing disorders tended toward the preoccupied classification, as had been indicated earlier in the study conducted by Patrick and colleagues (1994). In contrast, for more externalizing problems and disorders as identified in this study, such as antisocial personality disorder and conduct disorder, there was an overrepresentation of the dismissing classification. (See also Frodi, Dernevik, Sepa, Philipson, & Bragesjö [2001] for a study that revealed an unusual proportion of dismissing transcripts among incarcerated males with psychopathy.) When unresolved and unclassifiable transcripts were taken into account in a four-way analysis, an “extremely strong” association was found among borderline personality disorder, abuse, or suicide. (See also Adshead & Bluglass [2005] for a first study of maternal factitious illness by proxy, in which 60% of these mothers were found to have unresolved transcripts.)

In a follow up study of 111 middle-class Australian mothers with postnatal depression and their infants (McMahon, Barnett, Kowalenko, & Tennant, 2006), chronically depressed mothers were found to be more likely to have infants who were insecurely attached. However, the relation between maternal depression and infant insecurity was moderated by maternal response to the AAI, with secure mothers with postpartum depression being less likely to have insecure infants.

Applications of the AAI to New Populations

By the second edition of this volume (Hesse, 2008), the AAI had been used to determine (1) whether, among adults, rates of AAI security are decreased by disadvantages such as deafness or blindness (they are not; Van IJzendoorn & Bakermans-Kranenburg, 2008; see also McKinnon, Moran, & Pederson, 2004); (2) whether the daughters of Holocaust survivors in Israel are significantly more likely than daughters of control participants to be insecure on the AAI (they are not; see Sagi-Schwartz et al., 2003); (3) whether concordance rates of attachment are similar between identical twins, when compared to each other as well as to their non-twin siblings (they are, indicating preliminary evidence for shared environmental influence; Constantino et al., 2006; see also Torgerson, Grova, & Sommerstad [2007] for monozygotic vs. dizygotic twins); and (4) whether foster infants' Strange Situation categories were correlated with their foster mothers' AAI classifications

(they are; Dozier, Stovall, Albus, & Bates, 2001; see also M. Steele, Hodges, Kaniuk, Hillman, & Henderson [2003] for associations between adoptive mothers' AAIs and emotional themes in their previously neglected/abused 4-to-6-year olds' doll play). In addition, the attachment status of infertile couples seeking to adopt was examined, and a majority were secure on the AAI (see Santona & Zavattini, 2005). The ways in which older adult mothers with dementia responded to reunion with their adult daughters acting as caregivers was also explored. Indices of reunion security were found to be significantly correlated with daughters' AAI coherence, with more pleasure being exhibited with coherent daughters (H. Steele, Phibbs, & Woods, 2004).

Attachment in relation to religious/spiritual groups has also been investigated. Granqvist, Ivarsson, Broberg, and Hagekull (2007) found that 46% of participants drawn from religious/spiritual groups were secure on the AAI. As expected, scores for mothers' loving behavior during childhood were linked to an image of a loving God. In contrast, New Age spirituality, which can include beliefs in personal contact with the dead, was associated specifically with the unresolved, cannot classify, and preoccupied AAI categories. Finally, strong majorities of devout Catholic laypeople and nuns have been found to be secure on the AAI (Cassibba, Granqvist, Costantini, & Gatto, 2008).

Intervention Studies

The AAI has also been increasingly utilized in clinical studies, both with individuals in therapy and with those in intervention studies focusing on parents and caregivers. I provide some examples of the latter first.

Heinicke and colleagues (2006; see also Heinicke & Levine, 2008) used the AAI as a prebirth assessment for 57 high-risk mothers in an intervention project involving multiple forms of assistance, including weekly home visits for the first 2 years of life. A regression analysis showed that a combined unresolved trauma/coherence scale from the prebirth AAI was the best predictor of toddler security assessed by the Attachment Q-Sort 2 years later. Additionally, as in Korfmacher, Adam, Ogawa, and Egeland (1997), a mother's coherence on the prebirth AAI predicted her involvement in the work of intervention.

In conjunction with Dozier's Attachment and Biobehavioral Catch-Up Program, Bick and

Dozier (2008) administered the AAI to 200 foster parents, just over half of whom were classified as secure. During the intervention, as in their AAIs, foster mothers with secure-autonomous transcripts were cooperative and collaborative, and were open to discussing potentially painful or sensitive topics. Foster mothers with dismissing transcripts tended to avoid discussing both relationship difficulties and the children's need for nurturance. In contrast, those classified as preoccupied seemed relatively comfortable discussing their attachment-related pasts but were described as fluctuating between seeking reassurance from the intervener and displaying annoyance. Finally, caregivers who were unresolved with regard to loss or trauma were described as seeming to (1) have trouble developing trust in their interveners, (2) have difficulties discussing having been frightened as children, and (3) have difficulty during sessions behaving in non-threatening ways toward children—all findings that accord well with our expectations that individuals with unresolved trauma exhibit frightening behavior toward their children.

Zegers, Schuengel, Van IJzendoorn, and Janssens (2006) administered AAIs both to professional caregivers in institutions and to seriously emotionally and/or behaviorally troubled adolescents placed in their care. Over time, more secure mentors were increasingly perceived as being available as a secure base, and more secure adolescents were perceived as increasing their secure-base use of their mentors.

The AAI has also been increasingly utilized in clinical studies to ascertain, for example, whether AAIs administered to psychoanalytic patients at the beginning and during the later course of psychotherapy can yield not only an increase in scores assigned for coherence of transcript over time but also eventual moves from insecure to secure AAI classifications (Ammaniti et al., 2008). As another example, Levy and colleagues (Levy et al., 2006) administered a preintervention AAI to patients with borderline personality disorder, and a second following 1 year of therapy. Ninety participants were randomly assigned to three different treatment conditions, one of which was Kernberg's (1984; see also Yeomans et al., 2015) transference-focused therapy. Transference-focused therapy revealed significant change in AAI status, specifically, increases in coherence of transcript and a more than threefold increase in secure-autonomous classifications.

More recently, Buchheim and colleagues (2016) have completed a study once more indicat-

ing the success of Kernberg's transference-focused therapy (as compared to therapy administered by experienced community therapists) with patients with borderline personality disorder. At entrance, 50% of the 104 borderline patients were identified on the AAI with unresolved trauma: Of interest, this subgroup of borderline patients was found to be especially impaired with respect to psychopathology. However, a significant shift from unresolved to organized attachment status was identified following the year of transference-focused treatment. Finally, patient scores on the AAI Coherence scale improved strongly in the transference-focused group ($d = 1.27$) and just moderately following treatment with experienced community therapists ($d = 0.32$). (For additional discussion of intervention studies, see Hesse, 1999, 2008.)

Longitudinal Studies

Many kinds of longitudinal studies predictive of eventual AAI status may, of course, be conducted. As one example, Beckwith, Cohen, and Hamilton (1999) found that maternal insensitivity to a child in the early months predicted dismissing AAI status at age 18. With one exception, I focus here on studies that have compared infant Strange Situation behavior with the mother to AAI status determined for the same individuals in young adulthood, and I confine even the majority of these descriptions to a secure–insecure analysis. Many of these studies were reviewed earlier (Hesse, 1999, 2008).

Four U.S. longitudinal studies have been undertaken, each indicating significant infancy-to-adulthood links. Waters, Merrick, Treboux, Crowell, and Albersheim (2000) conducted AAIs with 50 lower- to middle-class young adults seen in Ainsworth's Strange Situation at 12 months. For 72% of participants ($kappa = .44$, $p < .001$), secure versus insecure infant Strange Situation behavior was predictive of secure versus insecure AAI texts 19–21 years later. This correspondence was somewhat higher (78%; $kappa = .52$) when participants experiencing intervening trauma were eliminated. In the same year, Hamilton (2000) reported on the predictability of AAI responses in a sample of 30 adolescents (ages 17–19) who had been raised in unconventional settings (e.g., communal living groups). The two-way (secure vs. insecure) correspondence in this study was 77% ($kappa = .49$).

Using a sample of 42 participants, Main (2001; Main et al., 2005) compared Strange Situa-

tion classifications with mothers at 12–18 months of age to AAI status as assessed at age 19. As in Waters and colleagues' (2000) original study, a highly significant secure–insecure match was found across the 18-year period. As predicted in advance, among the 12 participants coded as *disorganized/secure* during infancy, not one was secure on the AAI at age 19. Intriguingly, although most avoidant infants had become dismissing, about half of the previously disorganized infants had become dismissing as well (for a much expanded description of this study, see Main et al., 2005).

In the Minnesota Study of Risk and Adaptation from Birth to Adulthood, a significant 18-month Strange Situation to 26-year AAI secure–insecure match has been reported ($p < .001$; $N = 125$), although the match from 12 months appears to remain insignificant¹⁰ (Sroufe, 2005). Interestingly, as in the Bay Area study of middle-class dyads, in this low-income sample, disorganized/secure infants were only rarely found to be secure in adulthood.

One study conducted in the United States and three outside the United States have yielded insignificant relations between Strange Situation responses and AAI status in young adulthood. The latter include both the Regensburg and Bielefeld longitudinal studies (in which, however, disorganized/secure infants were coded as secure), as described by Grossmann, Grossmann, and Kindler (2005), and the Haifa longitudinal study (Sagi-Schwartz & Aviezer, 2005), in which the infant disorganized category at the time apparently also had yet to be coded. Although it should be noted that only the three-way infant analysis was available to Waters and colleagues (2000) and to Hamilton (2000) as well, it would be prudent to await a four-way analysis including disorganized codings of infant Strange Situation responses before drawing final conclusions regarding the German and Israeli studies.

The SECCYD, a study utilizing the NICHD subsample of 857 adolescents (mean age 17.5 years) reported “evidence for weak stability in attachment security and disorganization” (Groh et al., 2014, p. 63). In this report, the Strange Situation distribution appears reasonably typical for community samples. At the level of the AAI response, however, Van IJzendoorn and Bakermans-Kranenburg (2014) point to the pervasive limitations entailed in the nonresponse bias that the researchers encountered. The nonresponse rate may be what led to the startling underrepresentation of both preoccupied and unresolved categories

(the preoccupied and unresolved categories were each assigned to just 3% of participants, in sharp contrast to the 11% preoccupied and 11% unresolved more usually uncovered in such samples). The study was further complicated by an overrepresentation of dismissing interviews. Finally, 21% of the AAIs were completed by phone (an approach that is not recommended by the originators of the instrument). Thus, although intriguing, the NICHD/SECCYD findings do stand in sharp contrast to the studies listed earlier, and as noted, are in need of replication in a context absent the sample bias encountered by the unusual distribution of consenting participants in this study.

Finally, one highly original longitudinal study of 26 dyads employed mothers' perceptions of their newborns to predict subsequent secure versus insecure AAI classification (Broussard & Cassidy, 2010). Here, Broussard's (1979; Broussard & Hartner, 1970) Neonatal Perception Inventory was used to identify mothers who had positive versus negative perceptions of their offspring. It was hypothesized that as adults, newborns perceived negatively by their mothers would be more likely to be classified insecure on the AAI than infants whose mothers had a positive perception of them. As expected, negative maternal perception of an infant at 1 month of age was associated with subsequent insecure AAI status, as assessed 27–43 years later. Whereas 86% (12 of 14) of positively perceived newborns were classified as secure on the AAI, only 25% (3 of 12) of the negatively perceived infants were secure on the AAI (Fisher's exact test, $p = .001$). Also of interest are findings that adults viewed negatively by their mother as infants were idealizing of the mother, whom AAI coders also identified as less loving and more rejecting.

Selected Recent Studies

Before turning to a closing section that reviews use of the AAI in conjunction with psychophysiology, genetics, and neuroscience, I very briefly summarize nine of the many important studies involving some of the interesting topical areas and issues currently being explored. I apologize for a majority of studies that could not be included here.

- Individuals prone to overuse of (addiction to) computer games involving role playing are largely classified as unresolved for loss or abuse (Schimmenti, Guglielmucci, Barbasio, & Granieri, 2012).

- In contrast to some folk beliefs regarding the likelihood of disproportionate emotional instability among artists, 88% of performing artists are secure in terms of three-way classifications in the AAI (Thomson & Jacque, 2012a, 2012b).
- A substantial portion of men who have post-traumatic stress disorder following war experience are coded as unresolved/secure (U/F), suggesting that even in the face of extreme trauma, an underlying security can remain (see Nye et al., 2008; also see a replication and extension by Harari et al., 2009).
- Sixty-five percent of individuals with scores equal to or above 4 (on an 10-point scale) on the Adverse Childhood Experiences (ACE) questionnaire are found to be unresolved/cannot classify on the AAI (Murphy et al., 2014).
- Among adult offspring whose parents divorced during their childhood, those who were classified as secure on the AAI prior to their weddings were less likely to divorce in the early years of marriage than their insecure counterparts (Crowell, Treboux, & Brockmeyer, 2009). However, parental divorce increased the likelihood of insecure adult attachment status.
- During a 15-minute conflict interchange, couples in which both members were classified as unresolved for trauma displayed more problematic interactions than partners with any other AAI configurations (Creasey, 2014).
- Two weeks after a 10-minute laboratory task completed with a peer whom they did not know, adolescents insecure (vs. secure) on the AAI remembered their interactions as less positive and more negative (and inclusive of greater hostility) than they had at the time (Dykas, Woodhouse, Ehrlich, & Cassidy, 2012).
- A four-category (secure, dismissing, preoccupied, unresolved) projective, picture-based system entitled the Adult Attachment Projective (AAP) described as providing strong *four-category* agreement with the AAI (George & West, 2011, 2012), has recently been found to have no relation either to AAI classifications themselves or to several of the well-known correlates of the AAI across a sample of 101 interviews. In this study, the AAP was coded by its originator (Jones-Mason, Allen, Hamilton & Weiss, 2015).
- Finally, based on 673 adolescents from the NICHD/SECCYD study, Harriet Waters' Attachment Script Assessment (ASA; Waters & Waters, 2006), which examines the degree to which participants are able to produce a "secure-

base" attachment script from a series of attachment-related prompt-words, has yielded a .42 correlation with coherence of mind as assessed in the AAI (Steele et al., 2014). The ASA is designed to provide a continuous, single-scale assessment of security, however, and does not identify varying forms of insecure attachment.

Psychophysiology, Genetics, and Neuroscience

In an early study, Gribneau (2006; see also Bahm, Simon-Thomas, Main, & Hesse, 2016) presented four categories of images (social positive, nature positive, blatant death/dying, and cemetery images) to young women who had experienced loss, half of whom (16/31) had been coded on the AAI as unresolved. The aim of the study was to examine physiological responses to subtle "generic" reminders of death (cemetery images). As predicted, electroencephalogram (EEG) event-related potentials (ERPs) demonstrated increased physiological responses to cemetery images specific to unresolved women, with the anterior N2 component arguably indicating fearful alerting, as well as involuntary attention. A right-sided asymmetrical posterior P3 component toward all images suggested continuing vigilance/arousal, also specifically for unresolved women. Bahm and colleagues (2016) suggest that

the early alerting to symbolic images of death via increased cemetery-evoked N2s for unresolved participants may be due to preconscious arousal of aversive implicit memories (Amini, Lewis, Lannon, & Louie, 1996). Such preconscious arousal of fright in response to distal reminders of loss suggests potential linkages to the production of FR behaviors, and may at the least partially explain the connection between unresolved states and such behaviors.

At least 14 studies examining psychophysiology, genetics, and neuroscience in relation to the AAI have been published since the 2008 edition of this handbook and are summarized below.

In recent years, researchers have begun investigating factors related to unresolved trauma beyond the individual's direct experiential domain. In 2009, Caspers and colleagues reported that their multivariate regression analysis indicated a relation between the short version of the serotonin transporter allele (*5-HTTLPR*) and an increased risk for unresolved trauma in 186 participants. Relatedly, in a pioneering article published

in *Biological Psychiatry* concerning epigenetics and unresolved trauma as identified via the AAI, Van IJzendoorn, Caspers, Bakermans-Kranenburg, Beach, and Philibert (2010) reported that in a sample of 143 adopted participants, higher levels of methylation of the 5-HTT promoter-associated C-phosphate-G (CpG) island were associated with increased risk of unresolved responses to loss or other trauma. At the same time, the *s/s* variant of 5-HTTLPR predicted more unresolved loss or trauma, but only in the case of lower levels of methylation. The authors concluded that associations between 5-HTTLPR polymorphisms and psychological problems are significantly altered by environmentally induced methylation patterns, and that methylation may at times serve positively as an interface between an adverse environment and the developing organism.

One year later, consistent with earlier findings regarding the genetics of differential susceptibility, Bakermans-Kranenburg, Van IJzendoorn, Caspers, and Philibert (2011) reported that among 124 adopted adults, parental problems experienced in childhood (e.g., maternal depression and marital discord) were associated with different outcomes. Participants with the (dopamine receptor) *DRD4-7-r* allele had the highest scores for unresolved loss or trauma. In contrast, those with the *DRD4-7-r* allele who had not experienced parental problems showed the lowest ratings.

Rifkin-Graboi (2008; see also Colizzi, Costa, Pace, & Todarello, 2013; Pierrehumbert et al., 2009; Pierrehumbert, Torrisi, Ansermet, Borghini, & Halfon, 2012) examined emotional regulation via cortisol output in college-age men. Home assays showed little relation to overall AAI security. In the laboratory, participants were presented with both cognitive and attachment-related challenges, the latter presenting hypothetical situations involving separation, loss, and abandonment. As expected, AAI scores for idealization of the parents (a frequent correlate of parental rejection) were associated with a significant rise in cortisol specific to the attachment-related challenge. For further discussion of studies examining links between the AAI and emotion regulation, see Hesse (2008).

Three studies have examined a critical issue within parenting: adult response to infant cries. In a first study of adult response specific to infant crying, which employed functional magnetic resonance imaging (fMRI; Riem et al., 2012), amygdala activation, feelings of irritation, and force, as indicated by a handgrip dynamometer were el-

evated in individuals insecure on the AAI during exposure to infant crying (compared to scrambled control sounds) in 21 women without children. In a related article, Ablow, Marks, Feldman, and Huffman (2013) examined physiological responses to recorded cries among 53 expectant primiparous women. Women secure on the AAI exhibited respiratory sinus arrhythmia (RSA) declines in response to recorded cries, consistent with approach-oriented responses, while insecure-dismissing women displayed RSA and electrodermal increases consistent with behavioral inhibition, and additionally rated the cries as more aversive. Nine months postpartum, the secure women were observed as being more sensitive to infant distress. Finally, using videotapes of crying infants, Leerkes and colleagues (2015) looked for predictors of maternal sensitivity to infant distress among 269 primiparous mothers who had been administered the AAI and found overall coherence of mind directly associated with higher maternal sensitivity to infant distress.

Ammaniti and his colleagues (Lenzi et al., 2013) conducted an especially innovative AAI/fMRI study with nulliparous young adult women, 11 classified as secure and 12 as dismissing. During the fMRI, subjects viewed pictures of infant eye gaze (gleaned from videotaped interactions with their mothers). Infant expressions were: joyous, distressed, and neutral. It was anticipated that individuals classified as secure would show greater empathic responses via greater activation of mirror and limbic brain areas than would individuals classified as insecure. Counterintuitively, viewing the pictures of infants, dismissing subjects activated motor, mirror, and limbic brain areas (including medial orbitofrontal and perigenual anterior cingulate cortex) to a significantly greater extent than those classified as secure. These results were interpreted as indicating that the young women classified as dismissing on the AAI may have shown hyperactivation (as opposed to hypoactivation, which had been expected) as a result of *dysregulation* caused by the arousal of the attachment system. Deactivation in the cortical areas might, in contrast, reflect an expression of the inhibition of attachment behavior, which would, of course, be consistent with the dismissing stance.

In their fMRI study, Galynker and colleagues (2012) found that distinct but overlapping neural networks subserve depression and insecurity on the AAI, which suggests that these interactions might explain the greater difficulty of treating depression in insecure patients.

Farina and colleagues (2014) evaluated cortical connectivity modifications via an EEG lagged coherence analysis following the AAI with 13 patients with dissociative disorders and 13 age- and sex-matched controls. An intriguing new finding was that cortical connectivity *increased* following the AAI in the control subjects but not in the dissociative subjects. In a later report (Farina, Speranza, Imperatori, Quintiliani, & Marca, 2015), again following the AAI, dissociative (but not control) subjects were observed to undergo unfavorable changes indicative of heart rate dysregulation. These results were interpreted as originating in the AAI's demand for a review of childhood attachment experiences impacting dissociative subjects differently.

Conclusions

The AAI is a unique research tool with the power to tap into multiple psychological and social domains, a point that has been made amply clear by the massive expansion in research since 2008. Nevertheless, there is room for further exploration utilizing the AAI in new areas, including linguistics, cognitive psychology, and, as just illustrated, biology and neuroscience (see Coan, Chapter 12, and Bretherton & Munholland, Chapter 4, this volume). In ending, I remain in agreement with my conclusion in the 1999 edition of this volume:

Within the AAI, the organization of language pertaining to attachment appears to be a manifestation of the “dynamics” of cognition and emotion as mediated by attention. Individual differences in attentional flexibility may therefore influence patterns of caregiving, which in turn may shape responses in the offspring that influence the organization of its own developing propensities. This has no doubt permanently altered the way language will be considered within the context of clinical and developmental research. (Hesse, 1999, pp. 427–428)

Appendix 26.1. The Adult Attachment Interview: Administration and Training

Protocol

The most recent AAI protocol (George, Kaplan, & Main, 1996; 72 manuscript pages) is available from Naomi Gribneau Bahm (ngbreliability@gmail.com).

Training in the Scoring and Classification of AAI Transcripts

Training in the analysis of the AAI takes place during 2-week institutes, involving one or two certified trainers and 10–20 participants. Usually about seven institutes focused on the Main, Goldwyn, and Hesse system of interview analysis are offered per year. These are taught only by the 10 individuals who have become certified to train by Mary Main and myself. As of 2016, these trainers are Anders Broberg, Nino Dazzi, Sonia Gojman de Millán, Erik Hesse, Tord Ivarsson, Deborah Jacobvitz, Mary Main, David and Deanne Pederson, and June Sroufe. Trainings are frequently offered in North America, Europe, and Mexico, and 10 new trainers from Australia, Austria, Canada, Japan, Sweden, and the United States (East and West Coast) are expected to be certified to train via 2-week training-to-train institutes by December 2016. For dates of upcoming institutes and information, including certified trainer contacts, please see June Sroufe's website (attachment-training.com).

It should be noted that having attended an institute held by a certified AAI trainer does not qualify individuals as certified coders. Those wishing to become certified in the analysis of AAI transcripts not only must attend an AAI institute with a certified trainer but also pass a reliability check in which agreement is established with Main and myself across 30 transcripts.

Finally, unfortunately, some individuals who are neither certified in AAI coding nor have attended an AAI institute are (1) claiming certification as AAI coders and/or (2) holding training institutes in the AAI. Some anomalous results will inevitably be incurred when individuals neither trained nor certified in the instrument attempt to implement it in empirical work. As one example, a recent study undertaken and published by untrained, uncertified coders reported a failure to find any link between parental AAI transcripts and infant attachment status as assessed in their offspring. This problem was first identified by Van IJzendoorn (1995), who noted that the extent of an individual's training in the AAI was very strongly related to the ability to predict infant disorganized attachment from parental AAI transcripts.

Acknowledgments

Parts of this chapter have been adapted from Main, Hesse, and Goldwyn (2008). Copyright 2008 by The Guilford Press. Adapted by permission. I am

grateful to Mary Main for her critical input regarding central organizational and substantive aspects of this and earlier editions of this chapter. David and Deanne Pederson made valuable suggestions regarding earlier editions of this presentation, as did Nino Dazzi, Avi Sagi-Schwartz, and Marinus Van IJzendoorn. Early empirical contributions by (listed alphabetically) Ainsworth and Eichberg; Bakermans-Kranenburg and Van IJzendoorn; Crowell and Waters; Fonagy, Steele, and Steele; Main, Kaplan, & Cassidy; Sagi-Schwartz and colleagues; and Ward and Carlson were invaluable to the continuing development of the AAI and inspired many of the researchers who followed upon their work.

With respect to this third (2016) edition of this chapter, I am grateful to Sarah Foster (Northumbria University, United Kingdom), a new and brilliant entrant into the field of attachment, for her extraordinary and meticulous assistance with identifying works suitable for this updated review of the AAI literature. I also thank the Wellcome Trust for supporting Sarah's work in this endeavor via Award No. WT103343AI to Robbie Duschinsky. Finally, I thank Naomi Gribneau Bahm for her invaluable and extensive feedback and assistance in the preparation of this manuscript.

Notes

- Violations of these maxims are permitted when "licensed" by the speaker (Grice, 1989). An excessively long speech turn can, for example, be licensed if the speaker begins with "Well, I'm afraid this is going to be quite a long story," whereas a very short turn can be licensed by "I'm really sorry, but I don't feel able to discuss this right now."
- In the 1999 edition of this volume, I described an Italian study in which coders attempted to apply Grice's four maxims to AAI interview transcripts (Dazzi, DeCoro, Ortu, & Speranza, 1999). Following Gricean maxims as closely as possible, but adding where necessary from the AAI manual (e.g., "passivity" indicators were added directly as violations of manner), these investigators found that, as stated in this chapter, violations of quantity (via excessive brevity) were most pronounced in dismissing texts, and violations of quantity (via excessive length), relevance, and manner were most pronounced in preoccupied texts, whereas relatively few violations of Grice's maxims occurred in secure-autonomous texts. However, more recently, a group of investigators in Leiden who have developed a Coherence Q-Sort have found that attachment-trained sorters place emphasis on different maxims than do naive sorters or linguists; this means that training in AAI institutes remains a necessary prerequisite to identifying the kinds of coherence most relevant to AAI texts (Beijersbergen, Bakermans-Kranenburg, & Van IJzendoorn, 2006).
- I have composed the quotations in this chapter to preserve confidentiality. Nonetheless, they closely approximate actual quotations from AAI transcripts, and none would seem unusual to an experienced AAI coder.
- This response is more elaborated than usual, but it has been seen in some interviews and is provided here for heuristic purposes.
- This does not mean that the same speaker might not also be unresolved.
- Within AAI manuals the development sample has been accurately described as consisting of 44 participants. However, Main and Goldwyn (1988) had referenced only the initial 36.
- Notice that, as is the case for infant Strange Situation coding, interview transcripts are always approached first to determine the best-fitting organized category. If the first AAI category placement will ultimately be unresolved or unorganized (cannot classify), the coder must nonetheless designate the organized category that the transcript may secondarily fit (e.g., unresolved/dismissing). The same holds for the Strange Situation, in which an infant judged primarily to be disorganized is also assigned to a best-fitting organized category (e.g., disorganized/avoidant).
- For both mothers and fathers, as would be expected, coherence of transcript was significantly negatively related to infant avoidance, as was angry preoccupation with either parent, except fathers' preoccupation with their mothers.
- In a high-risk clinical sample of 37 participants followed across 13 years by Crowell and Hauser (2008), secure-insecure stability was 84%; however, all but two participants were insecure at both time periods, and there was considerable movement among the insecure AAI categories.
- In an earlier edition of this chapter (Hesse, 2008), I included a first report (57 subjects; Weinfield, Sroufe, & Egeland, 2000). The researchers had used the traditional three-way analysis of behavior in the Strange Situation (disorganized/secure infants were considered secure), and no significant relation between 12-month attachment status and AAI status at age 19 was found. In the more recent report (Sroufe, 2005), disorganized/secure infants had been placed in the insecure infant group, more participants had been seen in the AAI, and the sample had been followed to age 26.

Chapter 27

Measurement of Individual Differences in Adult Attachment

Judith A. Crowell
R. Chris Fraley
Glenn I. Roisman

Human attachments play a vital role . . . from the cradle to the grave.
—John Bowlby (1969/1982, p. 208)

Bowlby and Ainsworth both addressed the importance of the attachment system across the lifespan, and beginning in the mid-1980s, research in adult attachment began to emerge from the theoretical and empirical groundwork laid with respect to the attachment system in infancy. Following an interest in attachment representations, George, Kaplan, and Main (1984, 1985, 1996) created the Adult Attachment Interview (AAI) “to assess the security of the adult’s overall working model of attachment, that is, the security of the self in relation to attachment in its generality rather than in relation to any particular present or past relationship” (Main, Kaplan, & Cassidy, 1985, p. 78). Around the same time the AAI was being developed, Hazan and Shaver (1987; Shaver & Hazan, 1988) began to consider the applicability of attachment theory in general, and of Ainsworth’s infant classification scheme in particular, to the study of feelings and behavior in romantic relationships.

Given the independence of these groups of investigators, and their different domains of interest and varied professional backgrounds, the lines

of research they initiated developed in different ways. Each inspired variations and offshoots, so that today there are a number of measures of adult attachment. Given their diverse origins, there has been confusion about what these assessments measure, what they are *intended* to measure, and how they are related to each other. In this chapter we aim to identify advances in the measurement literature in recent years, and to continue to provide up-to-date guidelines for researchers undertaking studies of adult attachment. There is a good deal of evidence that different measures of adult attachment do not necessarily converge empirically (e.g., Haydon, Roisman, Marks, & Fraley, 2011; Roisman, Holland, et al., 2007), even though they were all inspired by attachment theory and sometimes relate similarly to outcome variables. As such, not all measures can be used interchangeably in research, and choosing an appropriate measure requires careful thought about the goals of one’s study and its foundation in the literature.

We present in the first section of the chapter a brief discussion of attachment theory, especially

elements that are key to understanding the attachment system in adults and to assessing it. We discuss the AAI and other narrative measures derived from the developmental tradition, such as the Attachment Script Assessment and the Current Relationship Interview, in the second section. In the third section we describe advances in our understanding of the self-report measures of attachment that grew out of Hazan and Shaver's (1987) efforts to apply Ainsworth's discoveries to the study of romantic relationships, and include some discussion of priming assessments. In the final section we summarize the overlap and distinctions among measures developed in different lines of research on adult attachment.

Before beginning, we note that in the previous two editions of this handbook, this chapter reviewed a variety of self-report measures that have been used to assess attachment to parents and peers, and attachment history more generally. In the interest of conserving space, we have omitted those reviews in this edition. We refer interested readers to previous editions for further information about the Attachment History Questionnaire by Pottharst (1990), the Inventory of Parent and Peer Attachment by Armsden and Greenberg (1987), and the Reciprocal Attachment Questionnaire for Adults and the Avoidant Attachment Questionnaire for Adults (e.g., West, Sheldon, & Reiffer, 1987; West & Sheldon-Keller, 1994).

Adult Attachment: Theoretical Issues

Two themes from attachment theory are critical to measurement. The first is that the attachment system is *normative*—that is, relevant to the development of all people, and active and important in adult life. The second idea is that there are individual differences in attachment behavior and associated cognitive and emotional elements.

Adult Attachment

Although some of Bowlby's original inspiration for attachment theory came from his work as a clinician, he primarily drew from research in ethology, observations of animal behavior, and the cognitive psychology of his day. He described the attachment behavioral system as an evolutionarily adaptive motivational-behavioral control system.

The attachment system promotes safety in infancy and childhood through the child's relationship with an attachment figure or caregiver (Bowlby, 1969/1982). Attachment behavior is activated in times of danger, stress, and novelty, with the goal of gaining and maintaining proximity and contact with an attachment figure. Hence, the behavioral manifestations are context-specific (evident in times of danger or anxiety), although elements of the attachment system are active at all times via continuous monitoring of the environment and the availability of attachment figures (Ainsworth, Blehar, Waters, & Wall, 1978; Bretherton, 1985). A child can confidently explore the environment with the active support of a caregiver, secure in the knowledge that this attachment figure is available if a significant need or question should arise. Ainsworth and colleagues (1978) termed this interaction between child and caregiver the "secure base phenomenon," a concept central to attachment theory.

Ainsworth (1991) highlighted the function of the attachment behavioral system in adult relationships, be they parent and child, partner and partner, or adult child caring for aging parent, and emphasized the secure-base phenomenon as the critical element. She stated that a secure attachment relationship is one that facilitates functioning and competence outside of the relationship: There is "a seeking to obtain an experience of security and comfort in the relationship with the partner. If and when such security and comfort are available, the individual is able to move off from the secure base provided by the partner, with the confidence to engage in other activities" (p. 38). Attachment relationships are distinguished from other adult relationships in that they provide feelings of security and belonging, and without them there is loneliness and restlessness (Weiss, 1973, 1991). This function is distinguished from aspects of relationships that provide guidance or companionship; sexual gratification; opportunities to feel needed or to share common interests or experiences, feelings of competence, or alliance and assistance (Ainsworth, 1985; Weiss, 1974). Behavioral elements of attachment in adult life are similar to those observed in infancy: a desire for proximity to the attachment figure when stressed, increased comfort in the presence of the attachment figure, and anxiety when the attachment figure is inaccessible (Shaver & Hazan, 1988; Weiss, 1991). Grief is experienced following the loss of an attachment figure (Bowlby, 1980; Fraley & Shaver, Chapter 3, this volume).

Individual Differences and Mental Representations or Working Models

The study of adult attachment processes has not tended to emphasize adult attachment relationships and the normative developmental aspects of the attachment system (yet see Zeifman & Hazan, Chapter 20, this volume). Rather, the field has focused largely on individual differences in the organization of attachment behavior and cognitions, and in expectations regarding attachment relationships. The idea of individual differences emerged from the work of Ainsworth and her colleagues (1978), who broadly characterized the infant patterns of attachment as “secure” and “insecure” (which she sometimes called “anxious”). In addition to the security–insecurity distinction, Ainsworth and colleagues drew a second distinction between “avoidance and conflict relevant to close bodily contact” (p. 298)—the avoidant and resistant behaviors that distinguish two of the major insecure patterns. It is important to note that individual differences in attachment security represent differences in the quality of the attachment relationship: “The most conspicuous dimension that has emerged so far is not strength of attachment but security vs. anxiety in the attachment relationship. This does not imply substitution of degree of security for degree of strength” (p. 298). These dimensional aspects of attachment are increasingly relevant to our understanding of adult attachment (Fraley & Roisman, 2014; Fraley & Spieker, 2003b).

Differences among attachment patterns are thought to develop primarily from different experiences with an attachment figure, rather than being directly influenced by genetics, child temperament, or other child characteristics (Ainsworth et al., 1978; Luijk et al., 2011; Roisman, Booth-LaForce, Belsky, Burt, & Groh, 2013; Roisman & Fraley, 2008; Vaughn & Bost, Chapter 10, this volume). The secure pattern characterizes the infant who seeks and receives protection, reassurance, and comfort when stressed. Confident exploration is optimized because of the support and availability of the caregiver. The child comes to feel secure with the attachment figure; hence, the behavioral system corresponds closely with cognitions and emotions in the context of attachment-related experiences. The two major insecure patterns (“avoidant” and “resistant”) develop when attachment behavior is met by rejection, inconsistency, or threat from the attachment figure, leaving the infant “anxious” about the caregiver’s

responsiveness. To reduce this anxiety, the infant’s behavior adapts to fit or complement the attachment figure’s behavior in the service of minimizing psychological and/or physical distance from a nonoptimal caregiver; in other words, it is strategic within the context of that relationship (Main, 1981, 1990). However, attention to the caregiver in this anxious, strategic way compromises both direct approaches for help and exploratory behavior, and thus is potentially maladaptive outside of that particular relationship.

Current theory and research on adult attachment draw heavily on Bowlby’s concept of attachment representations. Importing ideas from cognitive psychology, Bowlby (1973, 1980) hypothesized that individuals develop representations of the functioning and significance of close relationships that make early experiences “portable” to other interpersonal contexts, possibly into the years of maturity. These representations consist of a person’s beliefs and expectations about how attachment relationships operate and what he or she gains from them. These cognitive–affective connections mirror the behavioral patterns that emerge in the context of behavioral interactions between an infant/child and parents (Bowlby, 1980).

These cognitions are variably called working models, representations, or states of mind because they are the basis for action in attachment-related situations. They are hypothesized to be relatively stable and can operate automatically, without the need for conscious appraisal; they guide behavior in relationships with parents, and influence expectations, strategies, and behavior in later relationships (Bretherton, 1985; Bretherton & Munholland, Chapter 4, this volume; Main et al., 1985). Nevertheless, at least some aspects are open to revision as a function of significant attachment-related experiences (Booth-LaForce et al., 2014; Crowell, Treboux, & Waters, 2002).

Bowlby’s incorporation of mental representations into attachment theory allowed for a lifespan perspective on the attachment system, providing a way of understanding developmental change in the expression of attachment and its ongoing influence on development and behavior in relationships. Bowlby (1973, 1980) also wrote about the problems that arise when a child is presented with a negative view of self and other, and/or with incompatible data about his or her experiences—that is, when the child’s firsthand experience of the attachment figure is in opposition to what the parent tells the child about the meaning of the pa-

rental behavior. Because information relevant to characterizing an attachment relationship comes from multiple sources (Bowlby, 1973), a child may receive conflicting information that challenges the development of a coherent or efficient representation. Bowlby (1973) and Main (1981, 1990, 1991), among others, have described the strategies required to maintain cognitive organization in the face of stress and conflicting information. These “secondary” strategies (as opposed to the primary strategy of approach, contact seeking, and contact maintenance when the attachment system is activated) require “manipulating the level of output usually called for by the [attachment] system—[and, in addition, manipulating cognitive processes to maintain] a given attachment organization” (Main, 1990, p. 48). Such strategies develop because there are inconsistencies, incompatibilities, and a lack of internal connectedness in the elements of the attachment representation (Bowlby, 1973; Main, 1990, 1991). Strategies may include avoidance of the attachment figure in stressful situations (Main, 1981), oscillation between the two viewpoints (i.e., “child good, parent bad,” “child bad, parent good”), and/or acceptance of the parent’s view while denying one’s own experience (Bowlby, 1973).

A central idea in attachment theory is that early parent–child relationships are prototypes of later love relationships (Roisman, Collins, Sroufe, & Egeland, 2005; Waters, Kondo-Ikemura, Posada, & Richters, 1991). Bowlby hypothesized that early experiences are very influential, and there is a strong tendency toward continuity in parent–child interactions, which affects the continuing development of the attachment system. That is, in addition to having effects on individual personality characteristics, child–parent relationships influence subsequent patterns of family organization and therefore play a role in the intergenerational transmission of family attachment patterns. Much of adult attachment research has been based on the assumption that there are parallel individual differences in infant and adult patterns of attachment and attachment representations (e.g., Hazan & Shaver, 1987; Main et al., 1985; Mikulincer & Shaver, 2007).

Bowlby (1969/1982) also discussed change in attachment patterns. In childhood, if an attachment pattern changes, it is assumed to have been caused by a corresponding change in the quality of parent–child interactions. Bowlby also hypothesized that change in attachment patterns can occur in later life through the influence of new

attachment relationships and the development of formal operational thought. This combination of events would allow the individual to reflect on and reinterpret the meaning of past and present experiences (Bowlby, 1973, 1980, 1988)—for example, within a marriage or as a consequence of psychotherapy. In a couple’s relationship, partners can co-construct new attachment representations that take into account both partners’ attachment representations, as well as other elements of the relationship (Crowell, Treboux, & Waters, 2002; Haydon, Collins, Salvatore, Simpson, & Roisman, 2012; Oppenheim & Waters, 1995; Owens et al., 1995; Treboux, Crowell, & Waters, 2004). Furthermore, individuals may draw conscious conclusions about their romantic relationships, and their general or specific behaviors or feelings in these relationships.

In general, researchers have attributed the development of adult attachment patterns to three broad sources, although the relative importance and influence of the three sources has been an important research question (see, e.g., Fraley, 2002; Owens et al., 1995; Waters et al., 1991). These sources are: (1) parent–child attachment relationships; (2) peer and romantic relationship experiences, including exposure to one’s parents’ marriage; and (3) a current adult attachment relationship (Crowell, Treboux, Gao, et al., 2002; Crowell, Treboux, & Waters, 2002; Fraley, Roisman, Booth-LaForce, Owen, & Holland, 2013; Treboux et al., 2004; Zeifman & Hazan, Chapter 20, this volume).

In summary, two core propositions in attachment theory are key to understanding attachment in adulthood and to evaluating existing measures of adult attachment: (1) The attachment system is active in adults, and (2) there are individual differences in adult attachment behavior that have their foundations in attachment experiences and are embodied in both conscious and subconscious mental processes.

Narrative Assessments of Adult Attachment

The measures described in the following sections are based on the concept of *attachment security*, defined as the effectiveness of an individual’s use of an attachment figure as a *secure base* from which to explore and a *safe haven* in times of distress or danger (secure). The use of narratives to assess attach-

ment started with the idea that “mental processes vary as distinctively as do behavioral processes” (Main et al., 1985, p. 78), and that organized behavioral, cognitive, and affective processes are reflected in coherent, organized language. Narrative assessments have derived their validity from observations of attachment behavior in natural settings, and secondarily from their associations with each other.

The Adult Attachment Interview

In what Main and colleagues (1985) called “a move to the level of representation” (in contrast to the focus on behavior in parent–child attachment relationships), they developed a semistructured interview for adults about childhood attachment experiences and the meaning currently assigned by an individual to past attachment-related experiences (George et al., 1984, 1985, 1996). This AAI and its scoring systems are based on several key ideas about attachment, including the ideas that working models operate at least partially outside of awareness; that they are based on attachment-relevant experiences; that infants begin to develop models that guide behavior in attachment relationships in the first year of life; that representations provide guidelines for behavior and affective appraisal of experience; that formal operational thought allows the individual to observe and assess a given relationship system and, hence, the model of the relationship can be altered without an actual change in experiences in the relationship; and that the models are not templates but are mental structures that serve to “obtain or to limit access to information” (Main et al., 1985, p. 77). In some ways, the “working model” assessed by the AAI can be considered to be an attachment script, developing and elaborating in the context of experience, and serving as a guide for attachment-relevant behavior (see Roisman, 2009). In addition, the AAI scoring system is linked to Bowlby’s and Main’s ideas about secondary strategies and incompatible models described earlier.

During an AAI, the adult is interviewed about his or her general view of the relationship with parents; ordinary experiences with parents in which the attachment system is presumed to be activated (upset, injury, illness, separation); experiences of loss and/or abuse; and finally the meaning that the adult attributes to these experiences in terms of the parents’ behavior and the development of the interviewee’s adult personality and behavior. The resulting narrative is transcribed

verbatim, and the transcript is examined for material directly expressed, as well as for unintended qualities of discourse, such as incoherence and inconsistency. Scoring is based on (1) the coder’s assessment of the individual’s childhood experiences with parents; (2) the language used by the individual; and (3) most importantly, the individual’s ability to give an integrated, believable account of experiences and their meaning. The speaker’s discourse is considered a reflection of the current “*state of mind* with respect to attachment” (Hesse, Chapter 26, this volume; Main et al., 1985; Main & Goldwyn, 1984; Main, Goldwyn, & Hesse, 2003).

Main and Goldwyn’s Scoring System

The AAI scoring system (e.g., Main & Goldwyn, 1985; Main et al., 2003) was developed by examining parental interviews for which the Strange Situation procedure classifications of the interviewees’ infants were already known, and identifying qualities of content and discourse that distinguished among them. Hence, the AAI was expressly developed to capture the issues tapped by the Strange Situation, especially an individual’s ability to use an attachment figure as a secure base. The system has been refined over the past 30 years, but it has not yet been published. Extensive training is required to administer and score the interview.

Scoring is done from a transcript, and there are two sets of scales used to sort participants inductively into the primary attachment classifications described below: maternal and paternal *inferred childhood experience* scales and *state of mind* scales. Parental behavior is rated by the coder from the specific memories and descriptions given of parental behavior, not from the assessment of the parenting given by the individual. These inferred childhood experience scales, rated separately for mother and father, include the following: Loving, Rejecting, Neglecting, Involving (i.e., role reversal), and Pressuring to Achieve. The state of mind scales assess discourse style and particular forms of coherence and incoherence: Idealization, Insistence on Lack of Recall, Active Anger, Derogation, Fear of Loss, Metacognitive Monitoring, and Passivity of Speech. Using these ratings and the overall coherence of the transcript, the coder also assigns scores for coherence of transcript and of mind. The concept of *coherence* is based on Grice’s (1975) maxims regarding discourse: High coherence means that the narrative adheres to

Grice's maxims of *quality* (it is believable, without contradictions or illogical conclusions), *quantity* (enough, but not too much, information is given to permit the coder to understand the narrative), *relevance* (the individual answers the questions asked), and *manner* (the individual uses fresh, clear language rather than jargon, canned speech, or nonsense words).

Patterns of scale scores are used to assign an adult to one of three major classifications: a secure category ("autonomous") or one of two insecure categories ("dismissing" or "preoccupied"), with the coherence scales being used to make the secure–insecure distinction. The categories parallel the three infant attachment patterns identified by Ainsworth and colleagues (1978), and the discourse style reflects the behavioral elements in infant attachment patterns. Indeed, a recent analysis of coding of narrative secure-base content of the AAI indicated that the correlation between AAI coherence and a laboratory caregiving and care seeking assessment was largely (80%) accounted for by secure-base script knowledge (T. E. Waters, Brockmeyer, & Crowell, 2013).

Individuals classified as secure/autonomous maintain a balanced view of early relationships, value attachment relationships, and view attachment-related experiences as influential in their development. In parallel to the direct approach of the secure infant, the autonomous adult's approach to the interview is open, direct, and cooperative, regardless of how difficult the memories reported are to discuss. The interview itself contains consistent, believable reports of behavior by parents; simply put, the adult's general descriptions of the parenting he or she received correspond well to the specific memories given of parental behavior. Because security is inferred from coherence, any kind of childhood experience may be associated with being classified as autonomous, although in many cases parental behavior is indeed summarized as loving, and there are clear and specific memories given of loving behavior by the parents.

The two major insecure classifications are associated with incoherent accounts, which means that interviewees' assessment of experience are not matched by their descriptions of parental behavior. There is little support provided for a parent's serving as a secure base; and discourse, whether dismissing or preoccupied, mirrors the lack of exploration and inflexibility of insecure infants. Corresponding to the behavior of avoidant infants in the Strange Situation, adults classified as dismissing are uncomfortable with the topic of

the interview, deny the impact of early attachment relationships on their personality development, have difficulty recalling specific events, and characteristically idealize experiences. The classification is associated with descriptions of rejection in the coder's opinion (pushing a child away in attachment-activating situations) in the context of an adult's giving an overarching assessment of having loving parents. Just as resistant infants are ambivalent/resistant in the Strange Situation, adults classified as preoccupied display confusion or evaluative oscillation about past experiences, and descriptions of relationships with parents are marked by active anger and/or passivity. The preoccupied classification is associated with involving, even role-reversing parenting, in which the child needed to be alert to parental needs rather than the reverse.

Individuals may be classified as "unresolved," in addition to being assigned one of the three major classifications. Unresolved adults report attachment-related traumas of loss and/or abuse, and manifest confusion and disorganization in the discussion of that topic. The unresolved classification may be given precedence over the major classification in categorizing the individual, and in some analyses, it is considered an insecure classification. A "cannot classify" designation is assigned when the transcript does not fit any of the major classification categories, most commonly when scale scores reflect the co-occurrence of indicators typical of dismissing and preoccupied states of mind (e.g., high idealization of one parent and high active anger toward the other) (Hesse, 1996).

Kobak's Q-Sort Scoring System

The Adult Attachment Q-Sort is an alternative method of scoring the AAI and was derived from the original scoring system (Kobak, 1993; Kobak, Cole, Ferenz-Gillies, Fleming, & Gamble, 1993). Its latent structure, at least as originally conceptualized (see Kobak et al., 1993), parallels the Strange Situation and Main and Goldwyn scoring systems, but it emphasizes the relation between emotion regulation and attachment representations. Using Kobak's Q-sort, the AAI is scored from a transcript according to a forced distribution of descriptors, and yields scores for two conceptual dimensions: security–anxiety and deactivation–hyperactivation (although largely orthogonal dismissing and preoccupied state of mind prototype scores are also available to the analyst; see below). Security is inferred from coherence and cooperation within

the interview and often (although not necessarily) from memories of supportive attachment figures (in the coder's opinion). Deactivation corresponds to dismissing strategies, whereas hyperactivation corresponds to the excessive detail and active anger seen in the transcripts of many preoccupied subjects. These strategies lie at opposite ends of a single dimension, which was originally assumed to be orthogonal to the secure–anxious (insecure) dimension. The AAI transcript is rated by two or more coders, using 100 Q-sort items and instructions that impose a forced normal distribution along a 9-point continuum (Kobak et al., 1993). The sort is correlated with an expert-based prototypical sort for each dimension. The dimensional scores can be used to classify the adult into the categories of the original system, and Kobak and colleagues reported that approximately 80% of individuals receive the same classification with the Q-sort system as with the original system ($\kappa = .65$). The scoring system was created without an attempt to include the “unresolved” or the “cannot classify” categories.

Fonagy, Steele, Steele, Moran, and Higgitt's Reflective Functioning Scoring System

Building on the idea reflected in the Main and Goldwyn (1984) coding system that security in adulthood in part reflects metacognitive monitoring, Fonagy and colleagues' (1991) system for coding AAI transcripts assesses *reflective functioning*—that is, an adult's quality of understanding his or her own and another's intentions, motivations, and emotions. In a study of 200 parents, the AAI self-reflection function correlated highly with AAI coherence and was a stronger predictor of infant security. Evidence for the validity and utility of measures of reflective function are reviewed by Fonagy, Luyten, Allison, and Campbell (Chapter 34, this volume).

Distribution of Classifications

In the most recent meta-analysis of AAI classifications (Bakermans-Kranenburg & Van IJzendoorn, 2009), the distribution of AAI classifications in nonclinical samples of women, men, and adolescents was 58% autonomous (secure), 23% dismissing, and 19% preoccupied, with about 18% of individuals also receiving an unresolved classification in association with a major classification. Not surprisingly, the base rate of insecurity in clinical

and at-risk samples was much higher. Although this meta-analysis found no gender differences in distribution of classifications (Bakermans-Kranenburg & Van IJzendoorn, 2009), other large-scale studies relying on the dimensional scoring described below reveal evidence that women score higher on preoccupied states of mind and men score higher on dismissing states of mind (Haydon, Roisman, Owen, Booth-LaForce, & Cox, 2014).

Stability and Discriminant Validity

High stability of attachment classifications (78–90% for three classification groups across periods ranging from 2 weeks to 13 years) has been observed in a number of studies using the original scoring system (e.g., $\kappa = .73$, 86%, over 21 months; Crowell, Treboux, & Waters, 2002; see also Allen, McElhaney, Kuperminc, & Jodl, 2004; Bakermans-Kranenburg & Van IJzendoorn, 1993; Benoit & Parker, 1994; Crowell & Hauser, 2008; Sagi et al., 1994.) The secure classification is especially stable, but the unresolved classification often is not. Change from insecure to secure status across the transition to marriage has been associated with positive feelings and coherent cognitions about the relationship with the partner and living away from the family of origin (Crowell, Treboux, & Waters, 2002).

Because the ability to speak coherently about attachment could conceivably be based on non-attachment-related cognitive abilities such as intelligence or memory, the discriminant validity of the original AAI scoring system has been investigated. Security is weakly associated with intelligence in most studies (but see Haydon et al., 2014) and is not significantly associated with memory, social desirability, or discourse style on an unrelated topic (Bakermans-Kranenburg & Van IJzendoorn, 1993; Crowell et al., 1996; Sagi et al., 1994).

A New Look at the Latent Structure of the AAI

Since the publication of the second edition of the *Handbook of Attachment*, a number of fundamental measurement issues have arisen that should be considered if the AAI is being used as an assessment method. In short—and in some contrast to the conceptualization of the primary coding systems for the AAI that dismissing and preoccupied states of mind are mutually exclusive and rarely co-occur—there is increasing evidence that coherent

discourse during the AAI may in fact be distributed along *two relatively independent dimensions* (Roisman, 2009). According to this view, first, the coherent speaker is *internally consistent* when he or she discusses childhood attachment experiences during the AAI. Individuals who do not produce internally consistent discourse during the AAI often idealize their caregivers (e.g., are unable to provide specific memories that support their overly positive descriptions of their relationships with parents) or normalize objectively harsh childhood experiences. Second—and distinctively—the coherent speaker is able to discuss his or her early experiences without becoming emotionally overwrought while doing so, as reflected either in passive discussion of childhood memories (e.g., wandering off into irrelevancies) or, more commonly, by becoming actively upset while recounting early life experiences. A number of recent studies demonstrate the distinctive origins, correlates, and consequences of these individual differences (Fortuna, Roisman, Haydon, Groh, & Holland, 2011; Haydon, Collins, et al., 2012; Haydon et al., 2014; Whipple, Bernier, & Mageau, 2011).

Work supporting this updated conceptualization of the AAI began with path-finding exploratory factor analyses of the AAI state-of-mind scales reported in publications by Bernier and her colleagues (Bernier, Larose, Boivin, & Soucy, 2004; Larose, Bernier, & Soucy, 2005), which were replicated and extended in the context of two large sample studies (Haydon et al., 2012; Roisman, Fraley, & Belsky, 2007). In the first of these investigations, Roisman, Fraley, and Belsky (2007) examined the latent structure of individual differences in adult attachment via analysis of the rating scales used by AAI coders to index adults' states of mind regarding their childhood attachment experiences, scales that are used to sort participants inductively into attachment categories. Specifically, the study combined data from three publications (total $N = 504$) drawn from the literature on earned-security (Pearson, Cohn, Cowan, & Cowan, 1994; Roisman & Haydon, 2011).

Using principal components analysis, Roisman, Fraley, and Belsky (2007) found evidence that two- and three-component solutions accounted for the variation in AAI state-of-mind scales reasonably well. The two-component solution suggested that variation in AAI state-of-mind scales could be explained by components reflecting (1) scales used to differentiate secure from dismissing adults (i.e., mother idealization, father idealization, coherence of mind, lack of recall,

and metacognitive monitoring); and (2) scales used to identify both preoccupied and unresolved status (i.e., mother anger, father anger, passivity, unresolved abuse, unresolved loss, fear of loss, and overall derogation). The three-component solution suggested that variation in AAI state-of-mind scales could be explained by components reflecting scales used to differentiate secure from dismissing adults, as in the two-component solution, and an additional set of components that suggested two distinct forms of preoccupied discourse, one involving an active, traumatic enmeshment in earlier experiences (i.e., father and mother anger, derogation, and unresolved trauma) and the other a passive, loss-related preoccupation (i.e., unresolved loss, fear of loss, and passivity). This latter finding of two distinct forms of preoccupied discourse was somewhat surprising given that scholars might reasonably have expected separate preoccupied and unresolved sources of variation paralleling the preoccupied and unresolved classifications that can be assigned using the Main and Goldwyn (1984) approach to scoring the AAI. Complicating things further, in both the two- and three-factor solutions, two of the scales that are viewed by Main and Goldwyn as evidence of a dismissing state of mind (i.e., derogation and fear of loss) actually loaded with indicators of preoccupation/unresolved discourse.

In an extension of this work to a larger sample of college student and community participants ($N = 842$), Haydon, Roisman, and Burt (2012) examined the latent structure of Kobak's (1993) AAI *Q-sort*. Again using a principal components analysis—this time applied to item-level *Q-sort* data—Haydon, Roisman, and Burt found that a four-component solution best accounted for the variation in the data. Two of these components reflected relatively independent attachment states of mind (dismissing and preoccupied; note that when items that loaded highly and uniquely on each component were composited, they were correlated very strongly with their identically named Kobak *Q-sort* prototype scores) and two additional components reflecting inferred experiences with maternal and paternal caregiving figures (for replication of this finding, see Kobak & Zajac, 2011).

All of the factor-analytic research we just described has relied on exploratory techniques. Nonetheless, two publications based on large samples—the National Institute of Child Health and Human Development (NICHD) Study of Early Child Care and Youth Development (SECCYD; Haltigan, Roisman, & Haydon, 2014)

and a sample of African American and European American mothers in North Carolina (Haltigan, Leerkes, et al., 2014)—have recently provided *confirmatory* factor-analytic evidence that what is commonly referred to as secure/autonomous states of mind actually blends two *empirically distinct* aspects of attachment-related discourse—variation in the degree to which adults can freely evaluate their childhood experiences or are relatively dismissing of those experiences (dismissing states of mind) and variation in preoccupation (preoccupied states of mind; see Roisman & Booth-LaForce, 2014, for more detailed discussion). Haltigan, Leerkes, and colleagues (2014) demonstrated partial measurement equivalence of these factor structures across ethnic groups, as well as in associations between dismissing states of mind and lower levels of observed sensitivity (replicating work by Whipple et al., 2011).

Factor analysis does not address the empirically distinct question of whether individual differences in adult attachment are categorically or continuously distributed (Fraleley & Roisman, 2014; Fraley & Spieker, 2003a; Fraley & Waller, 1998; Roisman, Holland, et al., 2007). However, results from taxometric analyses of some of the same data sets described earlier (i.e., Fraley & Roisman, 2014; Roisman, Fraley, & Belsky, 2007) suggest that the primary distinction made by AAI coders between secure and dismissing states of mind within the Main and Goldwyn (1984) coding system is more consistent with an underlying *dimensional* rather than categorical model. (Analyses of the indicators of preoccupation were indeterminate; see Fraley & Roisman, 2014, for discussion.) Both of these reports also examined the inferred-experience scales within the Main and Goldwyn system, and relevant analyses suggested that the quality of caregiving experiences, as recalled by participants and scored by trained observers, is continuously distributed. In short, it does not appear to be the case that there are subsets of individuals who have qualitatively different experiences, as is often assumed in research on retrospectively defined earned security (Roisman & Haydon, 2011).

Research with the AAI

The AAI had its origins in investigations of the child–parent attachment relationship, and many of the studies based on the AAI have used it for this purpose. There is a consistent link among AAI classifications/dimensions, parenting behav-

ior, and child attachment status. The AAI has also been used to examine attachment between adult romantic partners.

Studies of Adults as Individuals: Prospective Longitudinal Studies

To examine the idea that early attachment patterns correspond to attachment patterns in adult life, several studies have assessed the relation between infant attachment security and AAI classifications in late adolescence and young adulthood. Although some small sample studies found a substantial degree of correspondence between Strange Situation procedure and AAI security–insecurity in late adolescents and young adults who participated as infants in studies of attachment (e.g., kappa = .44, Waters, Merrick, Treboux, Crowell, & Albersheim, 2000; see also Hamilton, 2000), the two largest studies in this area have produced test–retest stability coefficients that are more modest in magnitude in both a high- and normative-risk cohort (r 's ranging from .10 to .15; Groh et al., 2014; Weinfield, Sroufe, & Egeland, 2000).

Precise explanations of cross-study differences in observed continuity remain to be tested and replicated, but it seems likely that the effort to explain stability and instability will be successful (i.e., that discontinuity will turn out to be “principled” or lawful rather than mysterious or haphazard; for a recent example, see Booth-LaForce et al., 2014). In addition, it is important to emphasize that although the rank-order stability of security in the first two decades of life is relatively modest in larger sample studies, significant and fairly substantial proportions of the variance in AAI states of mind (10–20% of the total variance in the state of mind dimensions) were accounted for in the recent age 18 follow-up of the large NICHD SECCYD cohort ($N = 857$) by leveraging data on a range of key developmental assets and interpersonal risk factors (Haydon et al., 2014).

The Dismissing Strategy

Adults classified as dismissing use strategies that minimize, dismiss, devalue, or deny the impact of negative attachment experiences. During the AAI, college students who used dismissing strategies showed an increase in skin conductance (Dozier & Kobak, 1992; Roisman, Tsai, & Chiang, 2004). Despite efforts to minimize negative aspects of childhood and the importance of early relation-

ships, they showed signs of physiological distress when challenged with these topics. Indeed, adults classified as dismissing underreport distress, psychological symptoms, or problems in interpersonal relationships, compared with the reports of others who know them well (Dozier & Lee, 1995; Kobak & Sceery, 1988).

Adjustment and Psychopathology

Consistent relations have been found between security and ratings of social adjustment, social support, stress, and depression; the effect sizes have varied depending on ecological and methodological factors (Atkinson et al., 2000; Crowell, Trebous, & Waters, 1999; Kobak & Sceery, 1988; for a review, see Fearon, Groh, Bakermans-Kranenburg, Van IJzendoorn, & Roisman, in press). Clinical populations have a higher proportion of insecure classifications than the general population, but few specific relations between the “organized” AAI types and psychopathology have emerged (Riggs & Jacobvitz, 2002; Van IJzendoorn & Bakermans-Kranenburg, 1996; Van IJzendoorn et al., 1997; Wallis & Steele, 2001; Ward et al., 2001). The unresolved group, however, is over-represented in clinical samples, and this has led to suggestions that it is more pathological than “organized” insecure classifications (Van IJzendoorn & Bakermans-Kranenburg, 2009). We do not discuss this complex area of investigation further here, but as Lyons-Ruth and Jacobvitz explain in Chapter 29, this volume, it has led to important efforts to expand the AAI coding system to address a variety of trauma-related variations in AAI narratives.

“Earned” Security

The subset of individuals classified as secure (because they value attachment and are coherent in their discussion of attachment relationships), despite coders rating their parents as unloving, have been termed “earned” secure. Data from both the Minnesota Longitudinal Study of Risk and Adaptation (Roisman, Padron, Sroufe, & Egeland, 2002) and the NICHD SECCYD (Roisman, Haltigan, Haydon, & Booth-LaForce, 2014) demonstrate that such retrospectively defined “earned” secure individuals paradoxically experienced average or better early caregiving during childhood and adolescence, but due to a range of factors, including mood-related biases in their retrospective recall of early caregiving experiences, coders

tend to rate their parents as relatively unloving (Roisman, Fortuna, & Holland, 2006; Roisman et al., 2002, 2014). Although some scholars disagree with this interpretation (Hesse, 2008), to the best of our knowledge, they have yet to offer an alternative model that explains why (1) both normative-risk (Roisman et al., 2014) and high-risk (Roisman et al., 2002) longitudinal cohorts have provided evidence that the observed maternal and (in the SECCYD) paternal caregiving of retrospectively defined earned secure is average or better (regardless of how earned secure status is defined retrospectively) and (2) experimental mood manipulations can shift ratings on the inferred experience scales (even if not the coherence rating) (Roisman et al., 2006).

Studies of Child–Parent Attachment Classifications across Generations

Some of the first AAI investigations indicated high correspondence between parental AAI classifications and infant attachment assessed with the Strange Situation ($\kappa = .46$ for three classifications; $\kappa = .44$ for four classifications) and preschoolers’ attachment assessed with home observations (Cassibba, Van IJzendoorn, Bruno, & Coppola, 2004; Fonagy, Steele, & Steele, 1991; Posada, Waters, Crowell, & Lay, 1995; Sagi et al., 1992; Steele, Steele, & Fonagy, 1996; Van IJzendoorn, 1992; see the meta-analysis by Van IJzendoorn, 1995). Mother–infant correspondence is greater than father–infant correspondence (Main et al., 1985; Miljkovitch, Pierrehumbert, Bretherton, & Halfon, 2004; Steele et al., 1996; Van IJzendoorn, 1992).

Studies of Parents’ AAI Classifications and Parental Behavior toward Children

Mothers classified as autonomous on the AAI are observed to be more responsive, perceptive, sensitive, and attuned to their infants in the first year of life (Adam, Gunnar, & Tanaka, 2004; DeOliveira, Moran, & Pederson, 2005; Goldberg, Benoit, Blokland, & Madigan, 2003; Grossmann, Fremmer-Bombik, Rudolph, & Grossmann, 1988; Haft & Slade, 1989; Macfie, McElwain, Houts, & Cox, 2005; Slade, Belsky, Aber, & Phelps, 1999; Ward & Carlson, 1995; Zeanah et al., 1993). Similarly, parental security of attachment is associated with parents’ sensitivity with their preschool children, and providing help and support during

observed tasks and separations in both normative and clinical samples (Cohn, Cowan, Cowan, & Pearson, 1992; Crowell & Feldman, 1988, 1991; Crowell, O'Connor, Wollmers, Sprafkin, & Rao, 1991; Das Eiden, Teti, & Corns, 1995; Oyen, Landy, & Hilburn-Cobb, 2000). Marital functioning appears to have moderating effects (Cohn et al., 1992; Das Eiden et al., 1995). Ratings of child symptoms by parents, teachers, and children themselves indicate that children of insecure parents have higher ratings of problem behavior and child distress (Cowan, Cohn, Pearson, & Cowan, 1996; Crowell et al., 1991). Adolescents classified as secure in the AAI are observed to have secure base relationships with their mothers and are more socially skilled than those classified as insecure (Allen et al., 2002, 2004; Kobak et al., 1993; for a review, see Allen & Tan, Chapter 19, this volume).

Romantic Relationships

A meta-analysis of AAI attachment classifications of 226 couples showed modest concordance (50–60%, equivalent to a kappa of .20, for three major classifications) between partners for attachment status, accounted for by the secure–secure pairs (Van IJzendoorn & Bakermans-Kranenburg, 1996). Not surprisingly, this finding suggests that factors other than attachment security are active in partner selection and maintenance, although a recent analysis of a comparable number of couples assessed in the meta-analysis demonstrated somewhat more correspondence between *preoccupied* states of mind than dismissing states of mind within couple pairs (Haydon, Roisman, & Burt, 2012), a pattern of results that was also apparent among adult siblings in a study by Fortuna and colleagues (2011).

Little direct relation between the broad construct of marital satisfaction and AAI classification has been found, but reports of feelings of intimacy are related (Benoit, Zeanah, & Barton, 1989; Cohn, Silver, Cowan, Cowan, & Pearson, 1992; O'Connor, Pan, Waters, & Posada, 1995; Zeanah et al., 1993). In addition, feelings about the relationship are related to interactions among AAI status, representations of the adult partnership, marital behavior, and stressful events (Paley, Cox, Harter, & Margand, 2002; Treboux et al., 2004). Associations between attachment security and the use of physical aggression in couples' relationships are consistently obtained (Crittenden, Partridge, & Claussen, 1991; O'Connor et al., 1995; Treboux

et al., 2004). As we discuss later in this chapter, there is little correspondence between the AAI and self-reports of attachment (Roisman, Holland, et al., 2007; Waters, Crowell, Elliott, Corcoran, & Treboux, 2002).

Couples' Interactions

Studies have found associations between the AAI and attachment/secure-base behaviors in couples' interactions in samples of both late adolescents and adults (Cohn et al., 1992; Creasey, 2002; Creasey & Ladd, 2004, 2005; Crowell, Treboux, Gao, et al., 2002; Curran, Hazen, Jacobvitz, & Feldman, 2005; Furman, Simon, Shaffer, & Bouchey, 2002; Paley, Cox, Burchinal & Payne, 1999; Roisman, Madsen, Hennighausen, Sroufe, & Collins, 2001; Simpson, Rholes, Oriña, & Grich, 2002; Wampler, Riggs, & Kimball, 2004; Wampler, Shi, Nelson, & Kimball, 2003). These studies, combined with recent longitudinal evidence that predictive associations between AAI states of mind and observed relationship quality obtain even after researchers adjust statistically for the association between these variables at baseline (Holland & Roisman, 2010), provide compelling support for the AAI as an assessment of a generalized representation of attachment rather than being specific to a particular type of attachment relationship.

Relationship Interviews

Several interviews have been developed to assess attachment representations within romantic partnerships (e.g., Bartholomew & Horowitz, 1991; Cowan, Cowan, Alexandrov, Lyon, & Heming, 1999; Crowell & Owens, 1996; Dickstein, Seifer, Albus, & Magee, 2004; Furman & Simon, 2006). Most are rooted in the AAI tradition of examining coherence of discourse, and the findings of relations among these interviews, the AAI, self-reports of the relationship, and observed couples' behavior are similar (Alexandrov, Cowan, & Cowan, 2005; Dickstein et al., 2004; Furman & Simon, 2006; Owens et al., 1995). Of these, the Current Relationship Interview (CRI) is the most well established (Crowell & Owens, 1996; Crowell et al., 2002a; Crowell, Treboux, & Waters, 2002; Furman et al., 2002; Owens et al., 1995; Roisman et al., 2005; Treboux et al., 2004). The CRI investigates the representation of attachment within an adult partnership. It was developed as a way to examine the prototype hypothesis—the

hypothesis that adult close relationships are similar in organization to parent–child attachment relationships. More specifically, it has been used to explore the process by which a new attachment relationship may be integrated into an already existing representation of attachment, or by which a new representation develops.

As a narrative assessment, the CRI is intended to examine an individual's representation of attachment and ideas regarding the partner's and his or her own attachment behavior. The interview asks the adult for descriptions of the relationship and for instances of the use of and giving of secure-base support in the relationship. The interview is scored from a transcript, and the subject is classified into one of three groups according to the profile of scores on a variety of rating scales. Rating scales are used to characterize (1) the participant's behavior and thinking about attachment-related issues (e.g., valuing of intimacy and independence); (2) the partner's behavior; and (3) the subject's discourse style (e.g., anger, derogation, idealization, and overall coherence). The CRI and its scoring system parallel the AAI in structure. The secure–insecure dimension is based on coherent reports of being able to use the partner as a secure base and to act as a secure base, or the coherently expressed desire to do so. Individuals who cannot coherently discuss secure-base use and support in the interview are divided between those who avoid discussion of these behaviors or dismiss their significance, and those who appear to heighten or control the attachment elements of the relationship. CRI scoring is based on state of mind regarding attachment, as well as individuals' reports of their own specific attachment behaviors of secure-base support and use. These factors are given primacy in the determination of attachment security rather than the individual's reported feelings about the relationship or the behaviors of the partner.

The secure CRI interview is characterized by coherence; that is, the subject convincingly describes his or her own and the partner's secure-base behavior, or can coherently discuss negative partner behavior. The subject expresses the idea that an adult attachment relationship should provide support for the individuals involved and for their joint development, whether or not the relationship is actually providing these elements. The dismissing CRI classification is given when there is little evidence that the individual views attachment, support, and comfort within the relationship as important, even if the partner is convincingly described as loving. The relationship may be

“normalized.” A need for autonomy and separateness within the relationship may be emphasized, and there may be a focus on concrete or material aspects of the relationship (e.g., buying a house, going on vacations). The preoccupied CRI classification is given when the subject expresses strong dependence on the partner or attempts to control the partner. The individual may be dissatisfied or anxious about the partner's ability to fulfill his or her needs, and may express ambivalence or confusion about the relationship, the partner, and/or the self, regardless of the descriptions of partner behavior.

Distribution and Concordance of Classification in Couples

Empirical evidence suggests that the distribution of classifications may vary with the developmental stage of the participants and the relationship (e.g., Alexandrov, Cowan, & Cowan, 2005; Furman et al., 2002). For example, 46% of CRI transcripts were classified as secure in a sample of young engaged adults (Owens et al., 1995), whereas in a married sample with children, 71% were classified as secure with the Couple Attachment Interview (CAI; Alexandrov et al., 2005). Concordance between partners for CRI classifications was 63% premaritally ($\kappa = .29$) and 65% after 15 months of marriage ($\kappa = .30$); for the CAI, the concordance was 69%.

Stability and Discriminant Validity

Security on the CRI is unrelated to intelligence, education, gender, duration of relationship, or the endorsement of symptoms of depression (Owens et al., 1995). Unlike the AAI, the CRI draws on a current relationship and is subject to life events and partner behaviors. Hence the CRI classifications are expected to be less stable than those of the AAI, especially in the early phases of relationship development (Crowell & Waters, 1997).

Research with Relationship Interviews

Reports of Relationships and Marital Satisfaction

Individuals classified as secure with relationship interviews (RIs) report greater satisfaction with their relationship, greater commitment and feel-

ings of love overall, and fewer problems in the relationship than insecure individuals (Alexandrov et al., 2005; Owens et al., 1995; Roisman et al., 2005; Treboux et al., 2004). Investigations consistently reveal that security assessed with RIs is positively related to attachment behavior in couples' interactions (Alexandrov et al., 2005; Crowell, Treboux, Gao, et al., 2002; Furman & Simon, 2006; Roisman et al., 2005).

Correspondence with the AAI

The correlation of the security scores from concurrently obtained AAIs and CRIs in a normative risk cohort was $r = .51$ (Crowell, Treboux, & Waters, 2002); however, in the higher risk Minnesota Longitudinal Study of Risk and Adaptation (MLSRA) cohort, CRI and AAI classification were not significantly associated (Haydon, Collins, et al., 2012). Evidence suggests that the configuration of the AAI and the CRI within an individual is especially predictive of marital functioning, including divorce rates early in marriage (Dickstein et al., 2004; Treboux et al., 2004). Treboux and colleagues reported that individuals classified as secure on both the AAI and the CRI reported more positive feelings about the relationship, low observed and reported aggression, and divorce rates consistent with the overall mean. They appeared to tolerate stressful life events without marked change in these parameters. Individuals classified as insecure on both the AAI and the CRI are the most aggressive group, by observation and self-report. The behaviors and negative feelings about the relationship escalate in association with stressful events. Individuals classified as AAI insecure/CRI secure reported the *most positive* feelings about their relationships and had a significantly lower divorce rate in early marriage than other configurations. However, when stressed, such individuals report negative feelings about their relationships, and their conflict behavior is more aggressive. Last, individuals classified as AAI secure/CRI insecure report the *most negative* feelings about their relationships and have significantly higher divorce rates than the other configurations. They do not engage in aggressive conflict behaviors, however, even when stressed. These results were supported in the MLSRA study (Haydon, Collins, et al., 2012) in which AAI secure/CRI insecure individuals engaged in more conflict with partners than those with secure CRIs.

Furthermore, Haydon, Collins, and colleagues (2012) addressed the question of whether representations assessed with the AAI and the

CRI had shared developmental origins, or whether they were independent. Analyses indicated that these representations have shared origins in some early experiences and shared links to romantic behavior. However, romantic representations assessed with the CRI had distinctive roots in early development, as well as independent links to adult romantic behavior.

The Attachment Script Assessment

Borrowing from the cognitive literatures on narrative and memory, and based on seminal theoretical work by Bretherton (1987, 1990), developmental psychologists have recently taken another approach to the assessment of attachment representations in adolescents and adults by measuring individual differences in attachment-relevant *scripts* (Waters & Rodrigues, 2001; Waters & Waters, 2006). Cognitive scientists such as Schank (1999) argue that as we encounter similar experiences over time, we begin to summarize commonalities (e.g., the main character(s), causal chain of events, and resolution or ending) across those events and form a script for how those events typically unfold. Waters and Waters (2006) proposed that an individual's history of care and secure-base support is represented in memory as a *secure-base script*.

To assess individual differences in access to this secure-base script (i.e., secure-base script knowledge), H. Waters and colleagues developed the Attachment Script Assessment (ASA), although coding of secure-base script knowledge is also possible based on the autobiographical narratives produced within the AAI. The ASA uses a word-prompt outline in which participants generate short stories with attachment-related themes from a set of words. Ultimately, *secure-base script knowledge* is operationally defined in terms of the degree to which an individual produces narratives in which attachment-relevant events are encountered, a clear need for assistance is communicated, competent help is provided and accepted, and the problem is resolved. In an adult version of the ASA, four word-prompt stories are generated by each participant (two focused on adult–adult and two on adult–child scenarios; Waters & Rodrigues, 2001). In an adolescent version of the measure (see Dykas, Woodhouse, Cassidy, & Waters, 2006; Steiner, Arjomand, & Waters, 2003), participants use developmentally tailored word prompts specific to caregivers.

In the last few years, studies of the ASA examining the developmental significance of indi-

vidual differences in secure-base script knowledge have provided evidence that the ASA has attractive psychometric properties, including adequate test–retest reliability ($r = .54$, $n = 53$; Vaughn et al., 2006) and convergent validity with coherence of mind as assessed by the AAI (meta-analytic $r = .53$, $n = 87$; Coppola, Vaughn, Cassibba, & Constantini, 2006; Waters & Rodrigues, 2001). Secure-base script knowledge is positively associated with high-quality parenting, as well as attachment security in the next generation (e.g., Bost et al., 2006; Coppola et al., 2006; Veríssimo & Salvaterra, 2006). Although such studies address critical questions regarding the reliability and validity of the ASA as an assessment of secure-base script knowledge, less is known at present about the developmental origins of secure-base script knowledge. However, in the SECCYD, ASA secure-base script knowledge was as strongly associated with earlier infant–mother attachment and maternal sensitivity, as were AAI states of mind measured in the same cohort around age 18 years. Indeed, ASA secure-base script knowledge was actually *more* strongly associated with antecedent paternal sensitivity than were AAI state-of-mind scores (R. Steele et al., 2014).

Behavioral Assessments of Attachment

A number of investigators have developed systems of observing attachment behaviors between adult partners, many using a standard marital interaction task as the stressor that provokes attachment behavior (Alexandrov et al., 2005; Creasey, 2002; Creasey & Ladd, 2005; Crowell, Treboux, Gao, et al., 2002; Furman & Simon, 2006; Roisman et al., 2005; Wampler et al., 2004). An external anxiety-inducing stressor has also been employed (Simpson, Rholes, Oriña, & Grich, 2002). These assessments focus on support seeking and provision rather than positive and negative communication styles. There is evidence that the more specifically attachment behavior is assessed, as opposed to communication behaviors, the more likely it is to relate to narrative assessments of attachment (Crowell, Treboux, Gao, et al., 2002; Paley et al., 1999).

The Secure Base Scoring System (SBSS) is an example of one such behavioral assessment. Couples are assessed using a standard couples' interaction task that was videotaped and scored with

the SBSS (Crowell, Treboux, Gao, et al., 2002). When a partner introduces a concern into the discussion, their secure-base use is scored on four subscales ranging from high quality to low quality. Subscales indicate (1) the clarity of *initial signal* or expression of distress, (2) *maintenance of the signal* as needed, (3) *approach* to the partner for help, and (4) the *ability to be comforted*. Based on these subscales and the general overview of the individual's behavior, the coder assigns a score on the Summary of Secure Base Use scale. *Secure base support* is scored for the partner who is presented with the concern raised by the other. It is scored on four subscales: (1) *interest in the partner*, (2) *recognition of distress or concern*, (3) *interpretation of distress*, and (4) *responsiveness to distress*. A Summary of Secure Base Support scale encompasses the overall support provided by the individual. Because the summary scales are often very highly correlated (women: $r = .86$, men: $r = .88$; Crowell, Treboux, Gao, et al., 2002), the average of the summary scales may be used to represent overall quality of secure-base behavior.

Self-Report Measures of Romantic Attachment

The study of romantic attachment began in the late 1970s and early 1980s in an attempt to understand the nature and etiology of adult loneliness and the various ways that people experience love. It had been noticed that many lonely adults report troubled childhood relationships with parents and either distant or overly enmeshed romantic relationships, suggesting that attachment history might play a role in the experience of adult loneliness (Rubenstein & Shaver, 1982; Weiss, 1973). Also, social psychologists and anthropologists had observed that there is considerable variability in the way people approach love relationships (ranging from intense preoccupation to psychological distance), and they were developing individual-difference taxonomies to capture this variability (see Sternberg & Barnes, 1988, for examples). Despite these rich descriptions, there was no compelling theoretical framework within which to organize or explain the observed individual differences (Hazan & Shaver, 1994).

In an attempt to address this issue, Hazan and Shaver (1987) published an article in which they conceptualized romantic love as an attachment process, involving the interplay among attach-

ment, caregiving, and sexual behavioral systems. They noted that many of the emotional and behavioral dynamics characteristic of infant–mother attachment relationships also characterize adult romantic relationships. For example, both kinds of relationships involve caressing, ventral–ventral contact, and “baby talk.” More importantly, in each case, an individual feels safest and most secure when the other is nearby, accessible, and responsive. Under such circumstances, the partner may be used as a “secure base” from which to explore the environment. When an individual is feeling distressed, sick, or threatened, the partner is used as a “safe haven”—a source of safety, comfort, and protection.

Hazan and Shaver (1987; Shaver & Hazan, 1988) argued that the various approaches to love described by social psychologists reflect individual differences in the organization of the attachment system in adulthood. Specifically, they argued that the major patterns of attachment described by Ainsworth and colleagues (1978)—secure, anxious-resistant, and avoidant—are conceptually similar to the romantic attachment patterns observed among adults. Although Bowlby and Ainsworth had discussed the role of attachment in romantic relationships, no one had actually attempted to assess the individual differences noted among infants by Ainsworth and colleagues in the adult pair-bond context.

Attachment Style Questionnaires

When Hazan and Shaver (1987) began their work on romantic attachment, they adopted Ainsworth’s threefold typology from the Strange Situation paradigm as a framework for organizing individual differences in the ways adults think, feel, and behave in romantic relationships. In their initial studies, Hazan and Shaver developed brief multisentence descriptions of the three proposed attachment types—avoidant, secure, and anxious-resistant. The descriptions were based on an extrapolation of the three infant patterns summarized in the final chapter of Ainsworth and colleagues’ (1978) book. Research participants are asked to think back across their history of romantic relationships and indicate which of the three descriptions best captured the way they *generally* experience and act in romantic relationships. They refer to a person’s characteristic desires, feelings, and behaviors, and to comments made by relationship partners.

In their initial studies, Hazan and Shaver (1987) found that people’s self-reported roman-

tic attachment patterns related to a number of theoretically relevant variables, including beliefs about love and relationships (working models of romantic relationships) and recollections of early experiences with parents. With respect to their romantic relationships, secure people reported higher levels of happiness and trust. People endorsing the avoidant description perceived their mothers as cool and rejecting and, in their romantic relationships, reported a fear of intimacy, difficulty in accepting their partners, and a general belief that romantic love does not last. Anxious-ambivalent adults also reported conflicted relationships with parents and were more likely to report feelings of obsession and jealousy in romantic relationships. Not surprisingly, many researchers adopted Hazan and Shaver’s categorical, forced-choice measure because of its novelty, brevity, face validity, and ease of administration.

In 1990, Bartholomew published an important article that challenged researchers to reconsider the three-category model of individual differences in adult attachment. Integrating ideas from a variety of perspectives, Bartholomew argued that people hold separate representational models of themselves (Model of Self) and their social world (Model of Others)—models that have distinct consequences for the way attachment behavior is organized. The Model of Others reflects the expectations, beliefs, and strategies that people have concerning close others in general, and attachment figures in particular. Individuals with a positive Model of Others view attachment figures as trustworthy, reliable, and dependable. Individuals with negatively valenced Models of Others lack confidence in peoples’ trustworthiness and dependability. The Model of Self reflects the valence of peoples’ views of themselves. People with a positive Model of Self see themselves as competent, autonomous, and worthy of love. People with a negative Model of Self lack confidence, harbor self-doubts, and are vulnerable to psychological distress.

Bartholomew argued that when these two kinds of representational models are crossed with valence (i.e., the models’ positivity or negativity), it is possible to derive four, rather than three, major attachment patterns. She borrowed names for the four patterns from a mixture of the Ainsworth and colleagues’ (1978), Hazan and Shaver’s (1987), and Main and colleagues’ (1985) typologies, calling the positive–positive group “secure,” the negative–positive group “preoccupied,” the positive–negative group “dismissing,” and the neg-

ative–negative group “fearful” (see Figure 27.1). Following Hazan and Shaver’s lead, Bartholomew and Horowitz (1991) developed the Relationship Questionnaire (RQ), a short instrument containing multisentence descriptions of each of the four types.

The wording of three of the four type descriptions (secure, preoccupied, and fearful-avoidant) is very similar to the wording of the three Hazan and Shaver (1987) descriptions (secure, anxious-ambivalent, and avoidant). In fact, Bartholomew (1990) essentially equated the secure categories between the two systems, as well as the anxious-ambivalent pattern. In Bartholomew’s model, however, the avoidant type is split into two distinct types. The first kind of avoidance, *fearful-avoidance*, captures the vulnerable, insecure form of avoidance reflected in the Hazan and Shaver avoidant category. These individuals are avoidant of intimacy because they fear being hurt by someone they love. The second type, *dismissing-avoidance*, is not represented in the Hazan and Shaver system. These kinds of individuals avoid intimacy, not because they consciously fear being hurt, but because they value independence and autonomy.

The RQ was more fully developed by Griffin and Bartholomew (1994a) to form the Relationship Styles Questionnaire (RSQ), a 30-item inventory with content from both the Hazan and Shaver (1987) descriptions and the RQ descriptions. The RSQ can be scaled to create a score for each person on each of the four attachment patterns. Due to its multi-item nature, the RSQ exhibits somewhat higher reliability than the RQ (r ’s of about .65 for the brief scales assessing each of the four attachment patterns; Fraley & Shaver, 1997). Also, the RSQ can be used to score people on the two dimensions (Model of Self and Model of Other) that underlie these patterns. Roisman, Holland, and colleagues (2007) analyzed several alternative scoring systems and recommended one based on Simpson, Rholes, and Nelligan (1992) that provided a better fit to the data than some alternatives (see also Kurdek, 2002).

The Evolution of Measurement Systems

By the mid-1990s, there was some consensus in the social–personality literature that the Bartholomew

FIGURE 27.1. Two-dimensional model of individual differences in adult attachment, per the social–personality tradition.

model was better suited for capturing individual differences than the original Hazan and Shaver model. But there was still lingering concern over whether it was ideal to classify people or to scale them with respect to one or more dimensions. The classification system was potentially valuable because it provided a parallel to the developmental literature and the SSP and AAI attachment patterns. The classification system was also useful because it made it relatively easy to conceptualize the psychological dynamics underlying the various attachment styles.

Nonetheless, a number of limitations began to emerge with the categorical system. First, the classifications were not highly stable. For example, Baldwin and Fehr (1995) observed that the test-retest stability of the categorical measure was only 70% (equivalent to a Pearson's r of approximately .40). Some researchers began to wonder whether some of that instability was due to attempting to assign people to categories who might, in fact, be somewhere near the boundaries in a dimensional space. Second, the categorical system treated the four categories as if they were mutually exclusive, but data from continuous measurements suggested that they were not. Finally, the categorical system disregarded within-category variance that, in practice, seemed useful for predicting outcomes.

As a result of these tensions, some researchers began to use the ratings as a way to scale people in a dimensional space. This led to two problems. First, there was no principled reason for moving from categories to continua. Second, for each self-report measure that was developed and used, there was a different set of scales that varied in number and their interpretation. We discuss each of these problems in turn.

Types versus Dimensions

Although the gradual move from classifications to ratings was an important step toward improving the measurement of adult attachment, these shifts begged a larger theoretical question: Do people vary continuously or categorically with respect to attachment? This question, sometimes referred to as the "types versus dimensions" question, is a critical one for the study of adult attachment. If people actually vary continuously in attachment organization, but researchers assign people to categories, then important information about individual differences is lost. This loss can have deleterious effects on the study of continuity and change; on mapping of the developmental ante-

cedents and consequences of attachment experiences; on understanding whether certain experiences affect attachment organization; and on bridging the gaps between attachment research in social, personality, clinical, and developmental psychology.

How can one determine whether variation in an unobservable construct, such as attachment organization, is continuous or categorical? Historically, researchers relied on clustering techniques to identify groupings in data (e.g., Collins & Read, 1990; Feeney, Noller, & Hanrahan, 1994). One of the limitations of clustering techniques, such as cluster analysis or latent profile analysis, however, is that they reveal groupings in data regardless of whether natural groupings actually exist. Fortunately, Meehl and his colleagues (e.g., Meehl & Yonce, 1996; Waller & Meehl, 1998) developed a suite of techniques that allow one to uncover the latent structure of a domain and rigorously test taxonic (i.e., typological) conjectures. Fraley and Waller (1998) adopted two of Meehl's techniques, MAXCOV and MAMBAC, to address the types vs. dimensions question in the study of adult attachment. Taxometric analyses of the data from Griffin and Bartholmew's (1994a) RSQ from over 600 undergraduates provided no evidence for a categorical model of attachment, but were consistent with a dimensional model of individual differences (see also Fraley, Hudson, Heffernan, & Segal, 2015).

What Are the Fundamental Dimensions Underlying Adult Attachment?

In the 1990s, a number of investigators began creating multi-item inventories of adult attachment that could be used to produce continuous attachment scores. Although rooted in Bowlby and Ainsworth's attachment theory, the designers emphasized different constructs and used different methods of test development. Some researchers simply decomposed the items in the original Hazan and Shaver (1987) paragraphs. For example, Collins's (Collins & Read, 1990) Adult Attachment Scale (AAS) was developed by taking the individual sentence fragments in the original Hazan and Shaver descriptions and creating 18 distinct items, each of which was rated on a continuous scale. Based on her psychometric analyses of the items, Collins (Collins & Read, 1990) derived three composites: close, depend, and anxiety. Feeney and colleagues (1994) developed new items designed to capture themes in attachment

theory, such as trust, dependence, and self-reliance. A factor analysis of responses to their items uncovered five factors: self-confidence, discomfort with closeness, need for approval, preoccupation with relationships, and the belief that relationships are of secondary importance. Brennan and Shaver (1995) followed a similar approach, generating a large pool of items, which they then factor analyzed. Brennan and Shaver reported seven factors: ambivalence, anxious clinging to partners, jealous and fear of abandonment, frustration with partners, proximity seeking, self-reliance, and trust.

By the mid- to late 1990s, researchers were likely to be overwhelmed by the sheer number of self-report instruments in the literature. To address this problem, Brennan, Clark, and Shaver (1998) gathered all known self-report measures of adult attachment and administered the non-redundant items to 1,086 undergraduates. Factor analyses of the responses revealed two major factors that they labeled attachment-related *anxiety* and attachment-related *avoidance*. The anxiety factor was defined by items such as “I worry that my partner won’t want to stay with me” and “I don’t think my partner loves me.” The avoidance factor was defined at one end by items such as “I am uncomfortable depending on others,” and at the opposite end, “I turn to my partner for assurance.”

The Brennan report was a substantial advance for three reasons. First, the analyses revealed that the diverse pool of self-report measures of adult attachment was essentially tapping two fundamental domains. Second, it showed how measures originally developed with different objectives could be mapped onto a common dimensional framework. Finally, Brennan and her colleagues (1998) used their data to produce a new questionnaire, the Experiences in Close Relationships (ECR) inventory—a 36-item questionnaire based on the items that best tapped the dimensions of anxiety and avoidance. Brennan and colleagues showed that the 18 items for each subscale hung together well (alphas > .90) and the scales predicted a number of potentially relevant outcomes, such as emotions experienced in an intimate context. The ECR and its derivatives (e.g., the revised ECR [ECR-R]; Fraley, Waller, & Brennan, 2000) are currently the most commonly used self-report measures of adult attachment and are recommended as the primary self-report instruments for assessing adult attachment. The ECR-R is based on an item response theory

analysis of the original item pool used by Brennan and colleagues and produces scores that are highly correlated with those from the ECR. The ECR-S is a shorter version of the original ECR using 12 items instead of 36 items (Wei, Russell, Mallinckrodt, & Vogel, 2007). Each of these measures has excellent psychometric properties (e.g., Cronbach alphas of .85 or higher) and are in widespread use in contemporary research in social and personality psychology.

What do these two dimensions represent theoretically? Within Bartholomew’s framework, individual differences are conceptualized in terms of a person’s cognitive representations of the self and others. But most self-report instruments appear to be more explicitly concerned with motivations, thoughts, and feelings in close relationships rather than the valence of the cognitions they hold about themselves or others (e.g., Fraley & Shaver, 2000). Thus, in this chapter in the previous edition, we suggested that the dimensions be interpreted within the framework of behavioral–motivational systems rather than models of self–other per se. The distinction between these alternatives might be viewed as pedantic, but we have found that the behavioral–motivational system framing is helpful for situating the study of individual differences within normative models of how the attachment system operates. According to Hazan and Shaver (1994), individual differences in attachment patterns are attributable to two different components of the attachment system. One component involves monitoring of the psychological proximity and availability of the attachment figure. When either the attachment figure is perceived as being available and responsive (the “secure” stance), or the attachment figure’s availability is not viewed as relevant to or useful in attaining personal safety, an individual can focus on other issues and goals (e.g., exploration). Stable variation in these states is reflected in individual differences on the attachment anxiety dimension (Fraley & Shaver, 2000). The second component of the system concerns the regulation of attachment behavior with respect to attachment-related concerns. For example, to regulate attachment-related anxiety, people can either seek contact with an attachment figure (i.e., use the figure as a safe haven) or withdraw and attempt to handle the threat alone. The propensity to engage in secure-base strategies versus deactivating the system is reflected in individual differences on the avoidance dimension (see Mikulincer & Shaver, 2007).

The Nomological Network and Construct Validity

As explained earlier, the AAI coding system was initially developed empirically to maximize the prediction of an *infant's* classification in the Strange Situation paradigm. In this sense, there was an obvious “gold standard” for the AAI’s validity—the categories of the Strange Situation paradigm that are based on extensive home and laboratory observations of infants’ behavior. In contrast, the self-report instruments in the Hazan and Shaver tradition were not designed to predict any single criterion. Instead, their validity and the value of the research tradition from which they derive rest on their ability to reproduce empirically the network of covariates postulated by the theory (Cronbach & Meehl, 1955). In this section, we discuss the construct validity of measures of adult romantic attachment, focusing on relationship processes, the dismissing strategy in particular, and general adjustment and psychopathology (for more detailed reviews, see this chapter in previous editions of this volume; Mikulincer & Shaver, 2007).

The Rationale for Assessing Adult Romantic Attachment with Self-Report Methods

There are several reasons why self-report instruments are useful tools for investigating individual differences in adult attachment. First, according to Bowlby, attachment dynamics play an important role in people’s emotional experience. Thus, in many respects, assessing those experiences is an important step in studying the implications of attachment dynamics. Self-reports are an obvious means for doing so, although we recognize that rating scales per se represent only one of many ways in which researchers can study experience. Second, most adults have sufficient experience in close relationships to recount how they behave in such relationships and the kinds of things their partners have said to them about their behavior. We do not assume that such reports are error free or that they are not subject to various motivated biases (e.g., Simpson, Rholes, & Winterheld, 2010), but they are useful for studying statistical relations among constructs.

Some scholars have wondered whether self-reports can be useful to assess attachment dynamics when some of these dynamics are likely to be relatively inaccessible or unconscious. Indeed, some people may report that they are not anxious

when actually they are; others may simply lack insight into their true motives and behavior. Nonetheless, it is possible to use attachment theory to derive the kinds of beliefs that prototypically avoidant or dismissing people may hold about themselves. For example, a dismissing person should believe that he or she is “independent” and “self-sufficient,” does not “worry about abandonment,” and maybe even does not “need close relationships.” Holding such beliefs is an important part of defensively excluding unwanted thoughts and emotions. It is a separate question—and an important one—whether people endorsing such statements in a questionnaire actually do or do not function well without others. Although self-reports are frequently used to assess individual differences in attachment security, they are rarely used alone to investigate the dynamics of attachment. To probe these deeper issues, researchers often pair self-reports with a variety of behavioral, cognitive, and psychophysiological tasks (see Mikulincer & Shaver, 2007, for a review).

Attraction and Relationship Formation

Cross-cultural studies suggest that the secure pattern of attachment in infancy is universally considered the most desirable pattern by mothers. Similarly, adults seeking long-term relationships identify responsive caregiving qualities, such as attentiveness, warmth, and sensitivity, as most “attractive” in potential dating partners (e.g., Chappell & Davis, 1998; Frazier, Byer, Fischer, Wright, & DeBord, 1996).

Despite the attractiveness of secure qualities, however, not everyone is paired with a secure partner. Some evidence suggests that people end up in relationships with partners who confirm their existing beliefs about attachment relationships (Collins & Read, 1990; Frazier et al., 1996). In research that has employed social-cognitive methods for studying transference processes, Brumbaugh and Fraley (2006) found that people who held negative representations of significant others (parental or romantic) from their pasts were more likely to feel insecure with novel relationship partners. This suggests that although most people would prefer a supportive partner if given a choice, people tend to reexperience thoughts and feelings in new relationships due to the ways in which existing representations shape new experiences.

Recently researchers have attempted to explain how attachment-related anxiety may compromise relationship opportunities. McClure and

Lydon (2014), for example, studied the behavior of individuals who were engaged in a speed-dating task. Their analyses revealed that people who were high in attachment-related anxiety were more likely to feel conflicted in speed-dating contexts, and that their insecurities spilled over into their behavior (e.g., verbal dysfluencies and interpersonal awkwardness). As a result of these displays, individuals high in attachment-related anxiety were considered less desirable by other speed-daters, which reinforced the negative expectations that they held.

Relationship Maintenance: Implications for Secure-Base and Safe-Haven Behavior

Overall, secure adults tend to be more satisfied in their relationships than insecure adults. Their relationships are characterized by greater longevity, trust, commitment, and interdependence (e.g., Simpson, 1990), and they are more likely to use romantic partners as a secure base from which to explore the world (Feeney & Thrush, 2010; Fraley & Davis, 1997; see also B. C. Feeney & Woodhouse, Chapter 36, this volume). A large proportion of research on adult attachment has been devoted to uncovering the behavioral and psychological mechanisms that promote security and secure-base behavior in adults. There have been two major discoveries thus far. First, and similar to the developmental attachment tradition, secure adults are more likely than insecure adults to seek support from their partners when they are distressed and to provide support to their distressed partners. Second, the attributions that insecure individuals make concerning their partners' behavior during and following relational conflicts exacerbate, rather than alleviate, their insecurities.

Concerning the first dynamic, Simpson and colleagues (1992) found that overtly distressed secure women were more likely than insecure women to seek emotional support from their partners. Also, secure men were more likely than insecure men to provide support to their distressed partners. Fraley and Shaver (1998) found that secure women who were separating from their partners in an airport were more likely than insecure women to express their anxiety, seek comfort from their partners, and provide comfort for their partners. In contrast, avoidant women were more likely to pull away or withdraw from their partners. Collins and Feeney (2000) found that secure individuals were more likely to offer care and support to their partners during a laboratory discussion of a stressful event.

These findings suggest that part of the reason why some individuals feel more secure in their relationships is that they openly express their worries and receive reassurance and support (B.C. Feeney, 2007). Furthermore, the data suggest that some people feel insecure in their relationships because they cannot turn to their partners for comfort and support. There are at least two explanations for this. First, it may be that having a responsive partner influences the way an individual comes to think and behave in a relationship. Second, individuals who enter relationships with secure expectations are more likely to seek support from others and to elicit responsive behavior from them.

In support of the first interpretation, Simpson, Rholes, and Phillips (1996) observed partners who were instructed to discuss and resolve a major issue in their relationship. They found that anxious adults were more likely to view their partners in a negative light after a major conflict. These adults felt more anger and hostility toward their partners than less anxious individuals, and viewed their relationship as involving less love, commitment, and mutual respect. In contrast, secure individuals viewed their partners in a more positive light after discussing a conflictual topic. Thus conflictual relationship events, despite their negative valence, may provide an opportunity for secure individuals to build their trust in each other. In contrast, such conflicts appear to magnify insecure partners' insecurities and doubts.

Research also suggests that the beliefs and expectations people hold prior to entering a relationship affect secure-base behavior and relationship development. Collins (1996) conducted an experiment in which participants were instructed to read hypothetical scenarios depicting a partner behaving in ambiguous ways (e.g., losing track of the partner at a party). She found that anxious participants inferred hostile and rejecting intentions, whereas secure participants inferred more positive intentions.

Attachment Styles and Parenting Behavior

Although most of the early research on parent-child interactions was conducted in the developmental tradition using the AAI to assess parents' state of mind with respect to attachment, a growing number of investigators have begun to explore the association between self-reported attachment style and parenting behavior. In one of the earliest studies on this topic, for example, Rholes, Simpson, and Blakely (1995) found that adults who were

relatively avoidant were less likely than those who were secure to be sensitive and supportive in their interactions with their children. Jones, Cassidy, and Shaver (2015), who recently reviewed over 60 empirical studies on attachment styles and parenting, found that self-reported attachment was related to a variety of parenting outcomes, including parenting behavior (e.g., the provision of support), feelings about parenting and parenthood (e.g., the desire to have children, ambivalence about parenthood), and expectations and attitudes concerning parenting (e.g., perceptions of the child's difficulty). As Jones and his colleagues note, this kind of work is valuable for a number of reasons. For one, it demonstrates that attachment styles, as they are typically studied in the social-psychological tradition, have implications not only for romantic relationship functioning, but also for parenting. This helps make more explicit the interrelations among attachment and caregiving that have been central to the attachment-theoretical tradition but often are overlooked among social psychologists. This work also provides a point of contact between developmentally informed research and research in social psychology—a common ground that may be useful for understanding how alternative ways of assessing individual differences converge and where they diverge.

Continuity and Change

Researchers studying continuity and change typically focus on both *normative continuity* (i.e., continuity in mean-levels across time) and *rank-order stability* (i.e., preservation in the ordering of individual differences across time). With regard to normative continuity and change, large-scale cross-sectional research by Chopik, Edelstein, and Fraley (2013) indicates that attachment-related anxiety is highest among younger adults and lowest among middle-aged and older adults. Attachment-related avoidance shows less dramatic age differences but is lowest in younger adults and highest in middle-aged adults. In addition, across the lifespan, people who are involved in romantic relationships report lower levels of anxiety and avoidance than do single individuals.

With respect to rank-order stability, research suggests that self-report measures of attachment are relatively stable across time. For example, Sibley, Fisher, and Liu (2005) reported that test-retest measures of anxiety and avoidance, measured with the ECR-R, were approximately .90 over a period of 3 weeks. Using a derivative of the ECR-R (to

be discussed in more detail below), Fraley, Vicary, Brumbaugh, and Roisman (2011) found that the test-retest stability of attachment styles was relatively constant whether the test-retest interval was 6 months or 1 year. This pattern of associations implies that there is a stable component to measures of adult attachment that underlies the occasion-to-occasion changes observed across interim assessments.

Developmental Antecedents

A number of longitudinal studies that have emerged in recent years investigated the developmental antecedents of self-reported attachment styles. For example, in an analysis of data from 15 individuals followed longitudinally, Zayas, Mischel, Shoda, and Aber (2011) found associations between maternal caregiving assessed when infants were 18 months old and self-reported romantic avoidance at age 22. In a larger study involving 1,070 individuals followed from age 10 to age 21 and 27, Salo, Jokela, Lehtimäki, and Keltikangas-Järvinen (2011) found that early maternal nurturance was negatively prospectively related to avoidant attachment. Dinero, Conger, Shaver, Widaman, and Larsen-Rife (2008) found that the quality of observed interactions between adolescents and their parents predicted self-reported attachment at age 25. Chopik, Moors, and Edelstein (2014) found that individuals who had highly nurturing caregivers at age 3 experienced the largest decreases in avoidance over 20 years. Fraley and colleagues (2013) found that features of the caregiving environment, social competence, and the quality of peer relationships predicted some aspects of self-reported attachment at age 18. A variety of nonlongitudinal studies also suggests that variation in self-reported attachment is related to retrospectively recalled experiences, such as the quality of the parent-child relationship (e.g., Hazan & Shaver, 1987), parental divorce (e.g., Fraley & Heffernan, 2013), and the experience of parental abuse and neglect (e.g., Muller, Sicoli, & Lemieux, 2000).

A few broad conclusions can be drawn from this work, although we acknowledge that these conclusions are tentative given the relative dearth of large-scale, longitudinal research. First, although some research suggests that individual differences in attachment, as assessed via self-reports, may have their origins in early caregiving experiences, there is little compelling evidence to suggest that early experiences per se (i.e., independent of care-

giving experiences that come later) play a direct role in shaping those differences. The work by Fraley and colleagues (2013), for example, suggests that understanding variation in attachment requires attention to developmental history (e.g., changes in parental sensitivity or the quality of peer relationships) writ large and not merely what transpires in the early years of life (see also Steele et al., 2014). Second, self-reported attachment styles are likely multidetermined. Some investigators, for example, have found that the mere recall of different kinds of relationship experiences may affect the attachment style that people report (Baldwin, Keelan, Fehr, Enns, & Koh-Rangarajoo, 1996). Fraley (2007) suggested that attachment styles might represent an aggregation of people's attachment-related experiences, potentially with the most accessible experiences being those that are most recent or those that are chronically activated.

The Dismissing Strategy

According to attachment theory, people differ in the strategies they adopt to regulate the distress associated with nonoptimal caregiving. Following a separation and reunion, for example, some insecure children approach, but with ambivalence and resistance; others withdraw, apparently minimizing attachment-related feelings and behavior (Main & Weston, 1981). These different strategies have been referred to as "hyperactivating" or "maximizing" strategies and "deactivating" or "minimizing" strategies, respectively (Cassidy & Kobak, 1988; Fraley, Davis, & Shaver, 1998; Main, 1990). Researchers studying romantic attachment have attempted to illuminate some of the mechanisms underlying these behavioral strategies. In an experimental task in which adults were instructed to discuss losing their partners, Fraley and Shaver (1997) found that dismissing individuals were just as physiologically distressed (as assessed by skin conductance measures) as other individuals. When instructed to suppress their thoughts and feelings, however, dismissing individuals were able to do so effectively. That is, they could deactivate their physiological arousal to some degree and minimize the attention they paid to attachment-related thoughts. (Interestingly, preoccupied adults experienced an increase in arousal, relative to control conditions, when trying to suppress attachment-related anxiety.) Fraley and Shaver argued that such deactivation is possible because avoidant individuals (1) have less complex net-

works of attachment-related representations, (2) can effectively redirect their attention away from anxiety-provoking stimuli, and (3) can keep their interpersonal world structured so as to minimize attachment-related experiences.

In support of these propositions, Mikulincer and Orbach (1995) found that when asked to recall emotional childhood memories, avoidant adults recalled memories that were characterized by emotional discreteness. That is, when asked to recall a sad memory, avoidant individuals recalled memories that contained only elements of sadness and not elements of anger and anxiety, which tended to be present in the sad memories of secure and especially of preoccupied individuals. Fraley, Garner, and Shaver (2000) found that these recall processes were partly attributable to the way information is encoded rather than the way it is retrieved per se. Indeed, using both explicit and implicit tests of memory, Fraley and Brumbaugh (2007) found that highly avoidant individuals had difficulty remembering attachment-relevant information—even when they were offered financial incentives to recall as much of the information to which they had been exposed as possible.

Research has shown that highly dismissing individuals are less likely to engage in attachment behaviors with their partners (Fraley & Davis, 1997) and are less likely to engage in behaviors thought to promote affectional bonding, such as eye-to-eye contact, kissing, and open communication about feelings (Fraley et al., 1998). In summary, highly dismissing individuals organize their interpersonal behavior in a way that functions to minimize attention to and the experience of attachment-related thoughts and feelings (Fraley et al., 1998).

It should be noted, however, that these strategies can be undermined. Mikulincer, Dolev, and Shaver (2004) utilized a thought suppression paradigm similar to that used by Fraley and Shaver (1997) and found that highly avoidant people did not show even implicit indications of vulnerability after having thought about a relationship breakup; however, when they were placed under a cognitive load (having to remember a seven-digit number), concepts related to breaking up, as well as each avoidant person's own negative traits, became much more available, suggesting that avoidance can be broken down (as is the case with avoidant infants who are overstressed). These studies and others (Berant, Mikulincer, & Shaver, 2008) suggest that strategies used by avoidant individuals require cognitive effort.

General Adjustment and Psychopathology

In general, individuals who are secure with respect to attachment have high self-esteem and are considered well adjusted, nurturing, and warm by their peers (Bartholomew & Horowitz, 1991). As found in studies using the AAI, this kind of self-esteem is also meaningfully related to attachment organization. For example, although autonomous and dismissing adults typically report high levels of self-esteem, Brennan and Morris (1997) found that secure adults were more likely to derive their self-esteem from internalized positive regard from others, whereas dismissing adults were more likely to derive their self-esteem from various abilities and competencies.

Not surprisingly, adults with a variety of clinical disorders are more likely to report themselves as insecure (see Mikulincer & Shaver, 2007). Depressed adults are more likely to report themselves as insecure (Carnelley, Pietromonaco, & Jaffe, 1994), as are individuals with eating disorders (Brennan & Shaver, 1995; Burge et al., 1997). College students who felt their parents had drinking problems were more likely to rate themselves as insecure (Brennan, Shaver, & Tobey, 1991) and reported they were more likely to “drink to cope” (Brennan & Shaver, 1995).

Brennan and Shaver (1998) examined the structure of self-report measures of 13 personality disorders (e.g., schizoid, paranoid, avoidant, obsessive-compulsive) and discovered that two of the three dimensions underlying these scales are the now-familiar dimensions underlying adult romantic attachment patterns (see Crawford et al., 2006). Woike, Osier, and Candella (1996) examined the association between self-reported attachment and the use of violent imagery in the Thematic Apperception Test (TAT). They found that anxious individuals were the most likely to use violent imagery, and they suggested that such imagery may stem from frustration with romantic partners who thwart attachment needs. Consistent with this line of reasoning, Dutton, Saunders, Starzomski, and Bartholomew (1994) found a high incidence of fearful and preoccupied men (i.e., the two groups highest on the anxiety dimension) within a sample that had been referred for treatment for wife assault.

Discriminant Validity

Evidence for the construct validity of self-report measures of adult attachment comes from the no-

logical network (Cronbach & Meehl, 1955) of correlations between attachment measures and theoretically relevant variables. And the network corresponds with Bowlby's (1980) belief that attachment orientation is related to many aspects of a person's life. Still, the validity of self-report attachment measures would be called into question if they overlapped too much with measures of constructs viewed as theoretically distant from attachment. Some writers have expressed concern over the possibility that self-report measures of adult attachment are simply assessing relationship satisfaction (Bartholomew, 1994). Although security is correlated with relationship satisfaction, whether assessed with the AAI or with self-report attachment measures, the average magnitude of the correlation in the case of self-report attachment measures is only about .30 (see Mikulincer & Shaver, 2007, for a review). Thus, the correlation is not high enough to suggest that self-report measures of attachment and measures of satisfaction assess the same construct.

Research on adult personality has pointed to a five-factor model of personality (John, 1990; McCrae & Costa, 1990), with the factors being Neuroticism, Extraversion, Openness to Experience, Agreeableness, and Conscientiousness. Thus, questions arise concerning how the two major attachment dimensions fit into this structure and whether they are redundant with one or more of the five factors. Nofle and Shaver (2006) examined associations between the five traits and the attachment dimensions in over 8,000 students; they found that the anxiety dimension was correlated about .42 with Neuroticism, and that avoidance was correlated approximately -.22 with Agreeableness. Thus, the attachment dimensions, when assessed via self-reports, share variance with some of the major personality traits, but are not redundant with those traits. In fact, experimental studies of attachment processes (e.g., Mikulincer, Gillath, & Shaver, 2002) indicate associations between the attachment dimensions and theoretically predicted outcome variables, including behavior, when, for example, Neuroticism is statistically partialled out. Even in concurrent survey research, the attachment variables predict relationship outcomes better than the “Big Five” trait variables (e.g., Nofle & Shaver, 2006). Self-report measures of adult attachment are largely independent of verbal intelligence and social desirability response set (Fraleigh et al., 1998; Kuncze & Shaver, 1994; Mikulincer & Orbach, 1995).

Current Issues in the Measurement of Adult Romantic Attachment with Self-Reports

The field continues to evolve in new directions, and this growth has led to new challenges and opportunities. In the sections below, we highlight briefly two new issues that have become particularly salient since the previous edition of this volume.

Hierarchical Models

For the most part social–personality psychologists have conceptualized and assessed adult attachment orientations as if they were domain-general interpersonal constructs. In other words, attachment styles are typically viewed as being relatively general cognitive structures that represent the history of a person’s experiences in attachment relationships, and that have relevance for a broad array of contexts, including interpersonal relationships, mental health, and emotion regulation. Collins and Read (1994), however, suggested that there may be value in considering multiple working models in adult attachment research. Specifically, they noted that people hold not only global representations of attachment, but also relationship-specific models. Moreover, they argued that these attachment representations are hierarchically organized. People hold relatively global attachment representations of attachment relationships. But, nested within those, are representations of increasing specificity, including broad representations concerning parents and peers, and, nested within those, representations concerning specific individuals, for example, one’s partner, one’s mother (see Figure 27.2). Overall, Fletcher and Friesen (2003) provided empirical evidence in support of a hierarchical model by demonstrating that separate measures of attachment across multiple relational domains conformed to the predictions of a hierarchical model. Specifically, they showed that although a single latent variable could partially capture the associations among various relationship-specific measures of attachment, a hierarchical ordering in particular provided a better account of the data.

This hierarchical model has a number of implications for assessment and research (Overall et al., 2003). First, the stability of attachment representations may vary considerably as a function of the specificity of the representation (global vs.

relationship-specific). Research has shown that the test–retest stability of global representations in romantic relationships is larger than the stability of relationship-specific representations of partners. For example, the test–retest stability of scores on the ECR-R—a general measure of romantic attachment—is close to .90 over 3 weeks (Sibley et al., 2005), whereas the test–retest stability of attachment toward a specific romantic partner is .65 (Fraley, Vicary, et al., 2011).

The stability of self-reported attachment in different types of relationship contexts may vary, too. Fraley, Vicary, and colleagues (2011) found that relationship-specific self-reports of attachment in romantic relationships ($r \cong .65$) were weaker than those of relationship-specific measures of attachment in people’s current relationships with their parents ($r \cong .80$). They speculated that this differential stability may be due to people having more established histories with their parents relative to their romantic partners. Because many adults do not interact with their parents as frequently as they interact with their romantic partners, there may be less room for people’s cognitions of their partners to be updated in light of ongoing experiences. Regardless, estimates of stability can vary at different points in the hierarchy, and this can matter greatly for efforts to understand continuity and change in attachment organization.

A second implication of the hierarchical model is that different kinds of attachment representations may be differentially relevant for predicting outcomes. Cozzarelli, Hoekstra, and Bylsma (2000) modified Bartholomew’s RQ measure to assess separately people’s general thoughts and feelings about others and their thoughts and feelings about their current partner. They found that partner-specific attachment had stronger and more numerous associations with relational outcomes than did general working models. General attachment, however, was strongly associated with broad measures of psychological well-being (see also Pierce & Lydon, 2001).

Assessment

How should individual differences in attachment be assessed within the framework of a hierarchical model? For the most part, research on these issues has been improvised on a study-by-study basis. Some investigators, for example, have adopted Bartholomew and Horowitz’s (1991) RQ and framed it in different ways to tap the desired level

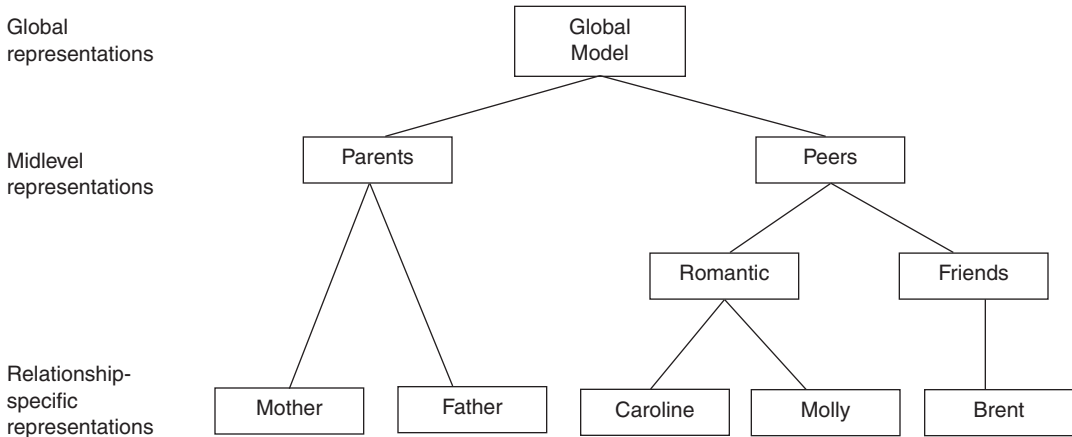

FIGURE 27.2. The hierarchical organization of attachment representations within the Collins and Read (1994) framework. The ECR and the ECR-R tends to focus on romantic representations within the midlevel tier. The ECR-RS tends to focus on relationship-specific representations. The RQ is typically used in a more general fashion or may be used to separately target parents and peers at the midlevel tier.

of generality (e.g., Cozzarelli et al., 2000). Other researchers have used measures such as the ECR (e.g., Brumbaugh & Fraley, 2006). The limitation of using different assessment strategies across laboratories, however, should be clear: Doing so makes it challenging to build a cumulative base of knowledge on the issues of interest.

Fraley, Heffernan, Vicary, and Brumbaugh (2011) attempted to solve this problem through the development of the Experiences in Close Relationships—Relationships Structures (ECR-RS), a self-report inventory modeled after the ECR and the ECR-R. They identified nine items that could be used to assess anxiety and avoidance separately in different relationship contexts (e.g., mother, father, partner, and friend). By using the same items but administering them separately across different relationship contexts, it is possible to study the convergence and divergence in attachment across domains without also conflating method with domain. The ECR-RS has been used with increasing frequency in the literature, and studies indicate that people who are relatively secure in one relationship domain also tend to be secure in another. However, there are noteworthy discrepancies. For example, Fraley, Heffernan, and colleagues reported that attachment-related avoidance with respect to how people felt about their mothers correlated only .15 with attachment-related avoidance in the romantic domain.

One limitation of the original ECR-RS is that it does not explicitly assess global attachment representations. It can be averaged across domains to estimate global attachment, which is useful strategy if one is simply trying to obtain a global measure as an end, in and of itself, but it complicates research if researchers are explicitly interested in modeling variation in an outcome as a function of both global and relationship specific models because the global models are fully linearly related to the specific models in such contexts. As such, Fraley and colleagues (2015) have more recently recommended assessing global models separately, but using the same ECR-RS item pool.

State-Based Assessment and Priming Individual Differences

A growing body of work has focused on experimentally manipulating attachment orientations as a means for testing conceptual models of how variation in attachment may shape thoughts, feelings, and behavior. Of course, there are no clear and obvious means to manipulate a person's attachment style experimentally in any kind of deep and fundamental way, but one way to gain insight into attachment dynamics is by manipulating situations in ways that temporarily lead to increases in experienced security or insecurity.

This reasoning has led to two new and exciting developments in the social-psychological study of adult attachment. First, researchers have developed methods for temporarily priming attachment styles in ways consistent with theoretical models of individual differences. Second, researchers have developed ways to assess attachment-related states separately from the more dispositional representations that people hold of themselves and their attachment figures. These measures allow for a more nuanced understanding of how various contextual and psychological manipulations may lead to temporary changes in attachment functioning.

Manipulating Individual Differences

Efforts to manipulate individual differences in attachment quality have their origins in social-psychological manipulations of context. For example, in their classic research, Simpson and colleagues (1992) exposed couples to a potentially distressing situation designed to activate their attachment orientations. As several investigators later realized, manipulating the situational context also provides an indirect way to manipulate components of the attachment system itself (e.g., Mikulincer et al., 2002). That is, placing a person in a situation in which the availability and responsiveness of his or her partner is called into question is comparable to manipulating the appraisals that people make regarding the availability and responsiveness of their partners. As such, these kinds of manipulations provide a potential means to probe the operation of the attachment system at a deeper level.

Mikulincer and his colleagues (2002) have utilized this strategy most overtly. For example, in one set of studies, they attempted to prime individual differences in insecurity by exposing people subliminally to threat- or neutral-word primes. They found that threat primes led to increased accessibility of representations of attachment figures as inferred from more rapid lexical decisions to the names of attachment figures.

This kind of strategy has been an influential way of probing the dynamics of the attachment system in the social-personality literature. But, unfortunately, there is not a *standard* way of probing the attachment system at the moment. Some researchers focus on using primes that are presented below the threshold of awareness (e.g., Mikulincer et al., 2002), whereas others use supraliminal primes and manipulations, and guided imagery tasks (e.g., Rowe & Carnelley, 2003). As a consequence of this diversity, it is unclear at the moment whether

some distinctions (e.g., sub- vs. supraliminal) matter for most purposes, which individual difference dimensions are most strongly affected by various manipulations, and which methods are more effective than others. To be clear: This kind of diversity is natural and expected when researchers are charting new empirical territory. But we believe that one of the core challenges for the field over the next few years will be to nail down these issues and create standard methods.

Another complication is that it is not clear which elements of the attachment system should be primed or what the appropriate reference group is. On the one hand, it seems straightforward to prime people's sense of insecurity with respect to anxiety. When people are asked to recall episodes in which they felt insecure about the availability or accessibility of their partners, such a manipulation is face valid with respect to its relevance for understanding variation in the extent to which people are concerned about the accessibility and responsiveness of their partners. But what about *security* priming? Some methods focus on priming security in particular, in part for ethical reasons (it is more defensible to attempt to experimentally manipulate something positive) and in part for theoretical reasons (e.g., to test the hypothesis that temporarily increasing security may lead to increases in prosocial behavior, such as compassion and altruism (e.g., Carnelley & Rowe, 2007; Mikulincer, Shaver, Gillath, & Nitzberg, 2005)). Such primes may involve exposing people to security-related words (e.g., *love*, *support*) or having people retrieve from memory episodes in which they felt loved and supported by attachment figures. Do existing security primes influence the anxiety dimension, the avoidance dimension, or both? Our guess is that many existing security primes create more movement on the anxiety axis than on the avoidance axis. But, ultimately, this is an empirical question. Based on an analysis of postpriming written protocols, Carnelley and Rowe (2010) suggested that security priming leads to increases in felt security, positive care, and a sense of merging with another, suggesting that such primes may move people through both dimensions of the two-dimensional space.

What is the optimal way of conceptualizing these issues? We do not have definitive answers, but we do offer two thoughts in the hope that they will be helpful for moving future research forward. First, in many respects, the core issue in the social-psychological tradition in attachment research is whether people feel safe, secure, loved, and ac-

cepted. Having a secure base, both literally and symbolically, enables people to explore the world in a less inhibited manner. Theoretically, this is what the anxiety dimension is designed to capture: individual differences in the extent to which people are concerned with the availability and responsiveness of close others. This may be the most natural variable to manipulate in an experimental context. Our guess is that current security primes manipulate the anxiety dimension in one direction and insecure primes manipulate it in the other, but that none of the existing priming procedures are manipulating avoidance in a way that is as direct as the way they are manipulating anxiety. More importantly, however, it might be the case that manipulating attachment-related anxiety is more theoretically central than manipulating avoidance, at least for most purposes.

Second, manipulating avoidance seems like a challenging task given the way avoidance is conceptualized in most theoretical models. In the process models typically depicted in the adult attachment literature (e.g., Fraley & Shaver, 2000; Mikulincer & Shaver, 2007), avoidance reflects a secondary strategy. Specifically, when a person's attachment system is activated (as may be reflected in a temporary boost in attachment-related anxiety), the person may attempt to regulate that anxiety by seeking proximity and comfort from attachment figures or withdrawing from others (i.e., engaging in deactivating strategies). Thus, the activation of anxiety fuels movement along the avoidance dimension and in a direction that is biased toward the person's habitual strategy for regulating attachment-related concerns. This suggests that it might not be possible to manipulate anxiety without also nudging people toward their prototypical strategies for regulating anxiety.

Nonetheless, Fraley and Shaver (1997), for example, attempted to manipulate deactivating strategies by instructing people to inhibit the expression of attachment-related concerns. They also attempted to manipulate anxiety separately by instructing people to imagine the loss of their partner. Mikulincer and colleagues (2004) used a similar procedure but attempted to disrupt the potential efficacy of deactivating strategies by depleting people's cognitive resources. That is, if fewer cognitive resources are available to the person, the strategies are less likely to be effective. This work suggests two possibilities: It might be possible to manipulate avoidance via explicit task instructions to avoid or suppress specific thoughts, feelings, or behaviors. In addition, if avoidance is

resource demanding, deleting a person's cognitive resources may provide an indirect means also to manipulate avoidance experimentally (more so than anxiety).

In summary, there are diverse methods that researchers have used to attempt to temporarily manipulate people's attachment orientations. In our opinion, most of these methods target variation in the anxiety dimension. However, we are not aware of systematic work that clearly maps these manipulations onto changes in attachment. We think future progress can be made by (1) creating standard or commonly used procedures for priming attachment, (2) delineating exactly which components of the attachment system are being varied with those manipulations, and (3) finding ways to vary attachment-related anxiety and avoidance separately to the extent to which it is feasible and useful.

State-Based Measures

The emerging interest in security priming in the social-personality tradition has led to a need to measure people's state-like thoughts and feelings with respect to attachment. State-based measures are designed to probe people about their momentary feelings, regardless of how they might feel in other moments. One recent measure that is proving useful in this regard is the State Adult Attachment Measure (SAAM; Gillath, Hart, Nofle, & Stockdale, 2009), which is based on a three-factor solution and provides state-based assessments of people feel in the moment. Research by Xu and Shrout (2013) suggests that the SAAM offers a highly reliable means for assessing state-based changes in attachment.

Discussion

From a topic area that hardly existed before 1985, the study of adult attachment has grown over the past three decades to become one of the most active and visible areas in developmental, social, personality, and clinical psychology. In general, the findings obtained by adult attachment researchers have been interesting, consistent, and compatible with Bowlby's and Ainsworth's theories. Nevertheless, the issue of measurement continues to present intriguing and important challenges. One problem is the lack of convergence among different measures of adult attachment. A number of

studies have included more than one measure of some aspect of adult attachment, including measures that tap different relational domains (e.g., relationships with parents or romantic partners) and embody different methods (e.g., interviews, self-reports). In the initial version of this chapter in first edition of the *Handbook of Attachment*, we reported an informal meta-analysis of such studies. The results indicated that the correlation between any two measures of adult attachment were affected both by domain (i.e., whether the measures were designed to assess some aspect of romantic relationships or some aspect of relationships with parents) and method (i.e., whether the measures were based on interviews or self-report). The correlation between different measures of security tended to be greater when there was a match between the method used (e.g., both measures based on self-report or both based on interviews) and the domain (e.g., both measures focused on parental representations or both measures focused on romantic representations).

One important example of this patterning is that the two most commonly used measures of adult attachment (i.e., self-reports of the attachment dimensions and the AAI classifications) have only a very weak association, despite the fact that the two kinds of measures sometimes have similar correlations with other variables (e.g., Granqvist & Kirkpatrick, Chapter 39, this volume; Simpson et al., 2002). Roisman, Holland, and colleagues (2007; see Haydon et al., 2011) published a meta-analysis of all available studies that included both the AAI and some self-report attachment style measure. Aggregating data from over 900 individuals, they found a correlation of only .09, which is a small association by the frequently used standards proposed by Cohen (1992). Moreover, in those particular studies, they found that although both measures predicted important aspects of close relationship functioning in adulthood, they did not necessarily predict the same outcomes in the same ways.

For example, AAI security seems to function as a general personal and interpersonal asset; highly autonomous or secure individuals were more likely to be collaborative in their laboratory interactions with their partners—just as scoring of the AAI itself addresses, in part, the ability and willingness of an interviewee to collaborate with an interviewer (see Hesse, Chapter 26, this volume). The attachment dimensions, in contrast, functioned more like what would be expected from a diathesis–stress perspective on attachment dy-

namics (e.g., Simpson & Rholes, 1998). Anxiety and avoidance were related to less collaborative interactions, but only among individuals who appraised the interaction as stressful or threatening (and, we suppose, were more likely to have their attachment systems activated).

Although we still do not fully understand how the different measures work and why, or precisely what they measure (as inferred from their broad and largely different nomothetic networks), it is clear that they should not be viewed as substitutes for each other in particular kinds of research. We therefore encourage researchers to use assessment techniques that are most relevant to the kind of relationship or attachment-related processes they wish to study. For example, if a researcher is interested in studying romantic attachment dynamics, he or she should use either one of the multi-item self-report measures (e.g., the ECR or ECR-R) or one of the romantic interview techniques (Crowell and Owen's [1996] CRI or Cowan and colleagues' [1999] CAI). If the researcher is interested in the coherence with which one describes early experiences with attachment figures, he or she should use the AAI. If the focus is on relationship-related emotions and behavior under stressful circumstances, especially as experienced and reported by the person him- or herself, the self-report measures may be more relevant. If the focus is on all of these things at once, it is possible that two kinds of measures will produce both useful findings and insights. Investigators interested in assessing the common variance underlying adolescents' and adults' various attachment orientations will have to assess attachment variation across multiple relationship domains (e.g., parents, close friends, romantic partners), preferably using a variety of methods (e.g., self-reports, interviews) and latent structural modeling techniques (see Griffin & Bartholomew, 1994b).

As we have explained throughout this chapter, each measure was developed for a particular purpose. Therefore, in determining which one or more instruments to use for a particular study, a researcher should consider the theoretical assumptions underlying each instrument. AAI coding is meant to tap an adult's generalized representation of attachment based on his or her current "state of mind with respect to attachment," as inferred from narrative measures of experiences with parents during childhood. Its focus on discourse is based on the assumption that the ability to describe secure-base experiences reflects the nature of those experiences. It is a rich and well-validated

measure that provides considerable information about perceived childhood experiences that may shape attachment patterns. Nevertheless, the AAI is expensive and difficult to score.

In contrast, the self-report attachment measures were designed under the assumption that the patterns Ainsworth described would reflect variation in the organization of the attachment system at any age. The self-report measures assume that people can accurately describe some of their thoughts, feelings, and behaviors in romantic or other close relationships. Such measures are not ideal for investigating mechanisms and strategies per se, but they have been effectively used in conjunction with other techniques (e.g., psychophysiological, behavioral, and cognitive procedures) to uncover important aspects of intrapsychic processes and behavior in close relationships.

In summary, before choosing a measure to assess adult attachment, researchers should consider (1) the assumptions underlying each technique, and the conceptual connection between a technique and the concepts and propositions of attachment theory, and (2) the relationship domain to be investigated (e.g., parents, close friends, romantic partners). In light of the substantial differences among adult attachment measures, we urge that considerable caution be taken in how researchers present their findings, and in how they generalize across measures with respect to attachment theory. Furthermore, we encourage researchers to continue to investigate the many measurement issues inherent in the study of adult attachment. There is still a great deal of work to be done before we understand relations and nonrelations among the various instruments and the best ways to assess normative development and individual differences in adult attachment organization. We hope this overview provides a useful basis for further exploration.

AND CLINICAL
APPLICATIONS**

Chapter 28

Attachment and Psychopathology in Childhood

Michelle DeKlyen
Mark T. Greenberg

The parent–child relationship has long been considered central to personality development (Bowlby, 1969/1982; Erikson, 1963; Freud, 1965; Greenspan, 1981). Numerous empirical findings link secure parent–child attachment with sociability, compliance, and effective emotion regulation, and insecure attachment to poor peer relations, anger, and poor behavioral self-control (Sroufe, Egeland, Carlson, & Collins, 2005).

The idea that social relationships both affect and are affected by developing psychopathology in childhood is fundamental to most theories of development. Object relations theorists (Mahler, Pine, Bergman, 1975; Winnicott, 1965) and ego psychologists (Freud, 1965) hypothesized that a child's earliest relationships have great impact on the development of mental health. However, despite Bowlby's (1969/1982, 1973) interest in psychopathology, early attachment research focused almost entirely on normative infant development. Although scattered projects in the 1970s and 1980s examined at-risk populations of children and adults with disorders, only recently have researchers seriously attempted to fulfill Bowlby's legacy by utilizing attachment theory to enhance our understanding and treatment of disorder (Cicchetti, Toth, & Lynch, 1995).

Over the last few decades, attachment theory has made major contributions beyond infancy, and

beyond its own proponents. Attachment theory provides a critical developmental frame for understanding *how* caregiving relationships influence processes central to emerging psychopathology—for example, the construction of cognitive–affective expectancies, the capacity for emotional and behavioral regulation, and strategies for coping with stress. In particular, the regulation of emotion—particularly negative emotions such as anxiety, anger, and sadness—plays a critical role in many forms of psychopathology (Izard, Youngstrom, Fine, Mostow, & Trentacosta, 2006).

This chapter reviews what is currently known about the association between attachment and psychopathology in childhood. We focus on *disorder*—that is, behavior serious enough to warrant clinical attention. We begin by briefly describing principles of developmental psychopathology and risk models. We next review research involving attachment, first as a risk factor, then as a central aspect of disorder. We address two fundamental questions: How do attachment constructs contribute to our understanding of childhood disorders, and how might the study of childhood psychopathology enrich the study of attachment? We then reflect on the current state of the field, noting where advances have been made and some of the barriers to further progress.

Developmental Psychopathology and Models of Risk and Protection

Most of the research linking attachment with psychopathology has considered attachment as a potential risk or protective factor, examining associations between attachment measures and maladaptive behavior in populations ranging from convenience samples to individuals with clinical diagnoses. As we have previously noted, the enthusiasm to utilize attachment theory has at times led to a fruitless search for a “Holy Grail” of psychopathology, seeking main effects of infant attachment on later psychopathology. Although meta-analyses demonstrate that attachment predicts both externalizing and internalizing problems when other factors are not controlled (Fearon, Bakermans-Kranenburg, Van IJzendoorn, Lapsley, & Roisman, 2010; Groh, Roisman, Van IJzendoorn, Bakermans-Kranenburg, & Fearon, 2012), it generally appears to exert its influence *in the context of other risk factors* (Cicchetti & Rogosch, 1997; Greenberg, Speltz, DeKlyen, & Jones, 2001; Keller, Spieker, & Gilchrist, 2005). A short digression will provide a frame for considering the role of attachment in the etiology of psychopathology.

Risk Factors

Research on risk factors for disorder leads to five general conclusions. First, a single cause is unlikely to be either a necessary or a sufficient cause for most pathology (Greenberg, Speltz, & DeKlyen, 1993); even disorders with established biological mechanisms are potentiated or buffered by other biological or environmental factors. Thus, it is doubtful that attachment insecurity alone will lead to disorder (Sroufe, 1990), although it may increase its likelihood. As a corollary of this principle, few childhood disorders will be eliminated by treating only causes that lie within the child (Rutter, 1982). Even when a powerful biological cause is implicated (e.g., autism), the parent–child relationship is often an appropriate focus for treatment.

A second tenet of developmental psychopathology states that *multiple pathways* exist to and from disorder (Cicchetti & Rogosch, 1997). Different risk factors may lead to the same disorder (*equifinality*), and a given risk factor may contribute to multiple disorders (*multifinality*). For example, poverty, family violence, and parental psycho-

pathology have all been associated with conduct problems, and attachment is a risk factor for both internalizing and externalizing problems. Also, a variable that confers risk for one problem may reduce risk for others (e.g., avoidant attachment may contribute to conduct disorder but decrease the risk of suicide; Adam, Sheldon-Keller, & West, 1995). Of particular importance, the influence of a risk factor may be moderated by other factors (e.g., gender, ethnicity, genetic allele variants). This is central to notions of *differential susceptibility* (Ellis, Boyce, Belsky, Bakermans-Kranenburg, & Van IJzendoorn, 2011), which may explain some mixed findings in past research and show a way forward to understanding the developmental processes leading to pathology.

Third, risk factors occur at multiple levels, including the individual, the caregiver, and the broader ecological context (Bronfenbrenner, 1979; Kobak, Cassidy, Lyons-Ruth, & Ziv, 2006). At each level, some factors have implications for attachment (social support may affect sensitive caregiving), but others may not (e.g., peer deviance, school quality).

Fourth, associations between risk and outcome may be nonlinear. Although one risk factor may not predict poor outcomes, the likelihood of disorder may increase rapidly with additional risks (Greenberg et al., 2001). It is as yet unclear whether certain risk factors or combinations of risks matter more than others.

A fifth guiding principle is that risk factors may differentially influence outcomes in different developmental periods. Attachment might have its greatest influence in early development, while cognitive ability becomes more critical in middle childhood, and peer relationships and parental monitoring are especially influential during adolescence. Although attachment theorists do not claim that there is a critical period with respect to attachment, early experience models suggest that infant attachment is particularly important and may influence later adaptation beyond what environmental continuity can explain (Fraleay, 2002).

Protective Factors

Protective factors reduce the likelihood of poor outcomes under conditions of risk. These include characteristics of the individual (e.g., temperament and intelligence); the quality of relationships (e.g., attachment); and ecological factors

(e.g., school quality, neighborhood safety, and laws that support children and families).

Considerable controversy exists regarding whether specific factors should be designated as risks or as protective (Masten, 2001; Stouthamer-Loeber et al., 1993). Socioeconomic status, attachment security, and peer group status may be conceptualized as risks in some studies and as protective in others, depending on the population being studied, the range of variation, and the investigator's theoretical bent. Attachment insecurity has been described as a risk factor (Sroufe, 1983), whereas secure attachment can be viewed as conferring protection under conditions of risk (Morisset, Barnard, Greenberg, Booth, & Spieker, 1990).

Coie and colleagues (1993) suggest that protective factors operate in several ways. They may directly decrease dysfunction, prevent the occurrence of a risk factor, buffer the effect of a risk factor, or disrupt the mediational chain by which risk leads to disorder. Well-planned prospective longitudinal studies are needed to identify the risk factors that predict psychopathology, the dynamic relation between risk and protective factors at different ages, and the factors most likely to serve as buffers against negative outcomes for persons with multiple risks.

A Proposed Risk Factor Model

On the basis of these principles, we proposed a model for conceptualizing the early onset of disruptive behavior problems, incorporating four risk domains for which considerable evidence has accumulated: (1) child characteristics; (2) quality of attachment; (3) parental management; and (4) family ecology (Greenberg et al., 1993, 2001). This model may apply to other forms of child psychopathology as well, although some domains are likely more important to certain disorders. Ineffective parenting may contribute more to externalizing than to internalizing disorders (Patterson, DeBaryshe, & Ramsey, 1989), whereas child trauma may especially relate to dissociative disorders (Liotti, 1995). Also, it is likely that different aspects of these risks predict different disorders. For example, reactive temperament may be associated with externalizing, and inhibited temperament with internalizing difficulties. Similarly, parental punitiveness and underinvolvement may create risk for conduct problems (Patterson et al., 1989), and overcontrol and the absence of autonomy pro-

motion may predict anxiety or depression (Kobak, Sudler, & Gamble, 1991). The type of insecurity has also been predicted to determine what type of disorder emerges. Finally, different risk factor combinations (e.g., insecure attachment and family adversity vs. difficult temperament and poor parent management) may lead to differing behaviors and require different treatments.

Here are a few examples: Assessing biological vulnerability, insecure attachment, poor parent management, and adverse family circumstances in a comparison of clinic-referred preschoolers and normally behaving children, we found that children with risk in all four domains were far more likely to receive diagnoses of oppositional defiant disorder (Greenberg et al., 2001). Child characteristics, parent management, and attachment security all uniquely differentiated the two groups, but family adversity did not. Person-oriented analyses demonstrated that increasing the number of risks substantially increased the likelihood of disorder: Clinic-referred children were 34 times more likely than comparison children to be at risk in all four domains. Relative improvement over chance (RIOC) was elevated for one pattern involving child characteristics, poor parenting, and family adversity, and for another including poor parenting, insecure attachment, and family adversity. Disorder occurred in individuals with other patterns, but those patterns were no more common among clinic-referred than comparison boys. Clinic-referred children rarely had risk in fewer than two domains.

Behavior problems are not always associated with insecure attachment, as evidenced by case studies of securely attached children with externalizing problems (Campbell, 1990; Greenberg, Speltz, DeKlyen, & Endriga, 1991). Symptoms may be triggered by recent stressors; in other cases, biological vulnerability or family disorder may be apparent. This is likely true for other forms of psychopathology as well.

In a study testing this model, Keller and colleagues (2005) found that risk in a single domain is insufficient to predict disorder. In two-domain analyses, insecurely attached children with high infant negativity were more likely to display the high-problem-behavior trajectory, whereas securely attached children with high negativity did not. In three-domain analyses, the high-problem-behavior trajectory was most likely when insecure attachment and high-risk parenting were combined with multiproblem family ecology or high infant negativity.

Process Models and the Contribution of Attachment to Disorder

Models are most likely to be useful when they specify linkages between *types* of insecurity and later disorder and describe mechanisms by which attachment is expected to influence development. Theory-based process models are essential to establish child attachment as causal. We have suggested four interrelated mechanisms that may link attachment to psychopathology: observed behavior, emotion regulation, cognitive–affective structures, and motivational processes.

Attachment may contribute to maladaptation through its direct effect on behavior. Behaviors labeled disruptive have considerable power to regulate caregiving, especially when other strategies are ineffective or unavailable (Greenberg et al., 1993). Thus, whining, noncompliance, and other negative forms of attention seeking may be viewed as attachment strategies that, although effective in the short-term (e.g., caregiver attention may be either increased or reduced by child negativity), serve as a setting condition for maladaptive interactions (e.g., coercive processes; Patterson, Reid, & Dishion, 1992). Similarly, the immature, angry, or dependent behaviors of the ambivalently attached child may maintain a caregiver's attention but become problematic in the wider environment (Cassidy & Berlin, 1994). Main and Hesse (1990) hypothesized that in the absence of a coherent and predictable environment, the disorganized infant may take control of aspects of the parent–child relationship during the preschool years. This role reversal, while maintaining a connection to the parent, may lead to maladaptive behaviors (e.g., bossiness, parentification).

Attachment may also affect later disorder through the emotion regulatory processes that develop within the parent–child dyad. Theory and research affirm the importance of emotion regulation in the etiology and maintenance of diverse disorders (Chaplin & Cole, 2005; Izard et al., 2006). Self-regulation strategies are believed to evolve from early interactions that shape subsequent responses to challenging situations (for a review of relevant research, see Calkins & Leerkes, 2011). Guttman-Steinmetz and Crowell (2006) elaborate how securely attached infants' experiences enhance their capacity to tolerate and manage affect, whereas the strategies of avoidant and ambivalent infants (minimization and exaggeration of emotion, respectively) interfere with

effective regulation. Dyadic interactions in early childhood may influence emotion regulation via neural organization and conditioning (Galynker et al., 2012; Greenberg & Snell, 1997; Hane & Fox, 2006; LeDoux, 1995; Olsavsky et al., 2013; Schore, 2005), and associations between attachment and cortisol, heart rate, and vagal tone suggest mechanisms common to emotion, the attachment system, and various disorders (Gunnar, 2000; Hertsgaard, Gunnar, Erickson, & Nachmias, 1995; Lyons-Ruth, Dutra, Schuder, & Bianchi, 2006; Spangler & Schieche, 1998; see also Hane & Fox, Chapter 11, this volume). However, empirical evidence regarding how attachment moderates the neural processes involved in emotion regulation is still preliminary (Coan, 2008; see, in this volume, Coan, Chapter 12, and Polan & Hofer, Chapter 6). Given the degree to which emotion regulation is central to both attachment and diverse psychopathological conditions, it is surprising that there has not been more research in this area.

A third mechanism involves developing social cognitions. Parenting is thought to shape the infant's cognitive–affective schema or “working model” of the self and others (Bowlby, 1973). This working model then biases perceptions of the actions and desires of others, influences behavior, and sets into motion a pattern of interactions that reinforce and stabilize these biases (Bretherton & Munholland, Chapter 4, this volume; Main, Kaplan, & Cassidy, 1985). Attachment patterns are therefore expected to be associated with social information processing. When a secure and trusting bond forms between parent and child, both develop positive working models of the relationship, which include attributions of responsiveness, warmth, and trust, setting the stage for cooperative interactions. Insecure attachment may crystallize working models characterized by anger, mistrust, anxiety, and/or fear. Dykas and Cassidy (2011) propose that insecure individuals either suppress painful information or process it according to negative schemas. They review evidence that attachment working models influence memory, theory of mind, attributional biases, emotional understanding, and coping strategies. For example, several studies have provided support for Dodge's (1991) hypothesis that children with insecure attachments are more likely to report hostile attributions when presented with hypothetical peer dilemmas (e.g., Cassidy, Kirsh, Scolton, & Parke, 1996; Raikes & Thompson, 2008), which may result in hypervigilance and anger and increase the likelihood of reactive aggression. Similarly, Zac-

cagnino and colleagues (2013) found that children with disorganized attachments had more hostile attributions, and both disorganized and ambivalently attached children reported more aggressive responses to social situations.

Attachment also is likely to contribute to maladaptation through motivational processes. Attachment may promote either a generalized positive or a resistant social orientation, providing differential levels of readiness for socialization (Richters & Waters, 1991). Children with warm, contingent relations are more likely to comply with parent control and to develop a prosocial orientation in early and middle childhood (Kochanska et al., 2010; Maccoby & Martin, 1983; Waters, Kondo-Ikemura, Posada, & Richters, 1991). Secure attachment might then deter children from deviance and facilitate the formation of positive bonds with other adults and institutions that protect against delinquency and social destructiveness, as explicated in social control theories (Hawkins, Arthur, & Catalano, 1995).

Theory and Research Linking Attachment to Childhood Psychopathology

Attachment theory and research have informed the study of child psychopathology in two major ways. First, a body of work has considered how attachment relationships influence disorder by increasing risk or buffering the effects of other risk factors. Second, in extreme cases, atypical attachment patterns can themselves be considered disorders (Lieberman & Zeanah, 1995)—for example, when caregiving is seriously disrupted or is pathogenic due to severe maltreatment or institutionalization. Each of these approaches is considered below.

Our task is complicated by the many ways in which researchers have assessed attachment and psychopathology, often making comparisons between studies difficult. Some studies use attachment classifications, and others use dimensional ratings. When using categorical measures, some report only secure versus insecure attachment, whereas others apply the three-category system, and still others include the fourth (disorganized or controlling) category. Some assess infant attachment, and others measure attachment later in childhood, often concurrent with the outcome of interest. Some use behavioral observations (e.g.,

separation–reunions), whereas others use parent- or observer-reported behavior descriptions (e.g., the Q-sort), and still others use representational measures (e.g., projective pictures, story stem narratives, or self-descriptive questionnaires). Which measure is appropriate depends to some degree on the subject's developmental age, but little research has examined how measures conducted at different ages and with different methodologies relate to each other over time. To what extent various measures assess equivalent constructs is an open question.

With respect to psychopathology, some researchers report on broad categories (externalizing and internalizing), and others assess specific disorders. Still others use dimensional measures of behavior, assuming that higher scores are worse—but sometimes few, if any, of the subjects have scored at clinical levels, and measures may not be linearly related to well-being (e.g., too little behavior may be as maladaptive as too much). Comparing studies within such diversity presents a challenge.

In our view, reliance on the secure–insecure dichotomy runs the risk of reducing analyses to little more than a comparison of generally good versus generally bad caregiving environments. It lacks the specificity that attachment theory can provide, and to the degree that there are meaningful differences between insecure categories, these may cancel each other out. Furthermore, the association between insecurity and psychopathology is often weak and clinically not very useful (Rutter, Kreppner, Sonuga-Barke, et al., 2009). Therefore, after briefly reviewing early findings, we focus on studies that assess specific categories of insecurity. For consistency and ease of reading, we generally use the terms *avoidant*, *ambivalent*, *disorganized*, and/or *controlling* to refer to the basic insecure classifications, although some authors use different terms for analogous categories. A strong association has been found between infant disorganization and later controlling attachment classification, and the two are often considered together. Unless otherwise specified, attachment has been assessed in relation to mothers.

We concentrate on psychopathology in childhood and rarely include research on adolescents, except when this might provide clues to fruitful future investigation. Given the heterogeneity of categories such as externalizing and internalizing, we also describe only a sampling of the studies that report these broad outcomes. Progress in the field will demand greater specificity to illuminate the processes and mechanisms that lead to particular

behavioral outcomes, along with theoretical rationales outlining why particular attachment experiences or representations are expected to relate to specific outcomes.

With those caveats, what follows is our best assessment of what theory and research indicate about the associations between attachment and child psychopathology.

Early Theory Linking Attachment and Disorder

From early on, theorists predicted differences in children's behavior in general and pathology in particular, based on the different forms of insecurity. Bowlby (1973) argued that the avoidantly attached child discovers that expressing anger in response to a caregiver's unresponsive or intrusive behavior will reduce the caregiver's proximity in stressful situations and so learns to redirect this anger toward the environment, perhaps resulting in hostile and aggressive behavior. In contrast, inconsistent or overprotective caregiving may engender vigilance and chronic anxiety in the ambivalently attached child, in response to fears that his or her needs will not be met. Bowlby traced depression to childhood experiences of separation from or loss of attachment figures, especially when hopelessness and helplessness ensue.

Rubin, Hymel, Mills, and Rose-Krasnor (1991) extended Bowlby's formulation to include child temperament, socioecological factors, and parental attitudes. They delineated a pathway in which an unresponsive, rejecting caregiver responds to an avoidant infant in an authoritarian, hostile manner, resulting in aggressive child behavior. Ambivalent infants are more likely to develop internalizing problems.

Sroufe (1983), on the other hand, suggested that both avoidant and ambivalent infants may develop externalizing problems, but the meaning and manifestations of these problems differ in predictable ways. Avoidant children might develop a hostile, antisocial pattern in response to rejecting, emotionally unavailable caregivers. The underlying anger, not directed at its source, might be manifested in lying, bullying, blaming, and insensitivity to others. Ambivalent children might be easily overstimulated and exhibit impulsivity, restlessness, short attention spans, and low frustration tolerance. Both kinds of children might be aggressive—but, Sroufe suggests, for different reasons.

These conceptualizations did not include the disorganized category, which has been demon-

strated to occur at high rates in samples characterized by parent psychopathology, child abuse, and social or biological risk (see Hane & Fox, Chapter 11, this volume). Given its prevalence in children at risk for psychopathology, this pattern requires special attention. Main and Hesse (1990) have postulated that when a traumatized mother is unpredictably frightening, her child's response becomes disorganized. Egeland and Carlson (2004) argued that the child with a disorganized attachment is placed in an "unresolvable paradox," in that the putative source of safety (the caregiver) is simultaneously a source of fear. Unable either to regulate his or her arousal or to enlist the caregiver's assistance, the child may mentally isolate and fail to process disturbing stimuli, resulting in dissociation. Lyons-Ruth, Bronfman, and Atwood (1999) proposed that the child's fear may arise from sources other than the caregiver (e.g., abuse at the hands of others); if the parent responds to this fear with disruptive or contradictory affective communication, disorganization may result. This could explain some disorganization that develops postinfancy, following a child's exposure to maltreatment or trauma. Disorganization appears to be only weakly associated with maternal sensitivity and to have a more significant genetic component than other classifications (Rutter et al., 2009). Given its links with emotion regulation and cognitive processes, disorganized attachment has clear relevance to childhood psychopathology and must be part of any comprehensive theoretical model.

Research Comparing Secure versus Insecure Attachment

Many early studies of the effects of attachment on development examined broad categories of secure versus insecure attachment. We reviewed this literature in the second volume of this handbook (DeKlyen & Greenberg, 2008) and only briefly summarize it here.

Initial work involved low-risk populations and asked whether insecure infant attachment was associated with behavior problems (e.g., Bates, Bayles, Bennett, Ridge, & Brown, 1991; Bates, Maslin, & Frankel, 1985; Fagot & Kavanaugh, 1990; Lewis, Feiring, McGuffog, & Jaskir, 1984). Main effects of insecure attachment on later problems were rarely found, and mediator or moderator effects were seldom tested. Studies of high-risk populations were generally more fruitful (e.g., El-Sheikh & Elmore-Staton, 2004; Lyons-

Ruth, Connell, Zoll, & Stahl, 1987; Munson, McMahon, & Spieker, 2001; Rodning, Beckwith, & Howard, 1991; Spieker & Booth, 1988; Sroufe et al., 2005; Vondra, Shaw, Swearingen, Cohen, & Owens, 2001).

The Minnesota Parent–Child Project was the most productive source of early results. A group of 174 infants of primarily young, single mothers was followed into early adulthood. Assessments during the preschool years (Erickson, Sroufe, & Egeland, 1985; Sroufe, 1983; Troy & Sroufe, 1987), the early elementary school period (Renken, Egeland, Marvinney, Mangelsdorf, & Sroufe, 1989; Sroufe, 1990; Sroufe, Egeland, & Kreutzer, 1990), preadolescence (Urban, Carlson, Egeland, & Sroufe, 1991), and adolescence (Carlson, 1998) consistently found that children in high-social-risk environments who exhibited early insecurity were more likely to have poor peer relations and symptoms of aggression, depression, and general maladjustment than children who had been secure. Later experiences that increased risk for secure infants or decreased risk for those who had been insecure also affected outcomes.

Other longitudinal investigations in high-risk populations confirmed the predictive value of early attachment (e.g., Cohn, 1990; Easterbrooks, Davidson, & Chazan, 1993; Goldberg, Gotowiec, & Simmons, 1995; Lyons-Ruth, Easterbrooks, & Cibelli, 1997; Lyons-Ruth, Easterbrooks, Davidson Cibelli, & Bronfman, 1995; Lyons-Ruth, Zoll, Connell, & Grunebaum, 1989; Turner, 1991).

Using sophisticated analyses to examine pathways linking attachment to subsequent antisocial outcomes, Kochanska and Kim (2012) assessed infant attachment (secure vs. insecure), child anger proneness, parent power assertion, and observed and parent-reported antisocial behavior in low-risk community samples. Although attachment security had no main effect on antisocial outcomes, it had an indirect effect, mediated by parents' power assertion and further modified by an interaction between child anger proneness and attachment. Insecure attachment in infancy appeared to create the context for coercive processes between a difficult toddler and his or her parent and for the emergence of antisocial behavior at age 6.5; this dynamic was not present in secure dyads.

Overall, these studies indicate that an insecure attachment in infancy may set a trajectory that increases risk for either externalizing or internalizing psychopathology, suggest that attachment serves as a general rather than a specific risk factor, and provide evidence of multifinality. In

the remainder of this chapter we seek evidence of specificity for type of insecurity and for particular disorders.

The Role of Specific Attachment Classifications in Disordered Behavior

Externalizing Problems

Externalizing behaviors include a group of problems (e.g., oppositional defiant disorder (ODD), conduct disorder (CD), aggression, and antisocial behavior) that are often not clearly differentiated in research.

THEORY

Several theories have been proposed concerning the role of attachment in the development of externalizing problems. Early theoretical arguments for expecting avoidantly attached children to be at increased risk for externalizing disorders have been reviewed above (e.g., Bowlby, 1973; Rubin et al., 1991; Sroufe, 1983).

Like Sroufe (1983), Mikulincer and Shaver (2011) suggest that antisocial behavior may result from either avoidant or ambivalent attachment models. The child with an avoidant stance might act out in order to maintain distance from or demonstrate a lack of concern for others. Ambivalently attached children, on the other hand, might do so to attract attention or to express anger or resentment.

Fonagy and colleagues (1997) present a model linking early insecure attachment, especially the avoidant classification, to later attachment and criminality. They hypothesize that as secure working models of attachment figures become more global, they facilitate bonding to social institutions and those who represent them (Hawkins et al., 1995). Children who lack this connection with institutions and have deviant peer relations are at increased risk for substance use and criminality. Secure attachments lead to greater awareness of the mental states of others, and this “mentalizing” inhibits malevolent acts and enhances relationship building. This theory raises a number of research questions that have only begun to be addressed (Dykas & Cassidy, 2011): How do “mentalizing” and related cognitive processes (e.g., joint attention, theory of mind) relate to attachment? Is this link relevant to depression and other disorders as

well? And what might counterexamples (e.g., children with insecure working models who do bond to social institutions) tell us about the process?

Others theorists (e.g., Solomon, George, & DeJong, 1995) hypothesize that the absence of a coherent strategy (i.e., disorganization) rather than insecurity predisposes children to antisocial behavior; disorganization is also expected to increase vulnerability to internalizing disorders.

Consistent with the argument we presented earlier, several authors emphasize mediating and moderating processes that may link attachment and later problems. Fearon and colleagues (2010) posit several potential mediators, including self-confidence, social expectations, socialization of moral values, modeling of behavior, continuity of caregiving, and emotion regulation. Fearon and Belsky (2011) tested moderators (gender, social contextual risk, and age) and found that infant disorganization interacted with social risk in predicting school-age externalizing problems. Maternal sensitivity subsequent to the infant attachment assessment appeared especially influential for children who had been classified avoidant.

Kochanska and Kim (2012) describe two major sets of developmental goals served by attachment, one behavioral and focused on protection, the other fundamental to creating the context for socialization: The child who does not feel safe explores less and is less likely to develop adaptive emotion regulation strategies, and the insecure parent-child dyad's failure to establish reciprocity and responsiveness undermines positive socialization. Both mechanisms may contribute to antisocial behavior. The association between attachment and behavior problems is indirect and probabilistic, influenced by child characteristics and a cascade of later interactions and experiences.

RESEARCH LINKING ATTACHMENT TO EXTERNALIZING PROBLEMS

A moderate association between attachment disorganization and externalizing problems was demonstrated in an early meta-analysis (Van IJzendoorn, Schuengel, & Bakermans-Kranenburg, 1999). More recently, Fearon and colleagues (2010) found that disorganization posed a higher risk than avoidant attachment, although both were associated with externalizing problems. Surprisingly, girls with disorganized attachments were significantly *less* likely than those with other classifications to be rated externalizing.

Following infants from the Minnesota Parent-Child Project, Aguilar, Sroufe, Egeland, and Carlson (2000) found that adolescents with early-onset antisocial behavior were more likely to have been avoidantly attached than adolescents with later-onset antisocial behavior or no disorder. However, they only compared avoidant with nonavoidant attachment, so no clear conclusions can be drawn regarding other classifications.

Avoidantly attached infants in the National Institute of Child Health and Human Development (NICHD) Study of Early Child Care had elevated externalizing scores in the first and second grades, but disorganized attachment predicted externalizing in grades 5 and 6 (Fearon & Belsky, 2011). For children with low contextual risk, there was no effect for any attachment classification, and few children had scores in the clinical range.

In high-risk samples, disorganized infant attachment predicted parent-rated externalizing problems when children were 5 years old (Shaw, Keenan, Vondra, Delliquadri, & Giovannelli, 1997) and teacher-rated externalizing in 7-year-olds (Lyons-Ruth et al., 1997). However, following children of teen mothers with high rates of depression, Keller and colleagues (2005) found that avoidant (but not disorganized) classification in infancy predicted an elevated trajectory for preschool disruptive behavior. The early-starting pattern, with escalating problems, was only prevalent when insecure attachment was combined with male gender and either high infant negativity or parenting risk, or when insecure attachment, parenting risk, and family ecological risk co-occurred. In the same sample, both avoidance and disorganization were associated with externalizing scores at 9 years of age (Munson et al., 2001).

Two low-risk samples in which attachment was assessed in early to middle childhood provide further evidence of the effect of the disorganized or controlling classification. In a French Canadian sample, children classified as controlling in a separation-reunion at ages 5-7 had the highest teacher-rated externalizing *and* internalizing problem scores concurrently and 2 years later (Moss, Cyr, & Dubois-Comtois, 2004; Moss et al., 2006). Both ambivalent and controlling children had elevated externalizing scores, using a composite of mother, teacher, and self-ratings. Controlling-punitive children had more externalizing problems, whereas controlling-caregiving children had more internalizing problems. Finally, using a story stem measure to assess attachment at 3-5 years of age, Roskam, Meunier, Stievenart, and Noel (2013)

found that disorganization (but not security–insecurity) modestly predicted externalizing scores 2 years later.

We turn now to research focusing on specific types of externalizing behavior.

In a low-income sample, 60% of children classified disorganized at 12 months had clinically significant levels of aggression¹ on the Child Behavior Checklist at age 5, compared to 31% of avoidant, 28% of ambivalent, and 17% of secure infants (Shaw, Owens, Vondra, Keenan, & Winslow, 1996). Children with both disorganized attachment at 12 months and difficult temperament at age 2 had mean scores at the 99th percentile. Lyons-Ruth and colleagues (1995) reported that infant disorganization was associated with teacher-rated hostility; 55% of the children with disorganized classifications *and* mothers with psychosocial problems displayed hostile behavior in kindergarten, compared to 5% of those with neither risk factor.

Among low-risk children assessed at age 6, only those classified controlling were more likely to have conduct problems, as rated by parents, teachers, and peers (Solomon et al., 1995). Similarly, a study of high-risk first graders in which a story stem measure was used found that disorganization was related to higher teacher and parent ratings of conduct problems (Futh, O'Connor, Matias, Green, & Scott, 2008). However, Moss and colleagues (2004, 2006) reported that children classified either ambivalent or controlling at ages 5–7 were judged by mothers to be more aggressive (see Note 1) and to have more conduct problems 2 years later than were secure children.

Clinical samples provide a different perspective but may be limited by issues of selection or by the limited range of values. In the first two cohorts of our own research, described earlier, 80% of clinic-referred preschoolers meeting criteria for ODD were insecurely attached to their mothers, as opposed to 30% of typically developing children matched for age, socioeconomic status (SES), and family composition (Greenberg et al., 1991; Speltz et al., 1990). A disproportionate number received controlling classifications, and many were punitive or rejecting toward their mothers. In a third group of 80 clinically referred preschool boys and 80 carefully matched controls, 55% of those with ODD were insecure, with high rates of both avoidant and controlling categories (Speltz, DeKlyen, & Greenberg, 1999). This was one of the few studies to assess father–child attachment, and clinic-referred boys also had higher rates of inse-

curity with fathers (55 vs. 15%; DeKlyen, Speltz, & Greenberg, 1998). Boys insecurely attached to *both* parents were at greatest risk of being in the clinic group.

Note that a significant proportion of these clinically diagnosed boys exhibited secure attachments, indicating that a measure of insecure attachment does not merely assess oppositionality and is not a component of every pathway leading to ODD. Campbell (1990) similarly found that in some families of children with high rates of aggression and hyperactivity, the mother–child relationship appeared warm and trusting. Also, only the first cohort included girls, and the relation between attachment and clinic status held only for boys (there was little power to test this, but insecurity did not appear to characterize clinic girls; Speltz et al., 1990). Finally, in the second cohort, high concordance between child attachment and mothers' Adult Attachment Interview classification increased the probability that clinic boys were also insecure in infancy and that early attachment processes may have contributed to the development of disruptive problems (DeKlyen, 1996).

In another clinic sample of boys with ODD or CD diagnoses, Pasalich, Dadds, Hawes, and Brennan (2012) found that disorganized attachment was overrepresented (49%), but it was not associated with parent-reported severity of conduct problems. Boys with higher callous–unemotional (CU) ratings were more likely to have disorganized attachments, as predicted by the presumed inability of psychopaths to form intimate relationships. However, one-fourth of the children with high CU ratings were securely attached. Contrary to prediction, there was no relation to avoidant attachment (the authors suggest that their story stem measure underestimated avoidance).

Thus, there is evidence linking externalizing problems with all three insecure classifications, but the most consistent evidence implicates disorganization or controlling attachment, especially as children grow older. Many variables, including gender, social risk, and age at which problem behaviors were assessed, likely contribute to the varied findings, and the need for multirisk, transactional models in future research is clear.

Internalizing Problems

As noted earlier, conceptual models have linked ambivalent attachment to internalizing problems because children with this pattern limit explora-

tion, have poor emotion regulation, and are likely to feel fearful and helpless when faced with stressors (e.g., Cassidy & Berlin, 1994). Brumariu and Kerns (2010a) propose that three child characteristics link insecure attachment with internalizing symptoms: maladaptive and biased cognitions; impaired ability to identify, regulate, and cope with emotions; and self-concept/sense of worth. Each of these has been associated with anxiety and depression, and with early relations with caregivers; all except a diminished sense of self-worth are also linked with externalizing problems, which calls their specificity into question. Brumariu and Kerns suggest that excessive parental control may predict anxiety, whereas rejection may be more associated with depression. Disorganization is not discussed in their formulation. Some of the previously discussed research supports links between disorganization and internalizing outcomes; perhaps this is because disorganized children perceive themselves as helpless and vulnerable, and their attachment figures as unable to provide protection.

Two studies provide contrasting findings with respect to internalizing problems. In a longitudinal sample of high-risk families, avoidant but not disorganized infant attachment predicted teacher-reported internalizing symptoms at age 7; neither predicted clinically significant scores (Lyons-Ruth et al., 1997). On the other hand, Moss and her colleagues (2006) found that 5- to 7-year-old children with controlling classifications, and particularly the controlling-caregiving group, had the highest teacher-rated internalizing scores concurrently and 2 years later.

ANXIETY DISORDERS

Given Bowlby's (1973) proposal that anxiety is fundamental to insecure attachment, it is surprising that little attention was initially paid to the relation between attachment and anxiety. Inadequate emotion regulation, manifested in intense fear or worry, is common to all anxiety disorders. Esbjorn, Bender, Reinholdt-Dunne, Munck, and Ollendick (2012) argue that children who experience an optimal balance of parent support and opportunities to establish self-regulation have the opportunity to develop flexible and effective strategies to regulate distress and reduce negative emotions. Both withdrawing and overly involved parents are more likely to have insecure children (avoidant or ambivalently attached, respectively) who either depend entirely on their own resources

or have limited opportunities for self-regulation and rely primarily on others and are therefore at risk for anxiety disorders.

Carlson and Sroufe (1995) posit that ambivalent attachment is predictive of separation anxiety and school phobia given the child's worry about the attachment figure's availability (see also Manassis, 2001). Disorganization also might involve excessive concern about the caregiver's well-being, but we are unaware of specific theorizing about its association with anxiety. The link between avoidant attachment and restricted expression of negative emotions might predispose to somatic complaints or obsessive-compulsive symptoms.

A meta-analysis by Colonnese and colleagues (2011) indicated a moderate association between ambivalent attachment and anxiety ($r = .37$); however, they compared only secure versus insecure and ambivalent versus nonambivalent categories. After surveying studies of attachment and anxiety, Esbjorn and colleagues (2012) also argued that insecure-ambivalent attachments increased children's vulnerability for anxiety, especially when combined with other risks. However, in their narrative review of the literature, Brumariu and Kerns (2010a) concluded that research attempting to link specific attachment classifications with childhood and adolescent anxiety has yielded mixed results and is limited because so few investigators have included measures of disorganization. A series of studies by their group used observational, story stem, and interview assessments of attachment, prospectively and concurrently, and found that disorganization, but not avoidance or ambivalence, was associated with anxiety in children age 10 years and older (Kerns & Brumariu, 2014). In contrast, in a multidomain study including concurrent attachment assessment at 4–5 years of age, insecurity had no direct effect and only a small indirect effect on anxiety symptoms (Hopkins, Lavigne, Gouze, LeBailly, & Bryant, 2013).

Studies including only three categories of attachment have generally found associations between ambivalent classification and anxiety. They have also often examined older children or adolescents. For example, in the Minnesota sample, adolescents with ambivalent infancy classifications were more likely to receive anxiety diagnoses; however, only nine children had an anxiety disorder and an ambivalent attachment in this follow-up sample (Warren, Huston, Egeland, & Sroufe, 1997). Only ambivalence predicted the number of anxiety disorder diagnoses; 28% of ambivalent infants had an anxiety disorder by age 17, com-

pared with 16% of avoidant and 11% of secure infants. In a questionnaire-based study, ambivalent children had higher levels of anxiety than either avoidant or secure children at 12 years of age; assessment included only two insecure categories and was concurrent (Muris, Meesters, van Melick, & Zwambag, 2001). With an older sample (grades 6–10), Lee and Hankin (2009) found that self-reported ratings of both ambivalent and avoidant attachment were related to concurrent anxiety symptoms and changes in anxiety levels; again, disorganization was not assessed.

Shamir-Essakow, Ungerer, and Rapee (2005) used a four-category separation–reunion classification to assess high-risk Australian preschool children. Those with either disorganized or avoidant attachment had elevated levels of anxiety symptoms, after the researchers controlled for mothers' anxiety.

Overall, the evidence is inconclusive with respect to the association between particular attachment classifications and broad assessments of anxiety. We now consider research examining specific anxiety disorders.

SEPARATION ANXIETY

Separation anxiety disorder is the most common anxiety diagnosis in prepubertal children, and both clinicians and researchers have theorized about the role played by parent–child relations (Klein, 1994; Manassis & Bradley, 1994; Thurber, 1996). Separation anxiety increases risk for a variety of adult psychiatric disorders, including depression, agoraphobia, and panic disorder; thus, research examining the association between attachment processes and separation anxiety could illuminate the pathways to these disorders as well.

Evidence linking infant attachment to separation anxiety is mixed. Dallaire and Weinraub (2005) found that children classified as ambivalent at 15 months reported higher levels of separation anxiety at 6 years than did secure (but not avoidant or disorganized) children, but the difference was marginal. Comparing only secure with ambivalent infant classifications, Bar-Haim, Dan, Eshel, and Sagi-Schwartz (2007) found that ambivalence was not associated with separation anxiety when children were 11 years of age. And comparing disorganization with organized patterns, MacDonald and colleagues (2008) reported no association between infant attachment and separation anxiety at 8 years.

In a study using a concurrent, four-category story stem measure, 10- to 12-year-old boys (but not girls) with ambivalent classifications were more likely to exhibit separation anxiety symptoms (Brumariu & Kerns, 2010b). However, the same investigators found no such association for children assessed with the Security Scale and Coping Strategies Questionnaire (Brumariu & Kerns, 2008).² Moss and colleagues (2006) reported that children classified controlling in a separation/reunion at ages 5–7 rated themselves higher on separation anxiety than did secure children.

Finally, in a unique clinical sample of 5- to 10-year-old children hospitalized for suicidal and/or assaultive behavior, Goodman, Strohm, and Valdez (2012) examined associations between attachment, based on the Attachment Story Completion Task, and separation anxiety, simple phobia, overanxious disorder, and posttraumatic stress disorder (PTSD). Their four-category measure was associated only with separation anxiety; the children with separation anxiety diagnoses were all classified either ambivalent or disorganized.

OTHER ANXIETY DISORDERS

Using the Child Attachment Interview in a community sample, Borelli, David, Crowley, and Mayes (2010) reported that 8- to 12-year-old children with disorganized attachments had more social anxiety symptoms than organized children, and their problems were more likely to be clinically significant. With a four-category story stem measure, Brumariu and Kerns (2010b) also found that disorganization was associated with social anxiety, school phobia, and somatic symptoms in 10- to 12-year-olds, but a questionnaire assessment of attachment by the same researchers indicated that ambivalent attachment was the best predictor of social anxiety (Brumariu & Kerns, 2008). Neither a comparison of infant disorganized versus organized attachment (MacDonald et al., 2008) nor a contrast of controlling versus secure childhood attachment (Moss et al., 2006) predicted phobia or generalized anxiety.

DEPRESSION

Bowlby and others have advanced theories for the role of attachment in the pathogenesis of depression (discussed earlier; also see Cicchetti & Cummings, 1990; Kobak et al., 1991). Egeland and Carlson (2004) postulate that ambivalence may

lead to depression because the child is unable to satisfy the caregiver's demands and therefore perceives later difficulties or loss as yet another failure. Avoidant children may come to feel they are unlovable or inadequate and to see others as hostile; their alienation and sense of hopelessness may also lead to depression. And the child with a disorganized attachment is likely to feel overwhelmed by later difficulties and regard him- or herself as incapable, and therefore become depressed.

Morley and Moran (2011) suggest a pathway from early attachment involving negative representations of the self, leading to a helpless response to failure and vulnerability to depressed feelings; negative life events may then trigger depression. That is, attachment experiences result in cognitive biases that influence the child's interpretation of and response to negative events. This view is consistent with both cognitive and helplessness theories of depression (Abramson, Seligman & Teasdale, 1978; Beck, 1987). Morley and Moran argue that the inconsistent care that results in an ambivalent attachment undermines the stability and coherence of one's sense of self and self-worth, resulting in feelings of helplessness following failure. Individuals with avoidant attachments may ignore their deficiencies, attribute negative events to external causes, and therefore not be threatened by failure, but if they lack this sense of self-sufficiency and respond to failure—especially interpersonal failure—with a sense of helplessness, they may also be vulnerable to depression. Individuals with disorganized attachment may have tenuous coping strategies that break down under stress, leading to maladaptive responses and, again, vulnerability to depression. In short, any insecure attachment style may set the stage for depression.

Brumariu and Kerns (2010a) note that surprisingly few studies have investigated attachment and childhood depression. Adolescent research strongly suggests that insecurity is associated with depression, but a somewhat dated meta-analysis failed to find a link between disorganization and children's depression (Van IJzendoorn et al., 1999). Our review of the literature indicates that findings are mixed with respect to specific types of attachment (both ambivalence and disorganization have been implicated) and raises questions about causal direction in studies relying on concurrent self-reports of attachment and depression.

In a high-risk population, Bureau, Easterbrooks, and Lyons-Ruth (2009) reported that infant disorganization (vs. organized attachment) predicted depressive symptoms at 8 years, but

insecurity did not. Every study we have reviewed that assessed disorganization or controlling attachment after infancy has found this category to be associated with depressive symptoms or diagnosis. For example, school-age children classified as controlling upon separation–reunion displayed more depressive symptoms than children with other classifications in a study by Graham and Easterbrooks (2000). Interestingly, low income predicted depressive symptoms for children with insecure attachments but not for securely attached children, suggesting that security might be protective against the effects of economic risk. Using the Child Attachment Interview to compare organized and disorganized 8- to 12-year-olds in a community sample, Borelli and colleagues (2010) found that disorganized children rated themselves as more depressed than children with organized patterns, but their parents did not. Disorganized children were also more likely to meet clinical criteria for depression. In the Moss and colleagues (2006) study, children classified as controlling at ages 5–7 rated themselves higher on depressive symptoms 2 years later than did secure children.

In Goodman and colleagues' (2012) sample of 5- to 10-year-old psychiatrically hospitalized children, assessed with a story completion task, disorganized children were more likely to meet criteria for a depressive disorder and reported more negative self-esteem than children with organized classifications. Although four-category attachment analyses were not significant, two-thirds of clinically depressed children, compared to one-fifth of those not clinically depressed, were classified as disorganized.

However, Lee and Hankin (2009), assessing only self-reported anxious and avoidant attachment, found that both were related to concurrent depression symptoms and to changes in depression levels of youth (grades 6–10). A middle childhood assessment using both three-category self-report attachment ratings and four-category scores from a story stem interview indicated that both self-reported avoidance and interview-based ambivalence and disorganization ratings were related to depressive symptoms (Kerns, Brumariu, & Seibert, 2011). These associations became insignificant after researchers controlled for demographics. The discrepancies between these results demonstrate the challenge of comparing findings based on three- versus four-category systems; how might the children rated as avoidant on the self-report questionnaire have been classified if disorganization were an option? Some researchers who have reported secondary organized classifications for

disorganized children report that the majority of these appear avoidant (e.g., Borelli et al., 2010).

Starr, Hammen, Brennan, and Najman (2013) illustrate the role differential genetic susceptibility may play in links between attachment and childhood disorder. Participants ages 15–20, oversampled for maternal depression, were genotyped for polymorphisms in the serotonin transporter gene (*5-HTTLPR*) and assessed using the Bartholomew Relationship Questionnaire (Bartholomew & Horowitz, 1991), a self-rating of depressive symptoms, structured psychiatric interviews, and a life stress interview. For boys only, the short allele of *5-HTTLPR* predicted increased likelihood of depression among less secure boys and decreased likelihood among boys with higher security scores. The authors suggest that secure attachment serves as a buffer against the vulnerability associated with the short allele, which has been described as a marker for social reactivity: Boys who are genetically predisposed to be more reactive may suffer from negative parenting environments but thrive in more optimal situations. For girls but not for boys, security had a main effect, resulting in lower depression scores. However, gene \times attachment classification interactions have often proven difficult to replicate, suggesting that this finding requires validation in other samples.

Other Disorders

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

We are unaware of theory linking specific attachment categories to attention-deficit/hyperactivity disorder (ADHD).

In Moss and colleagues' (2006) community sample (discussed earlier), children classified as controlling in a separation-reunion at ages 5–7 endorsed more ADHD symptoms 2 years later than did secure children. Using a child attachment interview, Borelli and colleagues (2010) found that disorganized children ages 8–12 had higher levels of parent-rated attention problems on the Child Behavior Checklist, and these problems were more likely to be clinically significant. Similarly, in a small Swedish cohort, disorganization, as assessed by a story stem measure at age 5, predicted ADHD symptoms at age 7 (Bohlin, Eninger, Brocki, & Thorell, 2012). Using the same sample, Thorell, Rydell, and Bohlin (2012) reported that children's representations of disorganized attachment at 8.5 years predicted ADHD

symptoms 1 year later. Finally, in a clinical sample of 4- to 9-year-old children with ODD or CD diagnoses, disorganization (vs. organization) was associated with a clinical diagnosis of ADHD (Green, Stanley, & Peters, 2007). Other types of insecurity were not analyzed in these studies, so comparisons between disorganized and avoidant or ambivalent attachments cannot be made.

Despite using a variety of measures and types of samples, this small set of studies is consistent in finding concurrent associations between disorganized or controlling attachment classifications and ADHD symptoms. Future research should differentiate between subsamples high in inattention and those characterized by hyperactive/impulsive symptoms.

OBSESSIVE–COMPULSIVE DISORDER

Models of obsessive–compulsive disorder (OCD) have implicated insecurity in general, and avoidant and ambivalent attachment styles specifically. It has been suggested that compulsions result from the avoidant child's rigid self-reliance or the ambivalent child's difficulty learning from experience, given an early inflexible focus on caregivers (Ivarsson, Granqvist, Gillberg, & Broberg, 2010). In another formulation, Rezvan and colleagues (2012) note that the parents of children with OCD are more likely to be intrusive and interfering, resulting in avoidant attachment. Alternatively, children with frightening parents (i.e., disorganized or controlling children) may attempt through ritualized behaviors to ward off fear and control unavoidable dangers.

Few investigations have examined the relation between OCD and attachment, and only one has done so in childhood. Rezan and colleagues (2012) reported that insecurity (assessed with a self-report inventory) was associated with the number of obsessive–compulsive symptoms in a sample of 10- to 12-year-olds. In an adolescent study, 60% of those with OCD diagnoses were classified as dismissing (analogous to avoidant) on the Adult Attachment Interview (Ivarsson et al., 2010).

POSTTRAUMATIC STRESS DISORDER

The correlates of disorganized attachment overlap with two of the three symptom clusters of PTSD diagnosis. The avoidance cluster includes dissociation (numbing), and the hyperarousal cluster includes irritability/angry outbursts; both are often

exhibited by individuals who have been exposed to severe trauma. For this reason, it is reasonable to expect that disorganized attachment might be associated with PTSD.

Recoding the Minnesota data to include the disorganized/disoriented scale, Ogawa, Sroufe, Weinfield, Carlson, and Egeland (1997) and Carlson (1998) examined how infant attachment, developmental factors, and trauma experience were related to dissociation at ages 17 and 19. Both avoidance and disorganization in infancy predicted clinically significant dissociation in adolescence. These findings partially support Liotti's (1995) model linking early disorganization and trauma to later dissociative disorders.

More recently, MacDonald and colleagues (2008) followed a small group of infants, about half of whom were exposed to cocaine *in utero*, through their eighth birthday. Disorganization in infancy predicted number of PTSD symptoms and, in particular, symptoms in the avoidance and reexperiencing clusters, after researchers controlled for gender, cocaine exposure, and continuity of care. Significantly, children classified as disorganized were no more likely than controls to report having experienced trauma, although 64% indicated some traumatic exposure.

AUTISM SPECTRUM DISORDER

Because the core criteria for autism spectrum disorder (ASD) involve impaired social interaction and communication, it was long assumed that children with these disorders might not form attachment relationships. They were also expected to exhibit some of the unusual behaviors associated with disorganized attachment.

Several studies have demonstrated that some children with ASD do form secure attachments (e.g., Dissnayake & Crossley, 1996; Rogers, Ozonoff, & Maslin-Cole, 1991), but insecure attachments occur more frequently than they do in nonclinical children. A meta-analysis of 16 studies concluded that although many children with autism exhibited secure attachments (53% in studies that assessed four categories), they were more likely than comparison children to be insecure (Rutgers, Bakermans-Kranenburg, Van IJzendoorn, & van Berckelaer-Onnes, 2004). However, this difference was evident only among children who were mentally delayed; studies with less delayed children showed no association with insecurity.

Studies examining multiple categories of attachment have provided mixed evidence, with some studies indicating an excess of disorganized attachments among children with ASD (e.g., Capps, Sigman, & Mundy, 1994) and others failing to do so. Notably, Capps and colleagues (1994) demonstrated that disorganization was overrepresented even when unusual behaviors typical of ASD (e.g., stereotypies) were disregarded during coding. In a small study of toddlers with pervasive developmental disorder (PDD; a broader diagnostic category including autism), mental retardation, language delays, or typical development, Van IJzendoorn and colleagues (2007) found that children with PDD were more likely than those without this diagnosis to be classified as disorganized (vs. organized). However, 72% of the children with PDD also had mental retardation, which increased the risk of both insecure attachment and disorganization. This parallels earlier findings that only children with both PDD and mental retardation had elevated rates of disorganization (Rutgers et al., 2004; Willemsen-Swinkels, Bakermans-Kranenburg, Buitelaar, Van IJzendoorn, & van Engeland, 2000).

Naber and colleagues (2007) also reported that children with ASD were more likely than children without disorders to have disorganized attachment. However, children with ASD did not differ in rates of disorganization from other children with PDD, mental retardation, or language development disorders; mental developmental level, rather than severity of autistic symptoms, again appeared to account for disorganization. In a study by Bohlin and colleagues (2012), neither attachment insecurity nor disorganization (assessed with a story stem procedure at age 5) predicted autism symptoms at 7 years.

Given the consensus that autism is largely biologically determined, these findings may be more useful as aids in supporting children and families than for etiological understanding.

GENDER DYSPHORIA

Few researchers have examined attachment processes in children with gender dysphoria (GD; formerly gender identity disorder). Goldberg (1997) reported a study in which boys with this disorder were more likely to be insecure than a community comparison group, and more likely to be ambivalent than a clinic comparison group. Secure, avoidant, and ambivalent classifications were approximately

equally represented among the boys with GD, and disorganization was the least likely classification. Insecure attachment (based on the Separation Anxiety Test) was also overrepresented in another group of clinic-referred boys with this diagnosis (Birkenfeld-Adams, 2000). A related construct labeled “gender contentedness” was negatively associated with avoidant attachment for girls and boys and with preoccupied (ambivalent) attachment for boys in a fifth-grade sample (disorganization was not assessed; Cooper et al., 2013). Thus, although youth with GD appear to be at increased risk for insecure attachment, there is no consensus about what form this insecurity is likely to take.

EATING DISORDERS

Although eating disorders are uncommon prior to adolescence, family relationships are frequently cited as a major etiological risk, so links with attachment are a promising target for research. Two studies are relevant. One involving Dutch preadolescents revealed that children reporting loss of control over eating rated their attachments with both parents as less secure (Goosens, Braet, Bosmans, & Decaluwe, 2011). In another, a unique investigation measuring prefrontal blood volume, Nagamisu and colleagues (2010) demonstrated that attachment-oriented images were particularly salient to young adolescent girls with anorexia nervosa. These youngsters responded with more prefrontal activation than comparison girls to images of mother-child interactions; surprisingly, no differences appeared in response to images of obese or slender bodies or of high-calorie food. The domain of eating disorders is one that requires further investigation.

Disordered Attachment: Response to Extreme Caregiving Environments

Diagnosing Disordered Attachment

So far we have focused on how attachment might serve as a risk or protective factor for specific disorders. What happens when a child has no specific caregiver to whom he or she can attach or when caregiving relationships are severely disrupted? Does this constitute disorder in itself, and if so, what might characterize this disorder?

These questions have informed studies of children raised in orphanages and others who

have experienced maltreatment or the loss of caregivers, resulting in either the absence of a figure with whom to build a relationship or the traumatic disruption of a caregiving relationship. For many years clinicians have been aware of a small but seriously impaired group of children whose difficulties are believed to result from distorted or disrupted caregiving. Concerns about these children led to investigations of the effects of “maternal deprivation” after World War II (e.g., Bowlby, 1953; Goldfarb, 1955; Spitz, 1946). Children living in institutions, adopted after institutionalization, or removed from home because of maltreatment or neglect have been the subject of considerable recent research (e.g., Dozier, Albus, Stovall, & Bates, 2000; McCall, Van IJzendoorn, Juffer, Groark, & Groza, 2011; Rutter et al., 2010; O’Connor et al., 2003; St. Petersburg–USA Orphanage Research Team, 2008; Zeanah, Smyke, & Dumitrescu, 2002).

Official diagnostic systems first acknowledged that distorted attachment relationships might constitute a disorder when the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III; American Psychiatric Association, 1980) included reactive attachment disorder (RAD). RAD was characterized as a pervasive disturbance across relationships, occurring before 10 months of age, with associated “failure to thrive” symptoms. The next revision (DSM-IV; American Psychiatric Association, 1994) and the *International Classification of Diseases* (ICD-10; World Health Organization, 1992) altered age of onset to 5 years or younger and dropped the failure to thrive criterion. Two types of the disorder were described: an inhibited form marked by hypervigilance, fear, withdrawal, and ambivalence, and a disinhibited subtype with indiscriminately friendly behavior and limited evidence of a specific attachment. DSM-IV also required documentation of pathogenic care.

These diagnoses recognized that disturbed attachment relationships may themselves represent disorder, but their formulation was inconsistent with attachment theory and research (Zeanah, 1996). Among other concerns, criteria focused on social behavior in general rather than relationships with primary caregivers, and the association between RAD and traditional attachment measures was problematic. Drawing from richly described case studies and their experiences with Romanian orphanages, Zeanah and Boris (2000) proposed alternative criteria, distinguishing “nonattachment,” “disordered attachment,”

and “disruption of attachments.” As in the DSM-IV and ICD-10 formulations, children in the first category (nonattachment), with no discriminated attachment figure, might either fail to differentiate among adults (indiscriminate sociability) or fail to seek or respond to caregivers in a developmentally typical manner. Zeanah and Boris did not require that these distortions occur in social situations beyond the caregiving context, and they specified that the child must have a mental age of at least 10 months, to distinguish attachment disorder from cognitive deficits or PDD. In the second category (disordered attachment), a selective attachment was thought to exist but to be disturbed, as evidenced by the child’s self-endangerment, extreme inhibition, compulsive compliance, or role reversal. Finally, the third group (disruption of attachment) included children whose attachment to a primary caregiver had been disrupted; they might display grief reactions ranging from protest to despair to detachment. Initial studies suggested that these criteria, grounded in both attachment theory and clinical experience, permitted more reliable description of cases than the DSM-IV criteria (Boris, Fueyo, & Zeanah, 1997; Boris et al., 2004).

Zeanah and colleagues (2005) also developed a coding system to determine the extent to which a child displayed attachment behavior to a particular caregiver. Sroufe and colleagues (2005) and others have emphasized the importance of quality, not strength, of attachment, as all children in normal caregiving environments are expected to develop attachment bonds. However, in extreme circumstances such as institutional care, fostering, or adoption, it becomes critical to assess the degree to which any attachment relationship has developed. The Strange Situation was not designed to be sensitive to this, so the new coding system provides an important tool for understanding disorders involving atypical caregiving.

More recently, DSM-5 (American Psychiatric Association, 2013) separated the subtypes of the previous diagnostic category into two distinct disorders. RAD now refers to the emotional withdrawal/inhibited pattern and a new diagnostic category, disinhibited social engagement disorder (DSED), describes those children previously referred to as indiscriminately friendly. Research suggests that these two diagnoses can be reliably assigned and that each is cohesive and relatively stable, with distinct and predictable associations (Gleason et al., 2011).

Very limited information exists on the emotional withdrawal/inhibited form, but Gleason and colleagues (2011) report that in their small sample, it was modestly related to caregiving quality, and children who met criteria all received insecure-other attachment classifications. These children might be considered to have no selective attachment relationships.

More is known about disinhibited children. Aside from an initial experience of insufficient care, there is little evidence of a continuing association between caregiving quality and the disinhibited pattern, and there appears to be considerable stability over time even when children appear to have adapted well in adoptive families (Chisholm, Carter, Ames, & Morison, 1995; Gleason et al., 2011; Rutter et al., 2007). Although these children are often classified as insecure using traditional attachment measures, a substantial number receive organized and even secure classifications (Chisholm et al., 1995; O’Connor et al., 2003; Rutter et al., 2007; Zeanah et al., 2004). Multiple investigators have therefore concluded that this diagnosis does not reflect a disinhibited attachment with a specific caregiver but, instead, a general failure to inhibit social behavior and recognize boundaries (Bakermans-Kranenburg et al., 2011; Bruce, Tarullo, & Gunnar, 2009; Gleason & Zeanah, 2010). Disinhibition may be an example of a behavioral pattern that results from extremely deficient early caregiving but does not necessarily preclude a child’s subsequent ability to form a secure attachment with caring adults.

Zeanah and colleagues found that children in standard orphanage care were more likely to exhibit indiscriminate behavior than either those in a special unit designed to provide more consistent care or a home-reared group (Smyke, Dumitrescu, & Zeanah, 2002; Zeanah et al., 2002). Interestingly, the pure withdrawn/inhibited pattern was relatively uncommon; most orphanage children displayed a mixture of inhibited and disinhibited behavior.

As noted, some children who have experienced extreme deprivation have been assigned organized and even secure attachment classifications, especially after receiving more adequate caregiving (Chisholm et al., 1995; O’Connor et al., 2003; Rutter et al., 2007; Zeanah et al., 2004), but it is not clear that their responses to traditional attachment protocols have the same meaning as those of other children (Bakermans-Kranenburg et al., 2011; Rutter et al., 2009). Also, most research has relied on the DSM-IV diagnosis, which

combined the inhibited/withdrawn group with disinhibited cases. With those caveats, what do we know about the attachment relationships of children whose early caregiving was severely deficient and whom we therefore might expect to have disordered attachment?

Reviewing six studies of institutionally reared children, Van IJzendoorn and colleagues (1999) calculated that attachments with a favorite caregiver were secure in 17.1% of cases, avoidant in 5.5%, resistant in 4.6%, and disorganized in 72.8%. Marcovitch and colleagues (1997) assessed 3- to 5-year-old Romanian children adopted into Canadian families and also found higher than expected rates of insecurity. Not one adoptee was classified as avoidant; the authors argue that avoidance is particularly maladaptive for an adoptee, and that parents motivated to adopt are unlikely to exhibit parenting patterns related to avoidance during relationship formation. Subsequent studies using conventional measures of attachment have likewise found high rates of insecurity and, in particular, disorganization (Van den Dries, Juffer, Van IJzendoorn, & Bakermans-Kranenburg, 2009).

The focus so far has been on children who have spent significant periods of time (generally over 6 months) in institutions. What about the population that clinicians are more likely to encounter, children who have been maltreated? Using an interview developed for their work with Romanian orphans, Zeanah and colleagues (2004) demonstrated that RAD could be reliably diagnosed in toddlers in foster care, with a prevalence of 38–40%. A significant number displayed both withdrawn and indiscriminate social behavior, and clinician interviews indicated that some children who met criteria for indiscriminate/disinhibited RAD nonetheless had selective attachments to a caregiver, similar to institutionalized children. Boris and colleagues (2004) compared three groups of children (ages 18–48 months): one with a history of maltreatment, a second from a homeless shelter, and the last from HeadStart. Using Zeanah and Boris's (2000) alternative criteria, they found that maltreated children were the most likely to have an attachment disorder. Children with this diagnosis were less likely to be concurrently securely attached (to foster mothers, in the maltreated sample) and had lower security scores. However, children with an attachment disorder were no more likely than the others to be classified as disorganized. Finally, using ICD-10 criteria, Minnis and colleagues (2009) reported

that children with RAD diagnoses were far more likely (relative risk 2.4) than comparisons to be insecurely attached (27% disorganized), but 30% were rated secure on the Manchester Child Attachment Story Task.

Other Disorders Associated with Severely Disrupted Attachment

Are there specific disorders that children with extremely deficient early caregiving or attachment disorders are particularly likely to exhibit? There is a good deal of evidence of impairment in this population, but less has been written about specific diagnoses. In a small sample, Hodges and Tizard (1989) reported that children adopted from an institution that provided adequate physical care but was deficient with respect to caregiver–child interaction had more problems with anxiety, antisocial behavior, and peer relationships than comparisons. In their sample of 3- to 5-year-old Romanian children adopted into Canadian families, Marcovitch and colleagues (1997) found that both length of institutionalization and insecure attachment to adoptive parents were associated with number of behavior problems. Comparing children in standard orphanage care with others receiving more consistent care and a home-reared group, Zeanah and colleagues reported that only those in the orphanage exhibited *severe* aggression, although many displayed no aggression at all (Smyke, Dumitrescu, & Zeanah, 2002; Zeanah et al., 2002). In contrast, home-reared children had relatively high rates of “moderate” aggression, so comparisons based on linear analyses were misleading. In a study by Gleason and colleagues (2011), children described as emotionally withdrawn/inhibited (similar to the new RAD category) had elevated depression symptoms. The indiscriminately social/disinhibited group was more likely to be characterized as impulsive and inattentive; 25% met criteria for ADHD. The disinhibited pattern has also been found by others to be associated with impaired attention regulation (Bakermans-Kranenburg et al., 2011; Bruce et al., 2009; Gleason & Zeanah, 2010). Examining a different population (high-risk home-reared infants) and using a new rating scale of infant–stranger engagement, Lyons-Ruth, Bureau, Riley, and Atlas-Corbett (2009) found that indiscriminate sociability, associated with early maltreatment or maternal psychiatric hospitalization, predicted aggressive and hyperactive behavior ratings at age 5.

Summary

A lingering problem complicating interpretation of all of these findings is the absence of a widely accepted system that includes the entire spectrum of attachment experiences and successfully integrates these with a conceptualization of disordered attachment that is consistent with attachment theory and research. Most studies continue to rely on standard attachment classifications, although these do not adequately describe children who have experienced extremes of caregiving (Bakermans-Kranenburg et al., 2011). Despite considerable attention to the category of disorganized attachment over the past several years, exactly how it and its subtypes fit into this spectrum, and the mechanisms relating it to experience, to various outcomes, and to disorder, are still unclear.

The study of children deprived of an average, expectable caregiving environment both confirms the importance of these experiences to psychological health and illustrates the limitations of the conventional attachment measures on which we have long relied. Although many children with these disorders exhibit insecure or unclassifiable attachments, others appear secure in standard assessments. Regardless of attachment classification, they often display a variety of disordered behaviors that are clearly related to caregiving history. More research is needed, particularly with respect to children in the child protective system. Such investigations will help to inform the design of more effective interventions and are also likely to contribute to a deeper understanding of basic processes critical to both typical and pathological social and emotional development.

Where Are We Now, and Where Should We Go from Here?

Since Mary Ainsworth first developed the Strange Situation, measurement has been central to our understanding of attachment and its relation with development. Measurement was a focal concern in our chapters in previous editions of this handbook (DeKlyen & Greenberg, 2008; Greenberg, 1999), and it remains a concern.

Significant progress has been made, for example, in creating tools to assess attachment in middle childhood, but we still know little about how measures from different developmental periods and using different methodologies relate to each other. Without such evidence, it is impos-

sible to determine whether outcomes are due to stable psychological structures established in early childhood, are dependent on the quality of ongoing relationships, or are perhaps caused by a third factor that influences both attachment and outcome. As Fearon and Belsky (2011) have argued, establishing causality will require well-validated measurement protocols that permit rigorous, cross-lagged longitudinal designs, and these are not yet available.

In 2008 we recommended a “return to the clinic.” In recent years a significant body of research has described children who have suffered extremely deficient caregiving, providing a great deal of detail about the cognitive, behavioral, and physiological sequelae of severe neglect (see, e.g., monographs edited by McCall et al., 2011; Rutter et al., 2010). However, we still lack an integrated model that combines a taxonomy of disordered attachment with the classic attachment categories. Such a classification system should include and further describe subcategories of disorganized/disoriented attachment (e.g., controlling–punitive and controlling–caregiving), so that we can better understand why each develops, how each relates to specific disorders, and the environments and biology associated with each of these. Further development of measurements appropriate to children in extreme caregiving environments is needed for both theoretical and practical reasons. It would help us answer important clinical questions: How does a new attachment relationship form? How can disrupted attachments be repaired? What determines whether a secure attachment develops following maltreatment or trauma and whether disruptions are likely to leave lasting impairment? The lack of measures appropriate to the many clinical situations involving removal from home, the effects of foster care, and adaptation to later adoption is a major impediment to the practical application of attachment theory to these urgent social issues. Unfortunately, attachment concepts have too often been applied in a manner that is unsophisticated, inaccurate, or even dangerous (Mercer, Sarner, & Rosa, 2003).

Relatively few studies have examined disorders or behaviors that meet clinical criteria for concern. Diagnoses can provide a threshold of severity, as well as a degree of specificity that is missing in terms such as *externalizing* or *behavior problems*, although they do not ensure homogeneity of symptoms or etiology.³ Some of the inconsistent findings reported in our review may be the result of poorly defined and heterogeneous constructs (e.g.,

externalizing, internalizing, behavior problems). Furthermore, when dimensional ratings are used, it is critical that authors provide information about the range of values represented in a given sample and their clinical significance. Also, low behavior ratings can be as much a cause for concern as elevated scores, so that interpreting scales solely by means of linear analyses may be problematic.

As already indicated, the field has been held back by lack of consistency in what researchers measure and how they report results. We have suggested that comparisons of secure versus insecure children are no longer very useful. Progress requires more specificity, and relatively few researchers have examined links between specific attachment classifications and specific disorders. Variability in how attachment is measured and reported (e.g., ambivalent vs. all other categories, three as opposed to four classifications) has further limited our ability to draw conclusions about specific attachment categories. Especially given the apparent significance of disorganization, we would encourage investigators always to assess and analyze all four attachment categories.

Researchers have begun to examine how differential susceptibility models, involving both environmental factors and gene \times environment interactions, may relate to attachment (e.g., Kochanska, Philibert, & Barry, 2009; Spangler, Johann, Ronai, & Zimmermann, 2009; Starr et al., 2013). Epigenetic research has also provided new insights, for example, suggesting that trauma and stress influence health and well-being by changing the expression of genes (in this volume, see Bakermans-Kranenburg & Van IJzendoorn, Chapter 8; Hane & Fox, Chapter 11; and Ehrlich, Miller, Jones, & Cassidy, Chapter 9). These and other new approaches promise to provide fresh perspectives on the relation between attachment constructs and children's psychopathology. However, we must exercise caution before embracing these new methodologies too enthusiastically or abandoning old ones; exciting early findings do not always replicate (cf. Roisman, Booth-LaForce, Belsky, Burt, & Groh, 2013).

Summary

In the *Handbook's* first edition, this chapter posed the following question: Do specific attachment patterns lead to specific disorders? Greenberg (1999) concluded that attachment insecurity

might be an important but nonspecific risk factor, increasing risk for several forms of psychopathology. It is not clear whether our inability to provide a more conclusive answer today is because the effect of attachment is indeed less specific than had been hypothesized, or because there has been insufficient research that reports on all attachment categories and clearly delineates outcomes to either confirm or dispute this assertion.

Although attachment processes show both predictive and concurrent associations with psychopathology in childhood, insecure attachment is rarely either a necessary or a sufficient cause of later disorder. Insecurity is not synonymous with disorder; secure children may be disordered and insecure children may function adequately. However, nonoptimal attachment experiences in infancy and beyond increase the risk for a variety of problems. With the intersection of multiple risk factors, maladaptation is increasingly probable. Further study of attachment as both mediator and moderator and the incorporation of concepts of differential susceptibility and gene \times environment interaction are likely to be productive.

We have presented evidence that both avoidant and disorganized or controlling attachments are associated with externalizing problems, at least for boys. Disorganization may be a stronger predictor. The few relevant studies that exist suggest that ADHD is also often associated with disorganized attachment. The evidence for links between specific attachment styles and anxiety is less conclusive. A major roadblock is inconsistent reporting of attachment categories. Studies that assess three categories have often found ambivalent patterns predictive, while those that assess four categories more often implicate disorganization. Theoretical arguments have been advanced for links between each insecure category and depression, and empirical findings have been mixed, perhaps reflecting the disorder's heterogeneity. This may change with adolescence, when girls become far more likely than boys to be diagnosed with depression. Theory suggests that disorganization should be associated with PTSD, but little research has tested this in childhood. PTSD presents an especially interesting case, since the trauma involved often occurs after infancy, so internal working models may have undergone change. How important might early versus later attachment relationships be in this case? Contrary to expectations, many children in the autistic spectrum do form secure attachments, although they are less likely to do so than typically developing children. Disorganization is the most

common form of insecurity in this group, but it appears to be more associated with cognitive delay than with the core symptoms of ASD.

Children in extremely compromised caregiving environments have been the subject of major studies in the last decade, and conceptualizations of RAD have undergone significant change. Youngsters meeting criteria for the new RAD diagnosis are likely to be classified as insecure, but many have likely failed to form a specific attachment. Children with disinhibited or indiscriminately friendly behavior are less associated with any one classification; some form secure attachments while maintaining indiscriminate social behavior. Standard attachment measures have proven inadequate to describe the relationships that many institutionalized, foster, adopted, or maltreated children have with caregivers, and we look for further development in this area.

The study of attachment and its relation to normality and psychopathology has advanced significantly in the past three decades. Yet further development and cross-validation of measures with older children and more comprehensive investigations that assess potential moderating and mediating processes and mechanisms are needed to illuminate the transactional relations linking attachment, other risks, and psychopathology. A continued emphasis on attachment-informed studies of children who have experienced extremes of caregiving will serve both to address urgent clinical and public health demands and to enrich our understanding of attachment. We look forward to more multifactorial, longitudinal studies of normative and high-risk populations and of samples with specific forms of psychopathology, utilizing complex models, to provide a fuller picture of the role of attachment in the development of childhood psychopathology.

Notes

1. The items on the Child Behavior Checklist Aggression subscale include only a few descriptions of actual aggression along with many other behaviors (disobedience, temper, etc.) and in our opinion would more accurately be labeled “disruptive” or “oppositional behavior.”
2. Kerns, Brumariu, and Seibert (2011) compared self-reported ratings of security, avoidance, and preoccupation with story stem interview ratings for security, avoidance, ambivalence, and disorganization. Security ratings assessed by the two methods were correlated ($r = .28$); neither avoidance nor ambivalence ratings were. Self-reported preoccupation (ambivalence) correlated with story stem disorganization ratings ($r = .24$).
3. The National Institute of Mental Health’s Research Domain Criteria (RDoC) initiative is likely to further complicate future comparisons, but it may ultimately result in more clarity in reporting maladaptive outcomes (Cuthbert & Kozak, 2013).

Chapter 29

Attachment Disorganization from Infancy to Adulthood

Neurobiological Correlates, Parenting Contexts, and Pathways to Disorder

Karlen Lyons-Ruth
Deborah Jacobvitz

In a seminal article, Main and Solomon (1990) chose the term *disorganized/disoriented* to describe an array of previously unrecognized fearful, odd, or overtly conflicted behaviors exhibited by infants during Ainsworth's Strange Situation procedure (Ainsworth, Blehar, Waters, & Wall 1978). Infants are considered disorganized/disoriented when, for example, in response to their parents' return following a brief separation, they appear apprehensive, cry, and fall huddled to the floor, or put their hands to their mouths with hunched shoulders. Other infants appear disoriented, freezing all movements while exhibiting a trance-like expression. This description of disorganized/disoriented behaviors in infancy led to an explosion of studies on the developmental origins, correlates, and outcomes of disorganized attachment relationships.

Since the first edition of this handbook, meta-analyses have underscored the relevance of disorganized relationships to the understanding of both child and adult psychopathology (Bakermans-Kranenburg & Van IJzendoorn, 2009; Fearon, Bakermans-Kranenburg, Van IJzendoorn, Lapsley, & Roisman, 2010; Van IJzendoorn, Schuengel, & Bakermans-Kranenburg, 1999). In addition, several new frontiers are emerging in the

study of attachment disorganization. First, genetic and neurobiological correlates of attachment disorganization are being actively explored. Second, the frightened, frightening, or disrupted forms of parent–infant communication also predict later psychopathology, in some cases more strongly than infant disorganization alone, and are now being studied in their own right. Third, there are new findings on the relations between attachment disorganization toward institutional caregivers and later indiscriminate attachment behavior toward strangers. Fourth, new observational assessments of disorganized parent–child interactions in adolescence have been developed, validated, and related to several aspects of young adult psychopathology.

We begin this review with an overview of attachment disorganization in infancy, its definition, prevalence, and associated infant characteristics, including temperament, genetics, and neurobiology. In the second section, we review family correlates of disorganization, including family risk factors, parental states of mind on the Adult Attachment Interview, and frightened, frightening, or disrupted parental communication with the infant. In the third section, we consider the re-

organization of disorganized infant behavior into controlling behavior during preschool and school age periods, along with evidence linking controlling behavior to childhood psychopathology. We explore in the fourth section the adolescent and young adult sequelae of infant disorganization and parental disrupted communication. In the final section, we discuss the recent introduction of an observational measure of disorganized attachment in adolescence. We conclude with some thoughts about important future directions for work on disorganized attachment.

Disorganized Attachment Behavior in Infancy: Definition, Prevalence, and Associated Infant Characteristics

Understanding the central role of fear in attachment theory is critical to understanding attachment disorganization (Hesse & Main, 2006; Main & Hesse, 1990). Bowlby's (1969) initial formulation of attachment theory emphasized the organization of observable behaviors around the set-goal of maintaining physical proximity to the parent. Signs of danger or potential danger, such as unfamiliarity, fatigue, illness, or injury, result in higher levels of activation of this attachment behavioral system. When the system is strongly aroused, physical contact with a caregiver (e.g., touching, clinging, cuddling) may be necessary to terminate attachment behavior. When the environment is benign and the mother's availability is clear, the child typically ceases to exhibit attachment behavior and turns to exploring the environment.

Ainsworth and colleagues (1978) initially described three organized patterns of behavior displayed by infants when they are distressed by a brief separation from their caregivers in an unfamiliar situation: secure, avoidant, and resistant/ambivalent. However, researchers observed that some infants did not fit these three patterns (e.g., Lyons-Ruth, Connell, Zoll, & Stahl, 1987; Main & Weston, 1981). Based on these observations, Main and Solomon (1990) reexamined over 200 anomalous Strange Situation videotapes. They concluded that most of the children lacked any organized strategy for dealing with the stress of separation. For example, infants were observed approaching the parent with head averted, rocking on hands and knees following an abortive approach, or screaming by the door for the par-

ent, then moving silently away on reunion. What these infants appeared to have in common was contradictory intentions (approaching a parent with head averted) or behavior that involved apprehension either directly (fearful facial expressions, oblique approaches) or indirectly (disoriented behaviors, including dazed and trancelike expressions; freezing of all movement at parent's entrance). Main and Solomon viewed these contradictory or out-of-context behaviors as indicating that the infant was unable to organize a consistent secure, avoidant, or ambivalent strategy toward the caregiver when experiencing a need for comfort. Thus, "fear without solution" was seen as the core dilemma at the heart of disorganized attachment behavior.

Main and Solomon (1990) proposed that infants be categorized as disorganized when, in the presence of the caregiver after a brief separation, they display behaviors falling under one or more of the following headings:

1. Sequential display of contradictory behavior patterns, such as very strong attachment behavior suddenly followed by avoidance, freezing, or dazed behavior.
2. Simultaneous display of contradictory behaviors, such as strong avoidance with strong contact seeking, distress, or anger.
3. Undirected, misdirected, incomplete, and interrupted movements and expressions (e.g., extensive expressions of distress accompanied by movement away from, rather than toward, the mother).
4. Stereotypies, asymmetrical movements, mistimed movements and anomalous postures, such as stumbling for no apparent reason and only when the parent is present.
5. Freezing, stilling, and slowed "underwater" movements and expressions.
6. Direct indices of apprehension regarding the parent, such as hunched shoulders or fearful facial expressions.
7. Direct indices of disorganization and disorientation, such as disoriented wandering, confused or dazed expressions, or multiple rapid changes in affect.

In addition to assigning a disorganized classification, coders assign a secondary "best-fitting" organized attachment classification (secure, avoidant, or resistant). A D-secure infant seeks contact with the mother without marked avoidance or ambivalence and is soothed by her presence but

shows other unusual signs of hesitation, confusion, apprehension, dysphoria, or conflict in relation to her. Disorganized-avoidant and disorganized-ambivalent infants often display unexpected combinations of distress, contact seeking, avoidance, resistance, or other apprehensive or conflict behaviors. Attachment disorganization, as a coding category, has been shown to be stable for periods ranging from 6 to 60 months ($r = .36$; $N = 515$) and has good interrater reliability (Van IJzendoorn et al., 1999).

Prevalence of Disorganized Attachment Patterns

Meta-analyses indicate that 15% of infants are classified as disorganized in middle-class, nonclinical groups ($N = 1,882$) and 34% in low-income samples ($N = 493$) (Van IJzendoorn et al., 1999). Attachment disorganization (D) is accompanied by a secondary classification of ambivalent in 46% of cases, avoidant in 34%, and secure in 14%. However, these subtypes may be differentially distributed in low- and high-social-risk environments. In middle-income samples, more D infants are classified D-secure (50%, $N = 110$, Jacobvitz, Hazen, Zaccagnino, Messina, & Beverung, 2011; 62%, $N = 268$, Main & Solomon, 1990; 52%, $N = 1,131$, National Institute of Child Health and Human Development Early Child Care Research Network [NICHD ECCRN], 2001; K. McCartney, personal communication, October 12, 2005).

Temperament, Genetics, and D Behavior

Given the contradictory nature of D behaviors, an important question is whether temperamental differences underlie them. Studies examining concordance in D classification across caregivers reveal that infants are unlikely to be classified as D with more than one caregiver (Fonagy et al., 1996; Main & Solomon, 1990). In addition, a meta-analysis showed a nonsignificant association between behavioral assessments of infant temperament and D ($r = .003$; Van IJzendoorn et al., 1999). Thus, the evidence does not indicate that infant temperament underlies D.

Only one study has examined temperamental variation *within* the D group. Padrón, Carlson, and Sroufe (2014) found that infants who were classified as D but did *not* display indices of fear during the Strange Situation were more likely than other

D infants to have exhibited limited emotion regulation as newborns.

An important new area of study concerns possible genetic influences on D. Using *behavioral* genetic methods, Bokhorst and colleagues (2003) found that only nonshared environmental factors contributed to twin concordances in D. The authors speculated that nonshared factors such as trauma or differential parenting may be important in the etiology of D.

With the recent advent of *molecular* genetic techniques, it is easier to detect small effects of particular genes with modest sample sizes. The D4 dopamine receptor gene (*DRD4*) has been considered a candidate gene for infant attachment behavior because it is preferentially expressed in the mesocorticolimbic dopamine pathway that mediates reward related to social interaction, including mother–infant attachment (Insel, 2003). In a low-risk Hungarian sample, the risk for D increased fourfold among infants carrying the *DRD4.7* polymorphism (Lakatos et al., 2000), and tenfold in the additional presence a $-521 C/T$ single-nucleotide polymorphism (SNP) of the same *DRD4.7* allele (Lakatos et al., 2002). Cicchetti, Rogosch, and Toth (2011), examining children with and without maltreatment, also found relations between the *DRD4.7* allele and D. At age 2, *nonmaltreated children* with the *DRD4.7* allele were more likely to be classified as D than children without the allele, replicating the Lakatos and colleagues (2000) finding. Also, 2-year-olds with the short allele of the serotonin transporter polymorphism (*5-HTTLPR*) were more often classified as D than children without that allele. These serotonin alleles have been associated with increased negative emotional response (Canli & Lesch, 2007). In contrast, for *maltreated children*, the *absence* of the *DRD4.7* allele was associated with attachment disorganization but only at 1 year of age prior to the intervention. Following the intervention, no genetic differences were associated with disorganization. Cicchetti and colleagues (2011) speculated that genetic effects may be more evident in benign environments, while very adverse environments may override genetic contributions. However, a recent report using two large samples (the Generation R Study from the Netherlands [Gen R] and the NICHD SECCYD) failed to replicate the association between attachment disorganization and either the *DRD4* or *5-HTTLPR* polymorphisms (Luijk et al., 2011). (For further discussion, see Bakermans-Kranenburg & Van IJzendoorn, Chapter 8, this volume.)

Disorganized Attachment and Gene–Environment Interaction

Studies have also examined *gene–environment interaction effects* in the formation of disorganized patterns of attachment. Gervai and colleagues (2007) reported that in the presence of the more prevalent *nonrisk* *DRD4.4* allele, infant disorganization was significantly related to disrupted mother–infant interaction, as expected on the basis of previous meta-analyses (e.g., Madigan et al., 2006). However, among infants with the *DRD4.7* risk allele, the expected relation between quality of caregiving and attachment disorganization did not hold. Luijk and colleagues (2011) found a similar interaction effect in the NICHD sample.

This interaction effect did not replicate in the Gen R study in the Netherlands (Luijk et al., 2011), possibly because the study did not adequately capture maternal behavior. Specifically, maternal sensitivity was not related to infant security of attachment, as would be expected (e.g., NICHD ECCRN, 1997; Van IJzendoorn et al., 1999). Thus, in the only two studies that have satisfied the prior expectation that maternal behavior would be related to infant attachment security, the *DRD4.7* allele conferred less sensitivity to maternal behavior.

In contrast, in relation to maternal unresolved (U) status on the AAI rather than maternal behavior, Van IJzendoorn and Bakermans-Kranenburg (2006) found that U predicted infant disorganization significantly *more often* if the infant also carried the *DRD4.7* allele. Thus, further work is needed to explore relations among dopamine function, maternal care, and infant attachment behavior. Also see Spangler, Johann, Ronai, and Zimmermann (2009) for a small-sample study of interaction between maternal insensitivity and children with two *5-HTT* short alleles. In summary, findings so far do not cohere in support of a strong genetic component. However, the *DRD4* polymorphism, in particular, warrants additional study. (See Bakermans-Kranenburg & Van IJzendoorn, Chapter 8, this volume, for further discussion of these issues.)

Stress Hormone Levels, Neurobiology, and Disorganized Attachment Behaviors

In animal models, cortisol secretion is correlated with an animal's inability to mobilize an effective strategy to cope with a stressor (e.g., Levine, Wie-

ner, & Coe, 1993). Consistent with Main and Solomon's (1990) view that D reflects the lack of an infant strategy for coping with stress, three studies report associations between D in infancy and infant reactivity to a stressor (Bernard & Dozier, 2010; Hertsgaard, Gunnar, Erickson, & Nachmias, 1995; Spangler & Grossmann, 1993).

In addition, infant D has been associated with atypical patterns of diurnal cortisol secretion. Whereas cortisol levels typically decrease over the course of the day, Luijk and colleagues (2010) reported that 2-year-olds previously classified as D at 14 months displayed a more flattened rate of change across the day than did those who were not D. In addition, differences in total daily cortisol were found *within the D group*, with D-secure infants secreting significantly more cortisol than either disorganized-avoidant or disorganized-resistant infants. Similar flattened rates of change in cortisol over the day have been observed among maltreated children in foster care (e.g., Dozier, et al., 2006), further suggesting that flattened slopes are markers for disturbed care.

Few studies have examined differences in brain structure or function among infants at risk for disorganization. Tharner and colleagues (2013) reported an increased risk for D among 14-month-olds with a smaller gangliothalamic ovoid at 6 months, assessed by ultrasound. The authors speculated that ovoid differences may contribute to difficulties in response selection and hence to the display of conflict behavior when distressed. Given current interest in how early relationships influence brain development, we can expect the literature on attachment and infant neurobiology to grow exponentially in the next decade.

Developmental Timing: Prenatal Effects on D?

Animal studies provide clear evidence for the influence of prenatal experiences on brain structure and function (Del Cerro et al., 2010). A fetal programming hypothesis has been proposed to account for these effects (Barker, 1998). However, only a few human prenatal studies have included attachment assessments. In particular, maternal prenatal exposure to alcohol has been associated with D (Hay, Jacobson, Molteno, Viljoen, & Jacobson, 2004; O'Connor, Sigman, & Kasari, 1992; Rodning, Beckwith, & Howard, 1991), but only O'Connor and colleagues (1992) controlled for postnatal alcohol consumption. Bergman, Sarkar, Glover, and O'Connor (2008) also found that ma-

ternal prenatal stressful life events predicted infant disorganization. Other studies suggest that postnatal attachment experiences can attenuate the effects of prenatal stress on infant behavior (Bergman et al., 2008, 2010). However, specific effects of D were not explored in those studies.

Is Indiscriminate Attachment Behavior Associated with D?

An important new area of study concerns how D may intersect with indiscriminate attachment behavior (IAB), now referred to as disinhibited social engagement disorder (DSED; American Psychiatric Association, 2013). DSED is a form of atypical attachment behavior first described among infants reared in orphanages with multiple caregivers, but it is also evident among some young children in high-risk home environments (Lyons-Ruth, Bureau, Riley, & Atlas-Corbett, 2009; O'Connor, Rutter, & English and Romanian Adoptees Study Team, 2000). DSED is characterized by non-normative engagement with strangers, including seeking close physical contact or going off readily with a stranger. DSED was first assessed by caregiver report, but direct observational assessments have now been validated (Gleason et al., 2014; Lyons-Ruth et al., 2009).

A few studies have examined how DSED is related to D. Zeanah, Smyke, Koga, Carlson, and the Bucharest Early Intervention Project Core Group (2005) found a high incidence of D (65%) and unclassifiable attachment behavior (13%) among 12- to 31-month-old institutionalized children in Romania (mean age 24 months). Only 3% showed a clearly recognizable pattern of organized attachment behavior toward the institutional caregiver. Consistent with normative samples, the quality of caregiver interaction was related to disorganized versus organized attachment. Surprisingly, institutional caregivers' reports of DSED were unrelated both to disorganized behavior and to quality of interaction with the institutional caregiver. However, at 54 months, Gleason and colleagues (2014) found that the only predictor of DSED was D with the institutional caregiver at study entry (mean age 22 months). At 54 months, DSED was assessed behaviorally rather than by institutional caregiver report, using the new Stranger at the Door procedure (see Gleason et al., 2014). No other measure at study entry predicted DSED, including quality of institutional care, time in institution, developmental quotient, or birthweight. These results are

particularly striking because half of the children had been placed in good-quality foster care at study entry. Thus, D predicted DSED over a 2½-year period regardless of quality of later care.

In the only other study to use a behavioral assessment of DSED, Lyons-Ruth and colleagues (2009) assessed home-reared socially at-risk infants and found that DSED was significantly more frequent among infants classified as D with the primary caregiver. In addition, DSED was associated with more severe caregiving risk and with more pervasive later behavior problems than was D behavior alone. Thus, in the only two studies that have assessed DSED in relation to infant attachment *with an early inadequate caregiver*, D behavior toward the inadequate caregiver was associated with DSED toward the stranger.

All other studies of the relations between attachment behavior in the Strange Situation and DSED toward a stranger have observed the child *with an adequate subsequent foster or adoptive parent*. Not surprisingly, those studies yield a very different picture, with DSED toward a stranger typically occurring in concert with organized, and often secure, behavior toward the new caregiver (see Lyons-Ruth et al., 2009, for review). Thus, it appears critical to distinguish between the quality of the original attachment relationship and the quality of later, more adequate attachment relationships in exploring the origins of DSED.

In the only randomized study of *change in D* among formerly institutionalized young children, Smyke, Zeanah, Fox, Nelson, and Guthrie (2010) found that after 19 months of foster care, children in foster care were significantly more likely than children in institutional care to exhibit organized rather than disorganized attachments. In addition, children in foster care displayed secure attachments at rates similar to those in the never-institutionalized comparison group. Yet, rates of DSED were not significantly different between children in foster placement and those who remained in institutional care, even after an average of 32 months in foster care. This converges with prior adoption studies, which also found that DSED can be shown long after placement into good care, at times in concert with apparently secure attachment behavior toward the new caregiver. Dozier and colleagues (2006) reported further that among maltreated children in foster care, these new secure-appearing behavioral organizations toward the foster mother may coexist with continued patterns of cortisol dysregulation. Hence, it remains unclear to what extent new attachment organiza-

tions can compensate for the preceding periods of disorganization in the original attachment relationship in infancy. Primary prevention of DSED may depend on preventing D from forming in the *primary caregiving relationship*.

Infant D and Family Risk Factors

Maltreatment

A recent meta-analysis examined the effect of maltreatment (10 samples; $n = 456$), as well as the effect of multiple socioeconomic risks, on the risk for D (Cyr, Euser, Bakermans-Kranenburg, & Van IJzendoorn, 2010). Large effect sizes were noted, with maltreated children more likely to be disorganized ($d = 2.19$) than other socioeconomically at-risk children ($d = 0.48$). However, children with five or more socioeconomic risks (eight studies; $d = 1.20$) were also at elevated risk for disorganization. These results support Bernier and Meins's (2008) cumulative risk model proposing that multiple social risks will increase the incidence of D. Mechanisms underlying this association remain unclear but may include changes in parental behavior due to multiple economic stresses or more distal effects, such as multiple caregivers.

Parental Psychopathology

Studies examining relations between maternal depression and D have yielded mixed results. A meta-analysis of 16 studies ($N = 1,053$) found only a marginally significant relation between maternal depressive symptoms and infant D ($r = .06$, $p = .06$; Van IJzendoorn et al., 1999). However, a second meta-analysis revealed a significant effect of maternal depression when only serious depressive disorders requiring treatment were considered (Martins & Gaffan, 2000; see also Toth, Rogosh, Manly, & Cicchetti, 2006). More chronic and severe maternal depression resulting in significant clinical impairment may be necessary to produce an increase in infant D.

Maternal borderline personality disorder (BPD), characterized by intense and unstable relationships and impulsive, self-damaging behavior, including suicidality, has also been associated with elevated rates of D in infants. Compared to infants whose mothers did not have BPD, a higher proportion (80%) of 12-month-olds with mothers with BPD were classified as D (Hobson, Patrick, Crandell, García-Pérez, & Lee, 2005). Disorganization

was also more prevalent among children whose mothers were drug-addicted compared to other low-income mothers (Melnick, Finger, Hans, Patrick, & Lyons-Ruth, 2008). (Associations between prenatal maternal substance abuse and D were reported in an earlier section of this chapter, "Developmental Timing.")

Parental Work Hours and Marital Conflict

In the Austin longitudinal study, Hazen, Allen, Umemura, Heaton, and Jacobvitz (2015) found an increased incidence of D if time in nonmaternal care exceeded 60 hours per week. A replication in the large NICHD sample confirmed that risk of D exponentially increased after 60 hours/week in nonmaternal care (Hazen et al., 2015). In the Austin sample, disorganization with fathers did not increase as a function of time spent in nonpaternal care, suggesting that D is not simply a function of lack of interaction. Conflict in the marriage is also related to infant D (Owen & Cox, 1997), but more research is needed to understand why this relation exists. It will be important to examine mechanisms underlying the relations between infant D and these family factors.

Parental Unresolved States of Mind

According to attachment theory, children build expectations about future interactions with parents and others based on repeated patterns of interaction in close relationships. As these largely unconscious expectations become elaborated and organized, they form "internal working models" (Bowlby 1973) that guide children's interpretations and behaviors in new situations. Main, Kaplan, and Cassidy (1985) found that when parents' representations of their childhood attachment relationships were explored in an open-ended interview, the Adult Attachment Interview, four classifications of adults' states of mind regarding attachment could be reliably assigned. These four classifications, labeled autonomous, dismissing, preoccupied, and unresolved-disorganized (U), are analogous to the four infant attachment classifications—secure, avoidant, resistant, and disorganized.

The U classification is assigned to adults who show signs of disorientation and disorganization during discussions of potentially traumatic events (i.e., deaths, physical abuse, or sexual abuse). As

detailed by Main, Goldwyn, and Hesse (2003), one sign of such lack of resolution is a lapse in the monitoring of discourse, whereby the speaker has “lost awareness of the discourse context.” Examples include falling silent for 20 seconds mid-sentence, then completing the sentence or failing to finish the sentence. Another sign of unresolved loss or trauma is a lapse in the monitoring of reasoning. These lapses in the monitoring of reasoning are usually brief and should not be confused with “irrational” thinking across the transcript. Lapses include disbelief that the person is dead (e.g., discussing a parent in the present tense even though the parent died 20 years earlier) or beliefs that go against normal ideas about causality (e.g., “I killed him by saying one sentence”). Hesse (1996) suggested that lapses in the monitoring of reasoning or discourse involve “frightening and/or overwhelming experiences that may momentarily be controlling or altering discourse” (p. 8). Hesse and Main (2006) proposed that adults classified Unresolved are still overwhelmed either by the trauma itself, which is inherently frightening, or by “incompletely remembered loss experiences.”

Similar to disorganized infants, adults classified as U are given a best-fitting alternate classification, identifying the pattern most closely corresponding to the overall organization of the interview (e.g., unresolved-autonomous). Main and colleagues (2003) also developed interview-wide criteria for designating an Adult Attachment Interview (AAI) item as “cannot classify.” This may occur if both a dismissing and a preoccupied attachment strategy are evident in the same interview or if the participant exhibits low coherence across the interview.

Notably, Ainsworth and Eichberg (1991) did not find a significant association between being classified as U and either the mother’s age when the loss occurred or her relationship to the deceased (attachment figure vs. someone else). Jacobvitz, Leon, and Hazen (2006) also found that the mother’s age when the loss occurred was unrelated to her resolution of the loss. However, mothers who were classified as U were more likely to have lost a parent than to have lost a less important figure.

Maternal Unresolved State of Mind and Infant D

Parental U state of mind is significantly related to infant D, with an effect size of 0.65 ($r = .31$, $N = 548$; Van IJzendoorn, 1995). This association

has been confirmed in studies throughout North America, Western Europe, the Middle East, Africa, and Mexico, and occurs even when adults’ attachment status is assessed prior to the child’s birth (Van IJzendoorn et al., 1999). However, very few studies have examined correlates of U states among fathers.

One unique study examined the intergenerational transmission of U states from mother to *adult daughter* among Holocaust survivors and controls with no Holocaust background. Holocaust survivors were more often classified as U. However, the U state was not transmitted to the next generation (Sagi-Schwartz et al., 2003). The authors note that the traumatic events were not created by attachment figures but emerged from an outside destructive force (the Nazis), which may have allowed the survivors to establish organized attachment relationships with their own children. Living in Israel was also found to be a protective factor in a meta-analysis of 12,746 Holocaust survivors and controls (Barel, Van IJzendoorn, Sagi-Shwartz, & Bakermans-Kranenburg, 2010).

U States of Mind and D Behavior in Adolescence

Obsuth, Hennighausen, Brumariu, and Lyons-Ruth (2014) examined the correlates of adolescent U states of mind in relation to observed adolescent–parent interaction in a conflict discussion paradigm at age 20 (details are provided in a later section). U states of mind were specifically related to patterns of interaction characterized by odd, out-of-context, or disoriented behaviors by both adolescent and parent but were not related to adolescent caregiving or punitive interaction with the parent.

U States of Mind and Dissociative Symptoms

U states of mind have been associated with altered states of consciousness, such as trance-like states. For example, individuals classified as U showed elevated scores on the Tellegen Absorption Scale (TAS; Tellegen & Atkinson, 1974), which includes items such as “I sometimes ‘step outside’ my usual self and experience an entirely different state of mind” (Hesse & Van IJzendoorn, 1999). Two other studies have found an association between elevated dissociative symptoms and U states among both low- and high-risk mothers (Bailey,

Moran, & Pederson, 2007; Schuengel, Bakermans-Kranenburg, & Van IJzendoorn, 1999).

Unresolved States of Mind and Other Psychiatric Symptoms

In a meta-analysis of the first 10,000 AAs, the distribution of classifications among North American nonclinical mothers indicated that 18% were U or cannot classify (U/CC) (Bakermans-Kranenburg & Van IJzendoorn, 2009). Distributions in European, Japanese and Israeli samples were similar. Gender was not associated with U/CC status. A lower than expected rate of U/CC was found among adolescent samples (11%), coupled with a higher than expected rate of dismissing classifications. The distribution in clinical samples was strikingly different, with U/CC strongly overrepresented (43% U/CC). U/CC was overrepresented among those with internalizing disorders (e.g., suicidality and borderline psychopathology) and externalizing disorders (e.g., antisocial personality disorder [APD]). Familial violence, extrafamilial violence, and violence against the self (e.g., childhood maltreatment, current posttraumatic stress disorder [PTSD]) were strongly associated with U/CC classification. Notably, however, depressed groups did not have a higher rate of U/CC classification, which echoes the lack of a clear association between parental depression and infant disorganization. U states were also more prevalent among veterans with PTSD than trauma-exposed veterans without PTSD (Harari et al., 2009). U states have also been related to substance abuse and parental separation/divorce, as well as suicidal ideation and emotional distress, in a nonclinical sample (Riggs & Jacobvitz, 2002). Though few relevant studies have been conducted, physical handicaps, including blindness and deafness, were not associated with attachment states of mind.

Elevated rates of cannot classify (CC) were found in adults diagnosed with BPD (Fonagy et al., 1996) and obsessive-compulsive disorder without depression (Ivarsson, Granqvist, Gillberg, Anders, & Broberg, 2010), and in criminal populations (Hesse, Hobson, Patrick, Maughan, & Main, 2011). Thus, higher rates of U/CC states were associated with many clinical presentations, pointing to the potential contribution of disturbed attachment relationships to a variety of clinical disorders.

Unresolved States of Mind and Functional Brain Responses

Only two small studies have examined neurobiological correlates of U states of mind. In one study, Buchheim and colleagues (2006) administered the Adult Attachment Projective (AAP), a picture-based alternative for assessing U states of mind, to 11 healthy adult females while undergoing functional MRI, with five women classified as U. When responses to all pictures were included, there was no differential activation of brain regions evident for U versus non-U participants. However, as the traumatic imagery in the pictures increased, individuals classified as U increased activation in several emotion-related brain regions, including right inferior prefrontal cortex (PFC), left superior temporal gyrus, left caudate nucleus, and bilateral medial temporal regions, while others did not. In a second study of 11 patients with BPD and 17 controls (Buchheim et al., 2008), the only effects were related to patient status and not to U states of mind. Further work with larger samples is needed to assess the generalizability of these results.

Unresolved Loss versus Unresolved Abuse

An individual can be classified as U in relation to loss or abuse, or both. Usually these are combined for analysis, but the few studies that have examined correlates of U-loss and U-abuse separately have found important differences. Vulliez-Cody, Obsuth, Torreiro-Casal, Ellertsdottir, and Lyons-Ruth (2013) found that U-loss was a correlate of maternal role confusion in relation to her child, whereas U-abuse was not. U-loss was accompanied by broad indicators of the parent's helplessness and need for the child's guidance, suggesting that mothers who experience U-loss may feel they need support from their child. In relation to this hypothesis, Moss, Cyr, and Dubois-Comtois (2004) found that maternal losses during the child's lifetime were related to the child's caregiving behavior toward the mother but not to punitive or disorganized behavior. Bailey and colleagues (2007) found that abuse was related to both U-loss and U-abuse in adolescent mothers, but Byun, Brumariu, and Lyons-Ruth (in press) found that only U-abuse, not U-loss, was related to the severity of the abuse in childhood. Thus, differential correlates of maternal U-loss and U-abuse deserve further exploration.

A “Transmission Block” in the Assessment of Maternal U States of Mind?

The meta-analysis cited earlier revealed that only 53% of D infants had mothers with U states of mind (Van IJzendoorn, 1995). Although this is a robust effect, it also means that 47% of D infants did not have U mothers. One explanation is that U can only be assigned if the participant reports a specific loss or abuse experience. Therefore, discourse about loss or abuse per se may constitute a narrow window for capturing all anomalous attachment states of mind seen among adults with more difficult childhood experiences. Thus, investigators have also developed coding systems to capture more pervasive anomalies in the AAI that are not confined to discourse anomalies related to loss or abuse.

CC States of Mind on the AAI

As noted earlier, one approach to coding transcriptwide anomalies is to code multiple states of mind in the same transcript, as noted earlier for the CC category (Hesse, 1996). However, to date, reliability and validity data on the CC classification has been limited, with Bakermans-Kranenburg and Van IJzendoorn (2009) noting that there were not enough reliably coded CC classifications in the first 10,000 AAIs to conduct a separate assessment.

Hostile–Helpless States of Mind on the AAI

In another approach to coding transcriptwide anomalies, Lyons-Ruth, Yellin, Melnick, and Atwood (2005) developed a coding system for hostile–helpless (HH) states of mind on the AAI. This coding system focuses on indices of pervasively contradictory evaluations of the attachment relationship itself, rather than on lapses in monitoring during discussions of loss or trauma. Research reviewed below suggests that the HH coding system may be particularly relevant to understanding processes involved in the intergenerational transmission of maltreatment.

The central feature of an HH state of mind is the extent to which the individual has positively identified with the psychological stance of a childhood caregiver whom he or she also globally devalues elsewhere in the interview. HH interviews may combine “hot” but unelaborated devaluation,

a concise narrative, apparently frank discussion of both positive and negative aspects of childhood attachment relationships, and in some cases, an entertaining quality. This combination provides a poor fit with other existing AAI classifications and may erroneously lead to placement in the “earned secure” subgroup (see Lyons-Ruth, Yellin, et al., 2005). Both hostile and helpless subtypes may be seen. In the hostile subtype, one or more attachment figures are represented in globally devalued terms as hostile or malevolent, but there is also evidence of a competing positive representation and continued identification with the same attachment figure. For example, in different parts of the AAI interview, one speaker said, “We were friends, . . . we were enemies. . . . We’re just alike but we fought all the time.” Contradictory mental contents are seen in the juxtaposition of positive and globally devaluing evaluations of the same caregiver over the course of the interview. Theoretically, a hostile state of mind is viewed as a potential outcome of a controlling/punitive stance in childhood (see section on childhood attachment below).

In the helpless subtype, the participant globally devalues but also positively identifies with a helpless or parentally abdicating caregiver; for example, “We’re best friends. . . . She’s a basket case.” Individuals with a helpless state of mind may describe having adopted a vigilant and protective caregiving role toward the parent in childhood. Anger is inhibited or expressed in assertions that are not integrated with the more predominant caregiving attitude. Theoretically, a helpless state of mind in adulthood is viewed as a potential outgrowth of a caregiving attachment stance in childhood. A “mixed” HH subtype is also commonly seen that includes aspects of both subtypes.

HH States of Mind and Infant Disorganization

Parental HH states of mind have been significantly related to infant disorganization in two studies (Lyons-Ruth, Yellin, et al., 2005; Melnick et al., 2008), and in both, HH states of mind accounted for variance in infant disorganization not accounted for by U states of mind. In the Lyons-Ruth, Yellin, and colleagues (2005) study, U and HH states of mind were similarly good predictors of D-secure infant behavior, but HH was a stronger predictor than U for infants classified as D-insecure (i.e., dis-

organized-avoidant or disorganized-ambivalent). In the second study, 62 mothers receiving treatment for methadone dependence were compared to 87 women in a nonaddicted low-income control group, and again, HH better accounted for infants classified as D-insecure (Melnick et al., 2008).

HH States of Mind and Maltreatment

Barone, Bramante, Lionettia, and Pastore (2014) evaluated factors that differentiated mothers who had murdered a child ($n = 23$) from mothers with mental illness ($n = 37$) and healthy controls ($n = 61$). Once variance associated with SES, traumatic events, and mental illness was accounted for, HH states of mind added to the prediction of child murder, but U states did not. Frigerio, Costantino, Ceppi, and Barone (2013) also found that HH states of mind were stronger in differentiating maltreating mothers from nonmaltreating mothers than were U states of mind. In addition, HH states of mind have been found to be prevalent among mothers followed by social services for documented neglect of a child (Milot et al., 2014), although U states were not examined in that study. Finally, among 104 young adults, HH state of mind mediated the relations between severity of childhood maltreatment and borderline and antisocial symptoms in young adulthood, whereas U state of mind was not a significant mediator (Finger, Byun, Melnick, & Lyons-Ruth, 2015). Thus, pervasively unintegrated evaluations of central attachment relationships may be particularly associated with experiencing, and possibly repeating, childhood maltreatment.

HH States of Mind and Adolescent Attachment Behavior

Obsuth and colleagues (2014), studying adolescent–parent interaction among 104 dyads, found that adolescent HH states of mind were related to punitive interactions with parents at age 20, but not to caregiving or disoriented interaction patterns with parents. This contrasts with the earlier mentioned association between U states and disoriented forms of interaction in the same study. Thus, it appears that U and HH states of mind are associated with different forms of disorganization in interaction with a parent. It will be important to explore further these potentially distinct pathways encompassed within the broader framework of D relationships.

HH States of Mind and Psychopathology

Other work has examined HH states of mind among adults with anxiety disorders and with borderline psychopathology. Young adults with anxiety disorders were rated higher on HH states of mind than were adolescents without Axis I diagnoses (Brumariu, Obsuth, & Lyons-Ruth, 2013). In relation to BPD, in a sample of 12 patients with BPD and 11 adult outpatients with dysthymia, significantly more women in the BPD group (100%) displayed an HH state of mind, compared to 55% of the dysthymic group. In addition, significantly more patients with BPD (75 vs. 27% in the dysthymic group) indicated in their responses on the AAI that in childhood they had engaged in punitive or caregiving forms of controlling behavior toward parents. These results indicate that in addition to U states of mind, patients with BPD exhibit a pervasive difficulty in integrating affective evaluations of attachment figures. Finally, as mentioned previously, Finger and colleagues (2015) found that HH states of mind mediate the relations between severity of childhood maltreatment and the extent of both borderline and antisocial features in young adulthood.

Parental Frightened, Frightening, or Atypical Behavior

Why are parental U or HH states of mind related to infant D? Main and Hesse (1990) hypothesized that when the still-traumatized parent responds to memories or ideas related to loss or trauma, he or she may engage in inexplicably frightened or frightening behavior. A frightened or frightening attachment figure is thought to provoke conflict for an infant because the attachment figure is “at once the source of and the solution to its alarm” (p. 163). Unable to implement a coherent strategy of approaching or fleeing, the infant shows D behavior.

Maternal Insensitivity

Ratings of maternal insensitivity, which have consistently distinguished secure from organized insecure infants (Van IJzendoorn, 1995), have not consistently distinguished infants displaying D (metaanalysis; Van IJzendoorn et al., 1999). Thus, the sensitivity scale may not be specific enough to capture the various forms of fear-related parental behavior related to infant D. Given this lack of prediction, both Main and Hesse (1992) and

Bronfman, Parsons, and Lyons-Ruth (1992) developed coding systems to capture the frightened, frightening, or other disrupted parental behaviors most strongly related to infant D. A number of subsequent studies have explored the hypothesis of “fright without solution” by examining whether frightening or disrupted parental behavior predicts infant D. A meta-analysis of studies using either of these two coding systems indicated that infants whose parents displayed frightened, frightening, or disrupted behavior were 3.7 times more likely to display D behavior ($r = .34$; $N = 851$; Madigan et al., 2006).

Frightened or Frightening Maternal Behavior

Main and Hesse (1992, 1998) developed six scales to identify subtypes of frightening or frightened (FR) parental behavior:

1. *Threatening*—postures, facial expressions and movements that appear aggressive (e.g., sudden movements into the area surrounding the infant’s face and eyes).
2. *Frightened*—behaviors indicating the mother is inexplicably frightened (e.g., a retreat sequence, as in pulling or backing away from the infant).
3. *Dissociative*—indications of possible entrance into an altered state of consciousness (e.g., stilling or freezing in trance-like postures or speaking in haunted voice tones).
4. *Timid or deferential*—behavior in which the parent appears submissive to the infant (e.g., very timid or deferential handling of the infant).
5. *Spousal or romantic*—excessive intimate or sexualized caressing of the baby.
6. *Disorganized*—parental behavior fitting Main and Solomon’s (1990) description of infant disorganized/disoriented behaviors.

Several researchers have examined FR behavior in relation to parents’ U states on the AAI. Jacobvitz and colleagues (2006) found that mothers classified as U displayed higher levels of FR behavior with their infants at 8 months but did not differ from other mothers on maternal insensitivity, interference, or rejection ($N = 125$). U was associated with FR regardless of the secondary secure or insecure subclassification. Moreover, U mothers who lost an attachment figure, or who were

younger than 16 at the time of the loss, were more likely to display FR behavior. Therefore, kinship and timing of the loss may contribute to whether the mother’s U state impinges on her caregiving.

In contrast, Schuengel, Bakermans-Kranenburg, and Van IJzendoorn (1999) found a relation between maternal U states and maternal FR behavior toward an infant but only among the subgroup of mothers classified as U-insecure on the AAI (analogous to the D-insecure infant subgroup). Abrams, Rifkin, and Hesse (2006) found that U parents had significantly higher dissociative-FR scores than other parents, but U was not associated with any other FR subscales. In addition, in a study of village-dwelling mothers in Mali, True, Pasani, and Oumar (2001) found that infants whose mothers displayed any FR behavior were more often classified as D. Finally, both Jacobvitz and colleagues (2011) and Schuengel and colleagues (1999) found that mothers’ FR behavior mediated the relation between maternal U states and infant D.

In the only study of high-risk participants to examine this issue, Lyons-Ruth, Bronfman, and Parsons (1999) also found that FR behavior was significantly related to infant D. However, when the two subgroups of D infants were examined, only mothers of D-insecure infants displayed more FR behavior. This finding resembled Schuengel and colleagues’ (1999) finding that FR behavior was only elevated among mothers in the U-insecure subgroup of the AAI. By meta-analysis (Madigan et al., 2006), the effect size for the relation between U attachment and FR was $r = .28$ ($N = 242$), and the effect size for the relation between FR and infant D was $r = .32$ ($N = 325$). One of the few studies including fathers found that fathers’ frightening-FR behavior ($N = 110$) predicted infant D with father, but only when fathers were both frightening and insensitive (Hazen, McFarland, Jacobvitz, & Boyd-Soisson, 2010). In addition, Abrams and colleagues (2006) examined the six FR subscales in both father–infant ($n = 25$) and mother–infant ($n = 50$) dyads. Both mothers and fathers of disorganized infants received significantly higher scores on the Threatening-FR and Dissociative-FR subscales. When all six FR subscales were considered simultaneously, only Dissociative-FR behavior uniquely predicted infant D. Given the importance of dissociative-type FR behavior, it is noteworthy that both Schuengel and colleagues (1999) and Lyons-Ruth, Hennighausen, and colleagues (2005) failed to find a relation between maternal scores on the Dissociative Experiences

Scale and infant D. Thus, *in vivo* interaction seems more important than symptom scores.

Jacobvitz and colleagues (2011) also created an assessment of FR maternal behavior with 24-month-olds. The infants' mothers were rated on four 9-point scales, including Frightening/Anomalous, Frightened by Child, Disoriented/Dissociated Behavior, and Boundary Diffusion (failing to keep appropriate boundaries with child). Maternal U states assessed prenatally, as well as FR behavior at 8 months and infant disorganization at 1 year, predicted mothers' FR behavior at 24 months. For related work on mother-toddler role confusion and infant D, see Macfie, Fitzpatrick, Rivas, and Cox (2008).

Maternal Disrupted Communication

Lyons-Ruth, Bronfman, and Parsons (1999) expanded on Main and Hesse's (1990) construct of fright without solution to develop a broader coding system for disrupted communication between parent and infant (Atypical Maternal Behavior Instrument for Assessment and Classification, or AMBIANCE). Lyons-Ruth, Bronfman, and Atwood (1999) theorized that for all infants, fear arises from a variety of sources, in addition to parental behavior. For the infant to organize a consistent attachment strategy in the face of such fears, the parent must provide minimally adequate comfort and proximity, even if the parent him- or herself is not the source of infant fear. For example, a mother may engage in contradictory forms of affective communication with the infant around the need for comfort, such as moving away while asking tenderly, "What's the matter?" Or the parent may engage in role-confused behavior such as asking the infant for a kiss when the infant needs comfort. More dramatically, the parent may leave the infant to cry on the floor with no response. In this view, the parent's inability to provide a consistent response to the infant's need for comfort is extreme enough, or contradictory enough, that avoidant or ambivalent strategies cannot be organized in relation to the caregiver.

The AMBIANCE coding system (Bronfman et al., 1992; Bronfman, Madigan, & Lyons-Ruth, 2007) includes the items on the 1992 version of the Main and Hesse (1992) FR coding system. The system also includes aspects of caregiving behavior not included in the FR system that were observed among mothers at risk and are theoretically related to unmodulated infant fear and D. Five broad dimensions of disrupted parental affective communication with the infant are assessed:

1. *Negative-intrusive behavior*—behavior that is frightening, behavior that interferes with the infant's ongoing directions, or behavior that communicates a hostile attitude toward the infant (e.g., mocking or teasing the infant).
2. *Role confusion*—behavior that prioritizes the parent's needs over the infant's needs (e.g., asking for reassurance or affection from the infant when the infant is distressed).
3. *Disorientation*—behavior that appears frightened or affectively odd (e.g., unusual changes in pitch and intonation of voice or stiff and awkward body postures when interacting with infant).
4. *Affective communicative errors*—contradictory communications or failures to respond to clear infant cues for comfort (e.g., verbally inviting the infant to approach followed by physical distancing; leaving the infant to cry on the floor).
5. *Withdrawal*—behaviors that communicate reluctance to interact fully with the infant (e.g., walking around the infant, hesitating before responding, or interacting silently with infant).

Meta-analysis of studies using the AMBIANCE (Madigan et al., 2006) confirmed a significant relation between maternal disrupted communication and infant D attachment ($r = .35$; $N = 384$). Meta-analysis also revealed high test-retest stability of the AMBIANCE over 10 to 72 months ($r = .56$, $N = 203$).

In an initial study using both AMBIANCE and FR coding systems in a low-income sample (see the earlier section on FR), Lyons-Ruth, Bronfman, and Parsons (1999) found that, with all FR behaviors excluded, the frequency of disrupted communication still significantly predicted infant D. Only 17% of maternal behaviors coded on the AMBIANCE were FR behaviors. This suggests that FR behavior is occurring within a broader matrix of disturbed communication between mother and infant. In addition, when using the AMBIANCE to compare the two infant D subtypes, mothers of D-insecure infants showed significantly higher rates of negative intrusive behavior and role confusion, while mothers of D-secure infants exhibited higher levels of withdrawal (Lyons-Ruth, Bronfman, & Parsons, 1999). Finally, Forbes, Evans, Moran, and Pederson (2007) assessed mothers and infants at both 12 and 24 months. At both ages, disrupted communication was related to infant D, and change in maternal

disrupted communication from 12 to 24 months predicted change in infant D.

Maternal behavior is not related to infant gender using either the FR system or the AMBIANCE (Lyons-Ruth, Bronfman, & Parsons, 1999). However, David and Lyons-Ruth (2005) found that gender differences in infant attachment behavior may emerge in the context of high levels of frightening maternal behavior. In the context of high levels of frightening behavior, males were more likely to show disorganized conflict behavior and avoidance than females, who often continued to approach their mothers. Thus, males' responses were more reliable indicators of the quality of parent–infant interaction.

Meta-analysis also confirmed a significant relation between maternal disrupted communication and U classification on the AAI ($r = .20$; $N = 311$; Madigan et al., 2006). Furthermore, among 45 adolescent mothers who were *not classified* as U on the AAI, Madigan, Moran, Schuengel, Pederson, and Otten (2007) found a robust relation between maternal disrupted communication and infant D. Therefore, the AMBIANCE may be helpful in identifying infants at risk of D whose mothers do not exhibit U states of mind on the AAI. Finally, Ballen, Bernier, Moss, Tarabulsky, and St-Laurent (2010) did not find an overall relation between U states of mind and disrupted communication among mothers interacting with a foster child. However, U-loss, in particular, was related to the Fearful/Disoriented subscale on the AMBIANCE, which captures more dissociative behaviors. Finally, in an innovative extension of work using the AMBIANCE, Crawford and Benoit (2009) developed criteria for coding the five dimensions of maternal disrupted communication at a representational rather than a behavioral level. Maternal disrupted communication coded on the Working Model of the Child Interview (WMCI) in the third trimester of pregnancy significantly predicted maternal U state, maternal disrupted communication, and infant D at 12 months.

As seen earlier, disrupted maternal communication can be patterned in many ways. Thus, it is also important to examine whether different patterns of disrupted behavior may predict different outcomes for the child. Lyons-Ruth, Bureau, Easterbrooks, Obsuth, and Hennighausen (2013) traced correlates of maternal withdrawal and maternal negative-intrusive behavior over the infancy, middle childhood, and adolescent periods, and found distinct correlates at each age. In infancy, maternal withdrawal was associated with continued attempts by the infant to approach and

gain contact with the mother, despite concomitant disorganized behavior (D-secure subtype). In middle childhood, maternal withdrawal in infancy predicted child controlling–caregiving behavior toward mother, but not punitive behavior. In adolescence, maternal withdrawal in infancy predicted the mothers' role confusion and caregiving helplessness (George & Solomon, 1996). Maternal role confusion on interview was further related to caregiving/role confusion in observed adolescent–parent interaction (see the later section on adolescents). Thus, a strikingly coherent construct emerges relating maternal withdrawal to maternal role confusion and child caregiving. In contrast, maternal negative-intrusive behavior in infancy was unrelated to any of these above outcomes but predicted child externalizing problems in preschool and middle childhood (Lyons-Ruth, Alpern, & Repacholi, 1993; Lyons-Ruth, Easterbrooks, & Cibelli, 1997). Additional studies relating disrupted maternal communication to psychopathology in adulthood are reviewed below in the section “Prospective Prediction of Psychopathology in Adolescence/Young Adulthood.”

Disrupted Communication among Fathers

We do not know whether a father's disrupted communication has a similar relation to infant D. In the only study of fathers, Madigan and colleagues (2011) found no relation between fathers' disrupted communication and father–infant disorganization at 18 months, but only 6 infants among 31 father–infant dyads were classified D.

Maternal Disrupted Communication and Maternal and Infant Cortisol

In one of the few studies examining maternal and infant cortisol, Crockett, Holmes, Granger, and Lyons-Ruth (2013) found that very disrupted maternal communication with a 4-month-old infant after a still-face procedure was associated with blunted maternal cortisol at study entry. Maternal cortisol, in turn, predicted infants' hyperreactive cortisol response to the still-face and recovery periods. Schechter and colleagues (2004) also assessed maternal cortisol levels in relation to disrupted maternal communication among violence-exposed mothers of preschoolers. Similar blunted levels of maternal cortisol were observed in mothers who exhibited disrupted, and, particularly, withdrawing behavior during reunion with their preschool child.

Maternal Affective Communication Early in the First Year

Unfortunately, only a few studies have examined whether mother–infant interaction in the first 6 months of life forecasts later infant D. Tomlinson, Cooper, and Murray (2005) assessed maternal depression and caregiving behavior of 147 mothers with their infants at 2 months and 18 months, and found that both remote-disengaged and intrusive maternal behavior at 2 months uniquely predicted D at 18 months. Jaffe, Beebe, Feldstein, Crown, and Jasnow (2001) found that “hypervigilant” vocal rhythm tracking by both mother and baby forecast D. The authors proposed that hypervigilance stems from maternal stress or anxiety. Furthermore, Beebe and colleagues (2010) found that mothers of 4-month-old infants later classified as D displayed multiple disturbances in affective communication at 4 months. Their babies also showed more vocal distress and mirrored the mother’s affective disturbances (e.g., smiling to mother’s smile, while simultaneously whimpering from mother’s rough handling). The authors suggested that D infants form working models characterized by emotional incoherence and expectations of emotional distress. More longitudinal studies over the first year are needed to explore how early parent–infant interaction and infant stress responses are related to the emergence of infant D.

Maternal Disrupted Communication and Offspring Regional Brain Volumes

A promising new direction is examination of regional brain differences in relation to maternal disrupted communication and infant D. Lyons-Ruth, Pechtel, Yoon, Anderson, and Teicher (2014) examined regional brain volumes among 18 low-income young adults studied longitudinally from infancy. Examining multiple family risk factors over time, including maltreatment, only D and maternal disrupted communication at 18 months predicted left amygdala volume at 29 years. In addition, early attachment risk was further associated with dissociation and limbic irritability at age 29, and these relations were mediated by left amygdala volume. Thus, consistent with animal models, the quality of early care may have enduring influences on brain development. Other magnetic resonance imaging (MRI) and functional MRI (fMRI) studies to date have examined infant security and maternal sensitivity rather than D (for a review, see Pechtel, Murray, Brumariu, & Lyons-Ruth, 2013).

In the next decade we should see an explosion of studies examining how early care influences children’s brain structure and function.

Maternal Mind-Mindedness and Infant D

Meins and colleagues (2012) assessed mothers’ mind-mindedness (MM) through maternal comments referring to infant mental states. They found that mothers of D infants did not differ from other mothers in attributing mental states to their infants. However, based on total comments, mothers of D infants made proportionately fewer *appropriate* mental state comments and proportionately more *nonattuned* mental state comments. Thus, mothers of D infants appear to think about their infants’ mental states but in nonattuned ways.

Randomized Interventions to Reduce D

The previous studies that relate parenting behavior to infant D are all correlational. Thus, they do not provide a strong basis for inferring causality. However, randomized controlled trials now provide strong evidence that D is amenable to change through interventions that focus on the mother–infant relationship (Bernard et al., 2012; Cicchetti, Rogosch, & Toth, 2006; Heinicke et al., 1999; Juffer, Bakermans-Kranenburg, & Van IJzendoorn, 2005; Moss, Bureau, St-Laurent, & Tarabulsy, 2011; Smyke et al., 2010; Tereno et al., 2014; Toth et al., 2006). These interventions have reduced the rate of D among dyads with a wide range of risk characteristics. However, despite the success of these programs, mechanisms contributing to change, such as changes in the caregiver’s interactions with the child, have not been studied. Future randomized trials should address underlying mechanisms in order to advance our understanding of how parent-focused interventions prevent D.

Disorganized/Controlling Attachment in Preschool and Middle Childhood

Main and Cassidy (1988), in a pioneering study of attachment beyond infancy, assessed 6-year-olds’ behavioral and verbal responses to a reunion with the parent after an hour-long separation. They found that children could be classified into four

categories that corresponded to the four infant attachment classifications, including secure-confident, insecure-avoidant, insecure-ambivalent, and insecure-controlling. Children were classified “insecure-controlling” if they “seem to actively attempt to control or direct the parent’s attention and behavior and assume a role which is usually considered more appropriate for a parent with reference to a child” (p. 418).

Age, Gender, and Stability of Disorganized/Controlling Attachment

Gender differences in the prevalence of D/controlling attachment were not found by meta-analysis (Van IJzendoorn et al., 1999; but see NICHD ECCRN, 2001). The effect size of the association between infant D and later D/controlling behavior has ranged from 20% (NICHD ECCRN, 2001) to 80% (Van IJzendoorn et al., 1999). However, the NICHD SECCYD assessed attachment behavior only up to age 3, so the lower stability in that study may reflect turbulence over the toddler period. Higher stability has been obtained when relating infant D to D/controlling behavior in the late preschool period. Finally, a sizable number of children who do not appear to have D in infancy begin to display controlling behaviors as preschoolers (Bureau, Easterbrooks, & Lyons-Ruth, 2009b; Main & Cassidy, 1988; NICHD ECCRN, 2001; Wartner, Grossmann, Fremmer-Bombik, & Suess, 1994).

Whether the child exhibits disorganized versus controlling forms of behavior also seems related to age. Moss, Cyr, Bureau, Tarabulsy, and Dubois-Comtois (2005) found that two-thirds of the young preschoolers classified as D/controlling displayed D behavior rather than controlling behavior. However, by age 6, two-thirds of the D/controlling group displayed controlling behavior. However, in high-risk samples, D behaviors continue to be observable through age 8 (Bureau et al., 2009b).

D/Controlling Attachment and Cognitive Correlates

Bowlby (1969) posited that continued activation of the attachment system should inhibit exploration of the environment. Consistent with this formulation, Jacobsen, Edelstein, and Hofmann (1994) found that D/controlling children ($n = 6$), assessed in middle childhood by the child’s re-

sponses to a story task, differed significantly from other children in adolescence on tasks assessing syllogistic reasoning, even after they controlled for self-confidence, IQ, and attention problems. Moss and colleagues (1998; Moss & St-Laurent, 2001; Moss, St-Laurent, & Parent, 1999) found that despite the similarity in IQ between children with and without D, D/controlling children showed the poorest school performance in middle childhood. Moreover, D/controlling children demonstrated poorer math performance and difficulty becoming cognitively engaged in a problem-solving task. Finally, Stacks and Oshio (2009) found that preschoolers who produced disorganized narratives using George and Solomon’s (2000) story completion task scored lower on assessments of school readiness than other children. This relation between D and less effective cognitive functioning has also been demonstrated in a Belgian cohort followed from ages 4 to 7 (Stievenart, Roskam, Meunier, & van de Moortele, 2011).

D/Controlling Attachment and Parental Attachment Representations

Three studies have found an association between maternal U status on the AAI and D/controlling behavior in childhood (Behrens, Hesse, & Main, 2007; George & Solomon, 1996; Greenberg, Speltz, DeKlyen, & Endriga, 1991). In addition, George and Solomon (1996) developed a semistructured Experiences of Caregiving Interview that probes mothers’ experiences of helplessness in the parenting role. A helpless stance could involve seeing the child in idealized terms as “larger than life” or could involve fear of the child and fear of one’s own loss of control in relation to the child. Maternal helplessness was also associated with D/controlling behavior at age 6. Furthermore, Vulliet-Coady and colleagues (2013) found that maternal helplessness assessed in adolescence was associated with adolescent D/controlling behavior.

D/Controlling Attachment and Children’s Representations

D behavior is thought to occur because the infant experiences fear without solution. To evaluate this hypothesis, Main and colleagues (1985) examined children’s depictions of self and caregiver on a doll-play story task, the Separation Anxiety Test. Children classified as D in infancy were more

likely to give fearful and disorganized narratives (e.g., remaining silent, elaborating fearful or passive themes, or engaging in catastrophic fantasies). Solomon, George, and De Jong (1995) found that D/controlling kindergartners more often depicted themselves as helpless and their caregivers as frightening. Jacobsen and colleagues (1994) also found an association between D/controlling behavior and disorganized responses to cartoons depicting parent-child separation. Examining family drawings of 7-year-old, high-risk children, Madigan, Goldberg, Moran, and Pederson (2004) and Fihrer and McMahon (2009) did not replicate these findings. However, the high-risk nature of these samples may have affected the drawings of those who were not D. Thus, story stems may be more discriminating of D in low-risk samples.

D/Controlling Attachment and Behavior Problems

Externalizing Problems

A meta-analysis has indicated that children classified as D using infant, preschool, or school-age attachment assessments are more likely to display behavior problems ($N = 734$; Van IJzendoorn et al., 1999). A more recent meta-analysis of 69 samples ($N = 5,947$) confirmed those findings, indicating that children classified as D are at risk for externalizing problems ($d = 0.34$), and this association is stronger than for other insecure classifications (avoidance: $d = 0.12$; resistance: $d = 0.11$; Fearon et al., 2010).

Internalizing Problems and Dissociative Symptoms

Other meta-analyses have shown that attachment disorganization in infancy does not predict internalizing problems (Groh, Roisman, Van IJzendoorn, Bakermans-Kranenburg, & Fearon, 2012; Madigan, Atkinson, Laurin, & Benoit, 2013), with avoidant attachment more strongly related to internalizing symptoms. However, future studies are needed that differentiate between internalizing problems that are comorbid with externalizing problems and those that are not comorbid, as these likely occur in different groups. Comorbidity, in particular, has been associated with D/controlling behavior in preschool (Moss, Bureau, Cyr, Mongeau, & St-Laurent, 2004; Moss et al., 2004; O'Connor, Bureau, McCartney, &

Lyons-Ruth, 2011). In addition, Jacobvitz and colleagues (2011) found that maternal FR behavior at 8 months and/or FR/anomalous behavior at 24 months forecast depressive symptoms at age 7, as rated by teachers.

Dissociative symptoms in childhood, as reported by teachers, have also been investigated in relation to D. Carlson (1998) found that D in infancy predicted teacher reports of dissociation, internalizing behavior, and poorer overall emotional health in grades 1, 2, and 3. Smeekens, Riksen-Walraven, and van Bakel (2009) found that infants classified as D scored higher on teacher ratings of dissociation and externalizing behavior and lower on ego resiliency, peer social competence, and school adjustment at age 5. However, this relation between infant D and teacher-rated dissociation did not replicate in the large, low-risk NICHD sample (Haltigan & Roisman, 2014).

Subtypes of D/Controlling Behavior in Relation to Behavior Problems

Meta-analyses have not yet evaluated whether there are differences in behavior problem profiles among the three D/controlling subgroups (*punitive, caregiving, behaviorally disorganized*). Moss and colleagues (2004), controlling for gender, IQ, and SES, found that controlling-punitive and behaviorally disorganized children, compared to secure children, were more likely to show externalizing behavior by age 8, whereas controlling-caregiving children were more likely to exhibit internalizing behavior. Parents of the three D/controlling subtypes also differed, with parents of caregiving children more likely to have experienced a loss, whereas parents of behaviorally disorganized children engaged in more marital conflicts (Moss et al., 2011). In the NICHD SECCYD data (O'Connor et al., 2011), behaviorally disorganized children at age 3 showed elevated rates of both internalizing and externalizing behavior, as well as poorer relationships with their teachers and peers, compared to other children. O'Connor and colleagues (2011) also found that mothers of behaviorally disorganized children had significantly worse partner relationships than did mothers of controlling-caregiving and controlling-punitive children. In addition, among 43 high-social-risk families, children higher in behavioral disorganization more often came from families who were referred for parenting help in infancy (Bureau et al., 2009b). Controlling-punitive behavior was as-

sociated with higher levels of maternal disrupted communication in infancy, whereas controlling-caregiving behavior was associated with greater maternal withdrawal in infancy.

D/Controlling Attachment and the Development of Peer Relationships

Only a few studies have obtained ratings of friendship quality, either from trained observers or from peers. Wartner and colleagues (1994) found that 6-year-olds classified as D/controlling or avoidant were less competent in peer play and conflict resolution than were secure children. However, Cohn (1990) found that neither ratings of peer socio-metric status nor peer nominations obtained from classmates differentiated D/controlling children from other children.

Jacobvitz and Hazen (1999), using case study data on 66 children ages 20–56 months, found that children classified as D in infancy more often engaged in fearful behavior and bizarre aggressive acts with peers, and more often acted very differently with different peers. They proposed that D children are more likely to carry unintegrated models of relationships into their interactions with others, so that they draw on different models with different peers. In two additional studies, D infants had poor peer relationships and greater difficulty adjusting to the stress induced by the school setting at age 5, as rated by teachers (Lyons-Ruth et al., 1997; Smeekens et al., 2009). Finally, McElwain, Booth-LaForce, and Wu (2011), using the SECCYD sample, found that children classified as D or avoidant in infancy experienced less maternal talk about mental states at age 2. Less mental state talk, in turn, mediated relations between D and poorer friendship quality at age 5. The authors suggested that restricted psychological discourse may hinder interactions with peers.

Very little is known about how D/controlling attachment relationships evolve from ages 8 to 18. An important agenda for future research will be to track the developmental pathways associated with these deviations in relation to the challenges associated with middle childhood and adolescence. In addition, we have very little understanding of the neurophysiological correlates of attachment strategies after infancy, even though the regulation of stressful arousal is at the heart of attachment theory. We need further studies of childhood attachment that incorporates biological markers.

In the final sections we review prediction of adolescent psychopathology from attachment in

infancy and childhood, then conclude with studies of disorganized attachment in adolescence, assessed both with the AAI and with a new observational assessment of adolescent–parent attachment.

Prospective Prediction of Psychopathology in Adolescence/Young Adulthood

Dissociative Symptoms

Based on the lack of integration shared by D in infancy and dissociation in adulthood, Liotti (1992) proposed that D in infancy increases a child's vulnerability to later dissociative disorders. Several studies have now tested this hypothesis. In a longitudinal sample of 129 children, Ogawa, Sroufe, Weinfield, Carlson, and Egeland (1997; see also Carlson, 1998) found that mother's psychological unavailability and infant D in the first 2 years of life were the best predictors of scores on the Dissociative Experiences Scale (DES; Bernstein & Putnam, 1986) at age 19. Sexual or physical abuse did not predict dissociative symptoms on the DES after the quality of early caregiving was controlled. Only with regard to teacher-rated "dissociative" symptoms in elementary school did contemporaneous physical abuse explain additional unique variance. In a second longitudinal cohort ($N = 56$), Dutra, Bureau, Holmes, Lyubchik, and Lyons-Ruth (2009) also found that mother's disrupted communication, lack of positive involvement, and flatness of affect in infancy predicted dissociation on the DES at age 19, accounting for 50% of the variance in dissociation. Again, childhood abuse was a weaker predictor of dissociation than maternal behavior. Thus, in both prospective studies, quality of parent–infant interaction before age 2 was the strongest predictor of dissociative symptoms, stronger than either infant D or abuse experiences.

Borderline Features and Suicidality

Two prospective studies have evaluated the contribution of early disorganized attachment relationships to features of BPD in adulthood (Carlson, Egeland, & Sroufe, 2009; Lyons-Ruth, Bureau, Holmes, Easterbrooks, & Brooks, 2013). Carlson and colleagues (2009) found that infant D predicted symptoms of BPD at age 28, but this relation was not significant when maternal hostility at 42

months and cumulative stress (3–42 months) were included in the model. However, the relation between infant D and BPD symptoms was mediated by children's self-representations at age 12. These self-representations were assessed by narratives designed to capture distortions in the organization of self–other relationships, such as feelings of guilt or fear, bizarre images related to the self, and/or references to violence related to the self.

Lyons-Ruth, Bureau, Holmes, and colleagues (2013) examined the interrelations between severity of childhood abuse and quality of attachment in predicting BPD features. Both abuse and attachment were significant predictors of BPD features at age 19, but maternal withdrawal on the AMBIANCE in infancy was the single most important predictor, accounting for unique variance in BPD features beyond the variance associated with abuse. D in infancy was not a predictor, but D/controlling attachment behavior in middle childhood also explained unique variance in BPD features. Taken together, the two studies suggest that mothers of 19-year-olds with elevated BPD symptoms may have been more withdrawn in infancy but became more hostile as the child moved into toddlerhood.

Lyons-Ruth, Bureau, Holmes, and colleagues (2013) also separately examined predictors of suicidality/self-injury at age 20. Maternal withdrawal in infancy again was the strongest predictor. In addition, suicidality was predicted by *D-secure* approach behavior toward mother in infancy. Neither *D-insecure* behavior in infancy nor D/controlling behavior in middle childhood predicted suicidality. Thus, suicidal young adults may have had a stronger propensity to seek proximity to the parent in infancy than did nonsuicidal young adults.

APD and Substance Abuse

Shi, Bureau, Easterbrooks, Zhao, and Lyons-Ruth (2012) examined infancy and childhood predictors of APD among 56 low-income young adults. Childhood abuse, male gender, and maternal withdrawal in infancy all explained unique variance in APD features 20 years later. Infant D was not a predictor, but behavioral disorganization in middle childhood added to prediction of later antisocial features. Studies of antisocial behavior in the Minnesota Longitudinal Study did not include infant D in the models (Aguilar, Sroufe, Egeland, & Carlson, 2000; Siebenbruner, Englund, Egeland, & Hudson, 2006).

Pechtel, Woodman, and Lyons-Ruth (2012) examined predictors of substance abuse, which is often comorbid with both APD and BPD. Early maternal withdrawal forecast substance abuse in young adulthood, but only for those with a low nonverbal IQ in childhood.

Depression and Anxiety

Two articles from the Minnesota Longitudinal Study have explored infancy, preschool, and school-age predictors of adolescent depressive or anxiety disorders but, again, D was not examined (Bosquet & Egeland, 2006; Duggal, Carlson, Sroufe, & Egeland, 2001). In the Harvard Longitudinal Study, mother's depressive symptoms in infancy, but not in childhood or young adulthood, were found to predict young adult depression (Bureau, Easterbrooks, & Lyons-Ruth, 2009a). Infant D did not add to the model.

In summary, the notable finding across all of the attachment-oriented prospective studies of maladaptation is that infant attachment behavior is an important predictor of some long-term outcomes, but more consistent and substantial prediction is obtained from maternal behavior (Belsky & Fearon, 2002; Dutra et al., 2009; Lyons-Ruth, Bureau, Holmes, et al., 2013; NICHD SECCYD, 2001; Shi et al., 2012; Sroufe, Egeland, Carlson, & Collins, 2005). This suggests that quality and consistency in parental care over time may account for continuities in children's development and underscores the need for additional focus on the deviations in parenting associated with a child's disorganization.

Assessing D in Adolescence

U States of Mind on the AAI in Adolescence

Assessment of attachment in infancy and childhood has primarily involved direct observation of parent–child interaction, but attachment assessments in adolescence and adulthood have relied mostly on the AAI. Also, the majority of adolescent AAI studies have examined organized patterns of attachment only (e.g., Kobak & Sceery, 1988; Waters, Merrick, Treboux, Crowell, & Albersheim, 2000). One exception is Allen, Hauser, and Borman-Spurrell's (1996) study of psychiatrically hospitalized adolescents and controls, studied from age 14. In that study, maternal behaviors

promoting adolescent autonomy and relatedness at age 14 predicted coherence of transcript on the AAI 11 years later, but they did not predict AAI classifications, including U status.

Only two studies to date have examined continuity from infant disorganization to U/CC on the AAI in adolescence or adulthood (Main, Hesse, & Kaplan, 2005; Sroufe et al., 2005; Weinfeld, Whaley, & Egeland, 2004). In a low-income sample, Weinfeld and colleagues found that D infants were more likely to be classified insecure at age 19 on the AAI but not as U/CC. In addition, at age 19, there was an atypical distribution of insecure AAI classifications, with 55% classified dismissing and only 15% as U despite the high-risk nature of the sample (Weinfeld et al., 2004). By age 26, D infants were more likely to be classified as U (Sroufe et al., 2005). Main and colleagues (2005), in a low-risk sample, reported a trend-level relation between infant D and U classification at age 19, again with an unexpectedly high proportion of dismissing classifications.

Observational Assessment of D in Adolescence

Given that adolescents who were disorganized in infancy may not be more likely to display U states on the AAI, the AAI may be limited as an index of disorganization in adolescence. This may occur because of coding constraints wherein individuals who do not report loss or abuse on the AAI cannot be judged U. One approach to this dilemma is to move away from a sole reliance on the AAI and include direct observational assessments of attachment in adolescence.

In the Minnesota Longitudinal Study, 175 mother–adolescent and 44 father–adolescent dyads were observed across a series of interaction and problem-solving tasks at age 13, but adolescent attachment scales/classifications were not specifically developed. Videotapes were rated on five scales: Engagement, Affect, Conflict, Conflict Resolution, Role/Boundary Maintenance, and Balance in the Relationship. Parent–child boundary dissolution at age 13 predicted change in behavior problems between grades 6 and 16 (Sroufe et al., 2005). Parental hostility at age 13 also discriminated heavy drinkers at age 16 (Englund, Hudson, & Egeland, 2003).

The Regensburg Longitudinal Study followed 96 families over time assessing adrenocortical responses during interactions between 12-year-

olds and their mothers during a talk show task eliciting fear and a computer game eliciting anger. Increased cortisol levels were found only among adolescents classified as D in infancy, especially those adolescents showing fear (Spangler & Zimmermann, 2014).

In the Harvard Longitudinal Study, an important focus was to develop and validate an observational measure of attachment in adolescence. A secure base in adolescence has been conceptualized as a goal-corrected partnership, or sense of freedom to explore thoughts and feelings with a parent in a collaborative way (Allen et al., 1996; Kobak & Sceery, 1988). As with earlier attachment assessments, secure-base behavior during adolescence may become most salient during times of negotiation, conflict, and stress. Therefore, 104 low-income late adolescents (mean age 20 years) and their mothers were videotaped in a 5-minute unstructured reunion and a 10-minute discussion of an area of disagreement in their relationship. Videotapes were coded using the Goal-Corrected Partnership in Adolescence Coding System (GPACS; Lyons-Ruth, Hennighausen, et al., 2005), which includes 10 rating scales for organized and disorganized aspects of parent and adolescent behavior. A confirmatory factor analysis on the 10 scales yielded four dyadic factors: one factor for collaborative interaction and three factors for aspects of D/controlling behavior: disorientation, caregiving/role confusion, and punitive behavior (Obsuth et al., 2014). Structural models specifying only two factors (collaborative/disorganized) resulted in a significantly poorer fit to the data. Thus, the first important finding was that there were several empirically distinct dimensions underlying disorganized behavior in adolescence.

Each of the three disorganized factors was associated with distinct validating measures (Obsuth et al., 2014). As in infancy and childhood, disorientation in interaction was characterized by odd, out-of-context behavior (e.g., suddenly freezing with arms up during interaction with mother) and was significantly related to D behavior in infancy. For each 1-point increase in the factor score for adolescent disoriented interaction, the participant was 50% more likely to have been D in infancy in interaction with the same parent. In addition, disorientation was associated with U/CC classification but not HH classification on the adolescent's AAI. These findings provide construct validity for disorientation as a behavioral measure of D. Disorientation was also associated with poor quality romantic relationships, but not

with partner abuse, suggesting a more distant relational stance. Finally, disorientation was robustly associated with concurrent dissociative symptoms. Notably, disorientation was not related to overall psychiatric morbidity, confirming that odd, out-of-context behavior with the parent is not simply the by-product of severe psychopathology.

Punitive and caregiving/role-confused interactions also had distinct correlates. Caregiving/role-confused adolescents reported providing more emotional and instrumental support to the parent, and mothers of caregiving adolescents were independently rated as more role confused on the Experiences of Caregiving Interview (ECI; Obsuth et al., 2014; Vulliez-Coady et al., 2013). Both punitive and caregiving/role-confused interactions were associated with maternal reports of helplessness on the Caregiving Helplessness Questionnaire (CHQ; George & Solomon, 2011) and with poor quality romantic relationships that included abuse to and from the partner. However, only punitive interactions were related to the adolescent's HH classification, but not U/CC classification, on the AAI.

Caregiving/role-confused interactions were not related to adolescent AAI classifications, so states of mind associated with caregiving behavior remain elusive. However, as noted earlier, *mothers* who were more role confused on the ECI interview were more likely to be classified U-loss on the AAI (Vulliez-Coady et al., 2013), suggesting that work exploring links between caregiving/role confusion, loss, and U-loss on the AAI would be fruitful.

A second validity study used GPACS attachment *classifications* rather than factor scores on a sample of 40 psychiatrically hospitalized and non-hospitalized adolescents and their families from the larger study of Allen and colleagues (1996). Significant four-way correspondence (73%, $\kappa = .51$) was obtained between GPACS classifications at age 14 during a conflict discussion (facilitating, deflecting, entangled, and disorganized/controlling), and the corresponding AAI classifications at age 25 (autonomous, dismissing, preoccupied, and U/CC) (Hennighausen, Bureau, David, & Lyons-Ruth, 2011).

Finally, studies using the GPACS further underscore the importance of the quality of adolescent-parent interaction in pathways to disturbed functioning. All three aspects of disorganization in adolescence were associated with increased adolescent depressive and dissociative symptoms, and both punitive and caregiving/role-confused aspects were also associated with overall psychi-

atric morbidity on DSM-IV-R Axis I (Obsuth et al., 2014). Furthermore, Lyons-Ruth, Brumariu, Bureau, Hennighausen, and Holmes (2015) found that role confusion and disorientation in adolescent-parent interactions accounted for unique variance in both borderline features and recurrent suicidality/self-injury, beyond the contribution of childhood abuse. Brumariu and colleagues (2013) found that disorientation was also elevated among adolescents with anxiety disorders, which are often comorbid with BPD. Finally, studying 166 low-income adolescents, Kobak, Zajac, and Rosenthal (2014) found that caregiving/role-confused interactions at age 13 on the GPACS predicted increases in impulsive self-damaging behavior by age 15 among girls, including substance abuse and risky sexual behavior. In summary, the GPACS breaks new ground in differentiating disoriented and role-confused aspects of behavior in adolescence from the more typically studied hostile/punitive interactions and links all three disturbed interaction patterns to impairment in key developmental outcomes.

Future Directions

We are now approaching the third decade of work on disorganized forms of attachment. The accumulated studies, including several meta-analyses of the literature, make clear that D relationships are associated with both current and future functional impairment, including impaired peer relations, poor adaptation to school, and child psychopathology. Thus, this work has several important implications for future research and policy.

First, our new understanding of epigenetics is creating a paradigm shift in the fields of genetics and development, which pushes work on D to the forefront of current science. Randomized rodent and primate studies have identified deviations in caregiving as one causal agent for change in the expression of numerous genes in early development (e.g., Meaney & Szyf, 2005; see Bakermans-Kranenburg & Van IJzendoorn, Chapter 8, this volume). Given these findings in other species, disturbed caregiving in humans may also contribute to changes in gene expression in the human infant.

It has become popular to frame neurobiological differences associated with psychopathology as the "underlying mechanisms" or potential root causes of behavioral disturbances. However,

the “underlying” causal contributors may be hiding in plain sight in the form of repetitive patterns of child–caregiver interaction that shape the expression of genes and mold responses to stress and fearful arousal. There are relatively few bodies of work that identify tipping points for what constitutes disturbed care in human infancy. State-documented abuse or neglect or multiple changes of caregiver in institutional or foster settings are among the few widely substantiated indicators of disturbed care, but these are quite extreme deviations and rely on secondary indicators of quality of care. The extensive body of work on D is one of the few literatures to identify and validate the boundaries between adequate care and disturbances in caregiving based on direct observation of the quality of parent–child interaction.

Thus, in the next decade, the clinical applications of the body of work on D need to be more fully explored. As reviewed here, there is now an impressive array of evidence on the reliability of both infant and maternal disorganized/disrupted classifications, as well as on their construct and discriminant validity in relation to other measures of attachment quality, maltreatment, and dysregulation of the infant hypothalamic–pituitary–adrenal (HPA) axis. Most importantly, there is now overwhelming evidence of predictive validity in relation to later functional impairment and psychopathology. The empirical support for the morbidity associated with disorganized attachment is at least as strong, if not stronger, than the evidence base for many child psychiatric disorders now listed in DSM-5, especially those that are evident in infancy and early childhood. Thus, D is likely to be an important contributor to public health costs in the form of outpatient and inpatient mental health care, special education, delinquency, and emergency room treatment.

Second, current National Institutes of Health (NIH) research priorities call for a focus on the broad underlying processes or vulnerability factors that predispose to psychiatric morbidity and are likely to cut across diagnostic categories. We have long known that family factors contribute risk across the spectrum of psychiatric disturbance, including schizophrenia, bipolar disorder, and depression, as well as the pervasive personality disorders. As very recent work now indicates, gene variants that contribute to a variety of serious psychiatric diagnoses are also particularly open to epigenetic modifications by the environment (Cross-Disorder Group of the Psychiatric Genomics Consortium, 2013). Thus, if caregiving affects

gene expression in humans, as well as other species, it would not be surprising if the influence of the caregiving environment cuts across conventional diagnostic categories and affects a broad range of psychiatric morbidity.

Third, in accord with the NIH emphasis on examining broad underlying processes that are prominent in the pathways to a number of disorders, the next decade should focus on how caregiver–infant interaction shapes the maternal and infant neurobiology associated with these disorganized relationships. We know relatively little about the infant stress response system and how it is affected by serious deviations in care. The still sparse literature on HPA axis function in infancy focuses most strongly on infant responses in normative environments. There are a few additional studies on infants in extremely adverse environments, such as foster care, but a coherent picture of the environments that produce either HPA hyperresponsivity or HPA hyporesponsivity has yet to be fleshed out. In addition, we have virtually no literature on structural and functional neurobiological concomitants of these infant adaptations. Such data are critical to developing biological indicators that can facilitate early identification and intervention in these disturbed pathways. As we approach a more truly developmental understanding of pathways to adult, as well as childhood, disorders, we will need to incorporate an increasingly sophisticated view of how early stressors and inadequate environmental buffering may alter subsequent neurophysiology.

Finally, although the neurobiological data are of great importance, we do not need to wait for these data to develop and validate a clinically useful set of evidence-based indicators of disorganized/disordered attachment in infancy. Given the 15% incidence of D in normative samples, it will be important to narrow the current research criteria for D to include only the forms to be considered disordered. These criteria should be more selective than current research criteria, perhaps by focusing only on children who display the more extreme forms of disorganized behavior, as represented by the higher ratings on the 9-point scale for extent of disorganization. Different cutpoints and different types of disorganization need to be validated in relation to current environmental risk and to later functional impairment.

Importantly, the past three decades of work also underscore that D behavior is associated with deviations in care, and that indications for disorder should include parental, as well as child,

behaviors. Indeed, there is a long-established historical precedent for including the caregiving environment in DSM and ICD criteria, as seen in the criteria for RAD and DSED, both of which specify a deviant caregiving environment as a criterion for diagnosis. The development of such criteria, combined with existing work on RAD and DSED, would give us an emerging scientific basis for early assessment and diagnosis of the spectrum of attachment disorders that present to clinical parent–infant services. Given the considerable childhood and young adult morbidity associated with D and disturbed parenting, it is now a priority to move this work into clinical application.

Chapter 30

Challenges to the Development of Attachment Relationships Faced by Young Children in Foster and Adoptive Care

Mary Dozier
Michael Rutter

Children are born biologically prepared to develop attachment relationships to primary caregivers. Parents are likewise biologically prepared to provide care for their young children (Numan & Insel, 2003). Foster care and adoption represent deviations from the more typical situation in which a child is raised continuously by birth parents. In some species, foster care and adoption do not occur, and in many other species, such care is rare (Maestripieri, 2005). The human caregiving system appears to be relatively flexible in this regard; nonetheless, there are challenges involved for both surrogate parents and children. Depending on the nature of the preplacement conditions, the postplacement conditions, and a child's vulnerabilities and strengths, different effects are seen across behavioral and biological systems.

In this chapter, we discuss young children in foster care, as well as those adopted both nationally and internationally. Although children in these groups experience different challenges, they are all raised by someone other than birth parents for at least part of their lives. Some of the challenges include institutional care, changes in caregivers, early experiences of maltreatment, and prenatal or genetic factors that confer vulnerability. We include a discussion of animal models of separation

and neglect because they richly inform our understanding of the effects of infants' early experience.

Changes Since Earlier Editions

The first edition of the *Handbook* did not include a chapter on foster care and adoption, partly because the then-current research base was not sufficiently well developed to justify it. Earlier, Bowlby (1969/1982), Spitz (1945), and others had written about the deleterious effects of neglect and institutional care, and nonhuman researchers had documented the problematic effects of disruptions in care (e.g., Levine, Johnson, & Gonzalez, 1985). Nonetheless, research in more recent decades had been somewhat limited. The research base has grown in the last several decades, although we suggest that this is an emerging area with great potential for further growth.

Several pioneering longitudinal studies have been conducted in the last two decades that have documented both the severe consequences of early deprivation on children's functioning within institutional settings, and the impressive catch-up that often occurs when children are subsequently

adopted or fostered (e.g., Bakermans-Kranenburg, Steele, et al., 2011; Nelson, Fox, & Zeanah, 2014; Rutter et al., 2007). Catch-up is seen across domains, with children showing dramatic physical, cognitive, and social growth upon placement in families (Bakermans-Kranenburg, Steele, et al., 2011; Nelson et al., 2014). Nonetheless, a minority of children continue to show deficits, most especially in domains of attention, indiscriminate sociability, and, although less frequently, quasi-autistic symptoms (Bakermans-Kranenburg, Steele, et al., 2011; Nelson et al., 2014).

These studies and others solidified the evidence that early deprivation has pervasive deleterious effects on children's biological and behavioral development, but that remediation is often possible when children subsequently have loving, supportive caregivers. The importance of subsequent care on children's ability to handle early adversity was not a new idea, but these studies are exemplary because some children showed dramatic recovery following such extreme neglect. Links between biological and behavioral functioning have been demonstrated in these and other studies in key ways (e.g., Nelson et al., 2014).

Types of Surrogate Care

Foster Care

About 400,000 children are in formal foster care in the United States, which represents a significant and linear decrease over the last several decades (U.S. Department of Health and Human Services [DHHS], 2013). Many children living in informal foster care arrangements (e.g., with relatives or neighbors) are not counted in this number. In the United States, about 6% of children entering foster care are less than 1 year old, and 26% are between 1 and 5 years of age. Thus, the associated disruptions in care and the forming of attachment relationships to new caregivers occur for many at a developmental point when forming and maintaining attachment relationships are key biologically programmed tasks. Children in foster care have a range of previous caregiving experiences, both prior to entering the foster care system and within it. With the exception of those placed into foster care at birth, most have been neglected by their birth parents, and some have experienced abuse, either by itself or in combination with neglect.

Although foster care is intended to be a temporary solution, children of all ages tend to stay

in care for relatively long periods in the United States. Only 12% stay in foster care less than a month, with an additional 5% staying for less than a year. Twenty-seven percent stay in foster care between 1 and 2 years, and 28% remain more than 2 years. When children leave foster care, approximately 51% are reunited with birth parents and 22% are adopted, sometimes by their foster parents (DHHS, 2013). For those who reunify, about one-third return to foster care within 3 years.

Adoption

The population of adopted children overlaps with the population of children who have been in foster care. The number of children adopted from the foster care system in the United States has been about 50,000 each year of the last decade (e.g., DHHS, 2013). About 8,700 children were adopted internationally during 2012 into the United States (U.S. Department of State, 2013). The number of children adopted internationally into the United States increased from 1990, when about 7,000 children were adopted, to 2005, when about 22,000 were adopted, but then decreased dramatically each year since 2005, to about 8,700 in 2012. Policies within various nations have partially driven these rates. Many of the children adopted internationally have been in institutional care for at least some period of time prior to adoption. The age of adoption has increased over the years, with about 50% adopted before age 1 in 1999, but few (10%) adopted before age 1 in 2012 (U.S. Department of State, 2013).

Experiences Prior to Placement in Foster or Adoptive Care

Human young have a long period of immaturity and therefore remain dependent on caregivers for a number of years. Nonetheless, the period when the formation of initial selective attachments has the most biological significance is probably the first several years of life. During the second half of the first year of life, children typically develop attachment relationships to specific caregivers. From an evolutionary perspective, one of the functions of attachment behaviors is to keep children close to caregivers under potentially dangerous circumstances. Even before children develop selective attachment relationships, caregivers play critical roles in helping their infants begin to regulate

physiological and behavioral states. For example, neonates are typically dependent upon their mothers for temperature regulation, and young infants are dependent on parents for physiological regulation. Thus, experiences of separation, maltreatment, and privation, even early in the first year of life, may have long-term developmental consequences.

Children experience a range of conditions prior to placement in foster care and adoptive care. At one end of a continuum are children who have lacked a caregiver altogether and experienced minimal stimulation. Although privation at this level is most often associated with institutional care, it is also sometimes seen among children reared with birth parents or foster parents. At the other end of the continuum are children who have been cared for by loving, committed caregivers who, for some reason (e.g., death, imprisonment), were not able to continue parenting. Many children who enter surrogate care fall between these two extremes; they have not been starkly deprived, but they also have not received consistently nurturing care. In the following sections, we consider experiences of institutional care, neglect, abuse, and separation from caregivers.

Institutional Care

Historically, many children who did not have parents to care for them lived in group care or institutional care settings (Bowlby, 1951). Attention to the effects of these conditions in the 1940s and 1950s ended the widescale use of institutional care in the United States and the United Kingdom. Nonetheless, such institutional care continues to exist in some places within the United States, where it is often referred to as “group care” or “congregate care.” About 15% of all children who are removed from their parents’ care are placed in facilities that house more than 11 children (DHHS, 2013). Older children are especially likely to be placed in institutional care, although infants and young children are placed in such facilities as well. Reasons given for these placements include the shortage of foster parents, the desire to keep siblings together, and the high quality of the facilities. Even high-quality institutional care, however, has problematic effects (Kaufman et al., 2004). An international group of scholars (Dozier et al., 2014, p. 219) has recently issued a consensus statement that “group settings should not be used

as living arrangements, because of their inherently detrimental effects on the healthy development of children, regardless of age.”

Compared to the United States and the United Kingdom, institutional care is seen more often in a number of other countries. The Children’s Bureau (U.S. Department of Health and Human Services, 2015) defines congregate care as homes with 7–12 children, and institutional care as facilities with 12 or more children. Institutional care is common in Asia, Central and South American, Africa, and the Middle East, with the highest proportion of children in institutional care in Eastern Europe and central Asia (United Nations International Children’s Emergency Fund [UNICEF], 2013).

In 1945, Spitz described the conditions of orphanages in the United States. In an attempt to reduce infection, and in response to low staff-to-child ratios, institutional environments had become increasingly sterile. Babies were handled as little as possible, kept in cribs from which they could not interact with each other or with staff members, and fed and changed in perfunctory fashion. Bowlby (1951) conducted a study of institutions in Europe for the WHO, describing similar conditions. Orphanages in Romania and St. Petersburg, Russia, were described in comparable ways over 50 years later (Groark, Muhamedrahimov, Palmov, Nikiforova, & McCall, 2005; Rutter, Kreppner, & O’Connor, 2001; St. Petersburg–USA Orphanage Research Team, 2008). For example, bottles were propped up so that babies could be fed without being held, and children were left lying in their cribs for extended periods.

Effects of Institutional Care on Development

Starkly depriving conditions are associated with the most pervasive effects on child functioning. At the very basic level, death rates are high. Furthermore, these children are often delayed in physical growth. They show deficits in motor development, with many of them crawling and walking well behind schedule (Johnson et al., 1996). Extensive delays in cognitive functioning and language development are also seen (Carlson & Earls, 1997; Johnson et al., 1996; Nelson et al., 2014). In addition to developmental delays, institutionalized children show highly anomalous behaviors, including stereotypies such as rocking and self-stimulating behaviors. Social behaviors are odd and often include one of two extremes:

Some children are withdrawn and depressed in appearance, whereas others are indiscriminate in their attachment behaviors (Chisholm, 1998; Chisholm, Carter, Ames, & Morison, 1995; Nelson et al., 2014; O'Connor, Rutter, & the English and Romanian Adoptees Study Team, 2000; Tizard & Rees, 1975).

Nonhuman primates raised under isolated conditions show similar deficits in functioning (Suomi, Chapter 7, this volume). For example, rhesus infants reared without appropriate mother surrogates show highly anomalous behaviors that persist when the infants are placed back in their home cages. These monkeys show stereotypies, inappropriate social behaviors, and (when mating does occur) inadequate parenting. Reintegrating these isolates with other animals is difficult because their inappropriate behavior patterns often make them targets for abuse (Suomi & Harlow, 1972).

Differences among Institutions

There are differences among institutions and even within institutions in the care provided (Groark et al., 2005; Gunnar, Bruce, & Grotevant, 2000). Key differences among institutions include different staff-to-child ratios and philosophies regarding staff interactions with children (Groark et al., 2005). There may be exceptions, and staff-to-child ratios and philosophies can be manipulated (Groark et al., 2005). Indeed, Groark and colleagues found that conditions in institutions can be substantially improved, resulting in changes in child behavioral outcomes. Reducing staff-to-child ratios, combined with altering expectations of child care workers, can result in profoundly altered interaction patterns.

Despite such results, even high-quality institutional care appears to have deleterious effects on young children's development (Kaufman et al., 2004). As a rule, children often miss the opportunity to develop selective attachment relationships to caregivers in institutions, and institutional care discourages caregivers from committing themselves to children. A number of forces operate to make caring for children in institutions perfunctory. Developing faster ways to feed and change children becomes important under such conditions. Institutional care seems to have specific adverse effects on children that other depriving conditions do not. In particular, the disinhibited attachment

seen among institutionalized children is rarely seen among children who have experienced other forms of deprivation, as we discuss later.

Neglect

Neglect accounts for about three-fourths of all substantiated cases of child maltreatment (Institute of Medicine [IOM], 2013). *Neglect* is a caregiver's failure to provide for his or her child's basic safety or welfare. Examples include leaving young children home alone, failing to provide adequate food or shelter, and failing to protect children from dangerous conditions (e.g., exposure to violence). On the one hand, although this may seem similar to the description of institutional care, neglecting parents usually have relationships with their children, and their children typically form selective attachments to them or to other caregivers in the home. From an evolutionary perspective, it makes sense that the attachment system is adaptable to a range of caregiving conditions. We expect that the formation of a selective attachment protects neglected children from the long-term effects seen among some institutionalized children.

On the other hand, although neglect is less toxic than conditions of privation, it has pervasive, long-term effects (for a review, see Smith & Fong, 2004). Children who experience early neglect are at increased risk for a host of problematic outcomes. During school-age years, children who have experienced early neglect exhibit more internalizing and externalizing behavior problems and have greater difficulties in relationships with peers than do other children (Egeland, Sroufe, & Erickson, 1983). As adolescents and adults, these children continue to be at significantly increased risk for a range of problems, including depression, anxiety, eating disorders, substance abuse, post-traumatic stress disorder, suicide, and criminal activities (e.g., Spertus, Yehuda, Wong, Halligan, & Seremetis, 2003). There is some evidence that the consequences are most serious for children who experience neglect early in life (e.g., DHHS, 2013; IOM, 2013; Keiley, Howe, Dodge, Bates, & Pettit, 2001).

Abuse

When abuse is documented, children are often removed from the home, at least for a period of

time. As with children who experience neglect, abused children typically form selective attachment relationships with caregivers. In fact, Roth and Sullivan (2005) argued that abuse heightens the connectedness children feel with their caregivers. They found, studying rodent pups, that the pairing of pain with the mother's presence is associated with enhanced positive feelings for the mother (see also Polan & Hofer, Chapter 6, this volume). Rajecki, Lamb, and Obmascher (1978) reported similar findings with a broader range of animal species.

Nonetheless, children who experience abuse are involved in a "paradoxical situation," in the words of Hesse and Main (2006, p. 336). When children experience abuse at the hands of a caregiver, they are frightened of the person from whom they would normally seek support. Under more typical parenting conditions, young children are frightened by a variety of things, including the dark, being left alone, and a dog barking, but they can typically turn to a caregiver to protect and soothe them. For example, when children receive inoculations, they are likely to be both hurt and frightened; caregivers, however, can buffer the effects of the stress (Gunnar, Brodersen, Krueger, & Rigatuso, 1996). But when caregivers themselves are the source of the fear, they fail to protect their children effectively from danger. Children's "paradoxical situation" is seen in their behavior when reunited with abusive caregivers in the Strange Situation (Hesse & Main, 2006). Typical responses include freezing upon reunion or moving away from, rather than toward, the parent. The fear that children experience interferes with their approach to parents. Thus, such children have odd, inexplicable behaviors that are classified as disorganized or disoriented (see also Lyons-Ruth & Jacobvitz, Chapter 29, and George & Solomon, Chapter 18, this volume).

Repeated exposure to frightening conditions may result in children developing a sensitized neurobiology, whereby minor threats elicit strong behavioral and physiological reactions. Other effects of maltreatment include children's difficulty in developing a trusting relationship with a caregiver (Milan & Pinderhughes, 2000), differential processing of angry faces (Cicchetti & Curtis, 2005; Pollak & Tolley-Schell, 2003), lack of empathy for distressed peers (George & Main, 1979), negative attributional biases (Dodge, Pettit, Bates, & Valente, 1995; Gibb, 2001), and later dissociative and externalizing symptoms (Lyons-Ruth, Alpern, & Repacholi, 1993).

Separations from Caregivers

Except when children are placed in foster or adoptive care at birth, placement involves separation from caregivers. Infants have a number of biological systems that maximize the likelihood of obtaining care from their biological mothers in particular. For example, at birth, an infant prefers the mother's smell to other smells, and this facilitates turning toward the nipple for breast feeding (Roth & Sullivan, 2005). Under benign conditions, the infant comes to anticipate certain rhythms of activity and responsiveness from the mother or caregiver (Beebe, Lachman, & Jaffe, 1997; Gianino & Tronick, 1988). Even prior to the development of a selective attachment, separations are likely to be experienced as dysregulating (see Polan & Hofer, Chapter 6, this volume).

Animal studies demonstrate how powerfully nonhuman primate and rodent young respond to separations from their mothers. Levine, Weiner, and Coe (1993) showed that infant squirrel monkeys never habituated to separations from their mothers. Even when infants had been separated many times, they continued to show neuroendocrine distress responses to the separations. A number of researchers (e.g., Levine et al., 1993; Sanchez, Ladd, & Plotsky, 2001) have found that these early separations have short-term and long-term effects on neuroendocrine regulation. For example, when rodent pups were separated from their mothers for periods of time longer than they would be separated in the wild, they developed a hyperreactive neuroendocrine system. Presumably, rodent pups' stress systems are not designed to deal with these long separations because there would be little chance of survival if their mothers did not return to the nest. Although these separations have been described as unnaturally long and therefore of limited usefulness in generalizing to the human condition, these longer separations may in fact be analogous to a human child's experience when placed in foster or adoptive care. Nonetheless, it is important to note that children often develop secure, organized attachments following transitions in care if placed in the home of nurturing parents (Dozier, Stovall, Albus, & Bates, 2001; Nelson et al., 2014).

Experiences of maltreatment and separation are often confounded for young children placed into foster and adoptive care, making it difficult to isolate effects. Animal studies may help point to which experiences are critical and which are not, although developing adequate models of abuse and

separation remains complex, as does the generalization across species.

Factors Affecting How Children Cope with Adversity

Child Vulnerabilities

A number of prenatal and genetic factors affect how children cope with adversity. Some of these factors, such as prenatal exposure to alcohol and premature birth, may be overrepresented in the population of children that enter foster and adoptive care (e.g., Barth & Needell, 1996). There are also high rates of prior maternal substance abuse among children placed into foster care and domestic adoptive care in the United States. The rates of prenatal substance exposure are often highest among children placed at birth because detection of maternal use of illegal substances is often a cause for placement into foster care. This is important because there is often an inverse association between prenatal and postnatal risk factors for children placed in domestic foster and adoptive care. For example, children who are placed in foster or adoptive care at birth are likely to have higher levels of prenatal substance exposure, but lower levels of postnatal risk (e.g., abuse, neglect, separations), than children placed at later ages.

The incidence of maternal smoking and drinking, as well as maternal use of illegal substances (e.g., cocaine and amphetamines), is high for children placed into foster and adoptive care in the United States (Barth, 1991). Prenatal exposure to substances has been linked with a wide range of problems for children, including attentional problems (Savage, Brodsky, Malmud, Giannetta, & Hurt, 2005), substance abuse (Glantz & Chambers, 2006), and conduct disorder (Wakschlag & Hans, 2002).

The preponderance of evidence suggests that the effects of risk are generally additive, with each additional factor increasing the odds of problematic outcomes (Appleyard, Egeland, van Dulmen, & Sroufe, 2005; Sameroff, Bartko, Baldwin, Baldwin, & Seifer, 1998). Some investigators, in fact, have found that the effects of risk factors are multiplicative, with three or four risk factors showing a much stronger effect than fewer risk factors (e.g., Appleyard et al., 2005). There is growing evidence for gene–environment interactions. Genetic variants often have little or no main effect on maladaptive psychological outcomes but are nonethe-

less associated with an increased vulnerability to risks such as child abuse (Rutter, Moffitt, & Caspi, 2006). For example, Caspi and colleagues (2002, 2003) reported evidence for a gene–environment interaction involving the monoamine oxidase A (MAOA) gene that affects antisocial behavior and another gene (the short-allele variant of the serotonin transporter gene) that affects rates of depression (see also Kaufman et al., 2006). Suomi (2003) similarly found that the short-allele version of the serotonin transporter gene in rhesus monkeys was associated with maladaptive outcomes in peer-reared, but not mother-reared, monkeys. Bakermans-Kranenburg and Van IJzendoorn (2006, 2011; Bakermans-Kranenburg, Van IJzendoorn, Caspers, & Philibert, 2011) found a significant interaction between the 7-repeat variant of the dopamine D4 receptor (*DRD4*) gene and environment in predicting outcome. The same genetic variant has been found to moderate the effects of an intervention to promote sensitive parenting and positive discipline (Bakermans-Kranenburg, Van IJzendoorn, Mesman, Alink, & Juffer, 2008).

Quality of Surrogate Caregiving Experiences

Among children in intact families and children who have been placed in foster or adoptive care, the later caregiving environment has proven to be important in affecting many outcomes (Ackerman, Kogos, Youngstrom, Schoff, & Izard, 1999; Duyme, Dumaret, & Tomkiewicz, 1999; Sinclair & Wilson, 2003). Children who are moved to privileged adoptive families after institutional care typically show a rapid catch-up in physical growth, followed by rapid cognitive development (Bakermans-Kranenburg, Steele, et al., 2011; Nelson et al., 2014). Nonetheless, some children continue to show deficits after being placed into stable foster or adoptive homes (Bakermans-Kranenburg et al., 2011; Nelson et al., 2014; Van IJzendoorn & Juffer, 2006). These issues are considered in more depth in a later section.

Sroufe and colleagues (Sroufe, Egeland, Carlson, & Collins, 2005; Weinfield, Sroufe, & Egeland, 2000) have suggested that when conditions in children's lives change, developmental outcomes follow rules of "lawful discontinuity." For the most part, the changes that have been studied have included parental death, divorce, and other similar life stressors. Although these changes are significant, they often pale in comparison with

the changes in the lives of children who enter surrogate care. Such children typically change caregivers, sibling groups, neighborhoods, SES, and sometimes even nations, cultures, and languages spoken. We expect that for infants and young children, the caregivers' characteristics are most critical to children's adjustment.

Hinde and McGinnis (1977) found that rhesus infants adjusted much more quickly following separations if their mothers' returned to normal behavior rather than exhibiting distressed or aberrant behavior. This is similar to findings regarding a child's ability to adjust to such stressors as death and divorce. When the remaining caregiver is able to function as an effective support to the child, the child's adjustment is much better than if the caregiver cannot serve this role (Harris, Brown, & Bifulco, 1986).

Adoptive, Foster, and Kinship Caregivers

In general, adoptive parents, traditional foster caregivers, and kinship caregivers represent somewhat different populations. Parents adopting across national boundaries are screened most extensively, and kinship caregivers are screened least extensively. Parents seeking to adopt internationally are typically screened to ensure that they do not present risks to any adopted child through their pattern of rearing. At the time of adoption, adopting parents have rates of psychopathology that are low by general population standards (Rutter, 2006). Accordingly, it might be expected that this population would mirror the general population with regard to attachment state of mind, or indeed might show high rates of autonomous states of mind.

Screening Caregivers

Screening of foster parents is somewhat variable. Most child welfare agencies attempt to place children in foster homes within the same city or county system from which children were removed. Therefore, in areas where removal of children is high per capita (e.g., in high-poverty areas), the available pool of foster parents is often much smaller than the number needed. A smaller foster parent pool typically results in less screening. Qualifications for becoming kin caregivers depend on whether the caregiver is licensed as a foster parent or the arrangement is informal. Combined with the fact that kin caregivers are

often the parents of the child's parents (who were unable to care for the child), it is not surprising that these kin caregivers have fewer resources and experience more stressors than traditional foster parents do (Brooks & Barth, 1998; Cuddleback, 2004). To our knowledge, the distribution of kin caregivers' attachment state of mind has not been reported in the literature.

There have been adoptions by lesbian couples for quite some time, with findings from several studies that the children generally fare well (Goldberg, 2010). What is relatively new is the adoption by gay male couples, although the numbers involved have been growing (Brodzinsky & Pertman, 2011). Golombok and colleagues (2014) compared 41 two-parent gay father adoptive families, 40 two-parent lesbian adoptive families, and 40 two-parent heterosexual adoptive families. The inclusion criteria were that the target child would be between 4 and 8 years of age and have been placed with the adoptive family for at least 12 months. The main finding was that there were few differences among the groups with respect to the development of the children, although there was a tendency for those in gay father adoptive families to do somewhat better in some domains. A major strength of the study was the multimethod approach, which included interview, observation, and questionnaire data and multi-informants (involving parents, child, and teacher).

The authors considered the possible reasons for the somewhat better outcome for the children adopted by gay men, and noted that unlike both lesbian couples and heterosexual couples, scarcely any of the gay father couples had tried to have children before and had therefore not gone through all the stresses involved with infertility and failed fertility treatments. Also, there was no clash between the gay men as to who was the "mother" (as there was in some lesbian couples) because clearly neither was the biological mother. For obvious reasons, the sample was not an epidemiological one because in the current circumstances that was not possible. Nevertheless, as judged by the agencies that kept records, the participation rate of 71% was high. A further limitation is that the children are still relatively young, and it is not known how they will turn out when older. Of course, too, especially with the gay men, they cannot possibly be regarded as typical of most gay men because most gay men do not wish to adopt. However, the policy implications are clear-cut in indicating that gay adoptive families constitute a largely untapped pool of potential adoptive parents.

Challenges for Children Forming Attachments to New Caregivers

To this point, we have considered the conditions associated with foster and adoptive care that are likely to affect children's adjustment. We now consider the challenges children face in developing attachments to new caregivers. The literature on attachment in relation to foster care and adoption falls into three general categories: foster placement, adoptive placement at birth or soon after, and adoptive care following institutional care. We consider each of these in turn.

Attachments of Children in Foster Care

The Process of Forming New Attachment Relationships

When developing in typical mother-child dyads, children form selective attachments as a result of maturation and an extended history of interactions. In contrast, children who are placed into foster or adoptive care are often at a developmental stage in which selective attachment relationships would already have been formed with caregivers. Therefore, the process by which new selective attachments are formed is likely to move along a different trajectory, or to take a form different from the usual one.

To study this process, Stovall and Dozier (2000) developed a diary method for tracking children's attachment behaviors. They examined the formation of attachment relationships from as close to the first day of a child's placement in a new home as possible. Foster parents were asked to report on children's behaviors during incidents likely to elicit attachment behaviors. In particular, they recorded how children responded to being frightened, hurt, and separated from them. Foster parents also recorded their own reactions to their children's behaviors and children's subsequent responses. These behaviors were recorded on a checklist developed to be as complete as possible.

Stovall-McClough and Dozier used the attachment diary to study children's developing attachment relationships in a new foster home (Stovall & Dozier, 2000; Stovall-McClough & Dozier, 2004). For children placed into care before about 1 year of age, placements became stable quickly. Within 1–2 weeks, most infants and tod-

dlers developed a consistent pattern of responding to their caregivers (Stovall & Dozier, 2000). For children placed later than approximately 1 year of age, the process appeared to take longer than for younger children. Even after 2 months, these children often did not show stable patterns of attachment behavior. Furthermore, in this early period of attachment formation, diary data suggested that the children "led the dance" (Stern, 2002). That is, children's avoidant and resistant behaviors elicited complementary (i.e., rejecting) behaviors from caregivers, even for caregivers with an autonomous state of mind.

These findings regarding the formation of attachments to new caregivers are probably neither as encouraging as they seem for the younger infants, nor as discouraging as they seem for the older infants. First, the finding that children younger than about 1 year of age show secure behaviors quickly with an autonomous foster parent is promising in terms of children's ability to organize their behavior in relation to a new caregiver. A period of 1–2 weeks (i.e., the length of time it appears to take young infants to develop expectations concerning a new caregiver's availability) is probably a long time in the life of a young infant. Although infants adapt to the new caregivers by organizing attachment behaviors in relation to caregiver availability, disruptions may still have had dysregulating effects. Second, the findings suggest that children who are more than about 1 year of age at the time of placement have some difficulty trusting new caregivers and behaving in ways that elicit nurturing behaviors. Stovall and Dozier (2000) were concerned, based on these early findings, that the children's behaviors would be self-perpetuating—that children who behaved in avoidant or resistant ways would fail to elicit nurturance from caregivers, and would therefore not experience an environment that could positively challenge and change their expectations. As we discuss in the next section on consolidated attachment relationships, however, these children are eventually able to develop attachment relationships that reflect their caregivers' state of mind rather than the children's anticipation of a non-nurturing world.

Consolidated Attachment Relationships among Foster Children

Dozier and colleagues (2001) studied the consolidated attachment relationships of children placed

into foster care for at least 2 months. Infant attachment quality in this study was assessed in the Strange Situation, and foster mother state of mind with respect to attachment was assessed with the Adult Attachment Interview (George, Kaplan, & Main, 1984, 1985, 1996; see Hesse, Chapter 26, this volume). Foster mothers' states of mind were concordant with infant attachment 72% of the time ($\kappa = .43$) in the Dozier and colleagues (2001) study, as compared with 76% ($\kappa = .49$) in the meta-analysis.

When children are placed with autonomous foster parents, it seems that experiences of maltreatment and separation do not affect their ability to form organized attachment relationships. These results are surprising in one sense but are also consistent with the evidence that attachment formation is a relationship-specific construct for young children. For example, the quality of attachment relationships that children form with mothers, fathers, and preschool teachers have been found to be relatively independent (e.g., Goossens & Van IJzendoorn, 1990; Howes & Hamilton, 1992; see Howes & Spieker, Chapter 15, this volume, for a review).

Whereas the attachment outcomes for children placed with autonomous foster parents were quite positive, children placed with nonautonomous caregivers were disproportionately likely to develop disorganized attachment relationships. This disproportionate distribution resulted from foster children developing disorganized attachment relationships when parented by foster parents with either dismissive or unresolved states of mind. Among biologically intact dyads, disorganized infant attachment is predicted only by parental unresolved state of mind and not by a dismissive state of mind. Dozier and colleagues (2001) interpreted these results as suggesting that children who have experienced early adversity are especially in need of nurturing care. Without such care, they do not appear to be able to organize their attachment relationships.

Attachment among Adopted Children

Children Adopted Early in Infancy

A meta-analysis of unpublished data suggests that attachment security (as measured in the Strange Situation) is somewhat less frequent in adopted children than in nonclinical, nonadopted samples (47 vs. 67%; Van IJzendoorn & Juffer, 2006).

Children Adopted Following Extended Institutional Care

Vorria and colleagues (2003, 2006) studied attachment among children in Greek orphanages, and with their parents at postadoption. There was a high rate of disorganized attachment (64 vs. 28%) while the children were in residential care, as found in other studies (Van IJzendoorn, Schuengel, & Bakermans-Kranenburg, 1999; Zeanah, Smyke, Koga, Carlson, & the Bucharest Early Intervention Project Core Group, 2005). At follow-up 2 years after adoption, attachment security, as measured with the Waters and Deane (1985) Attachment Q-Sort procedure (based on observer ratings), showed a lower level of security in the former Metera children than in a community comparison group, and less coherence and greater avoidance on the Bretherton (1985) Attachment Story Completion Task (ASCT). Thus, even after 2 years, there were continuing differences in attachment security associated with early institutional rearing. There was no effect of pre-adoption attachment security on the ASCT, and a negative effect on Q-sort-rated security. Disorganized attachment before adoption, as compared with security before adoption, was associated with more secure narratives after adoption. When studied at 13 years of age, these children showed generally positive attachment relationships with their adoptive parents, with only small differences between their functioning and that of a comparison group (Vorria, Ntouma, Vairami, & Rutter, 2015).

Atypical Attachments

Sroufe and colleagues (2005) have emphasized that among intact dyads, strength of attachment is irrelevant. Except under very atypical circumstances, all infants in intact parent-child dyads are expected to become attached to their primary caregivers. Even when children have maltreating parents, they appear to develop specific attachment relationships with those parents (e.g., Crittenden, 1985; Egeland & Sroufe, 1981). It is quality of attachment that differentiates most children, rather than whether they have developed attachment relationships of a certain relative strength or intensity. Among children who have been placed into foster or adoptive care, however, it appears critical to consider the *extent* to which children develop attachment relationships to new caregivers. The

Strange Situation, the standard way of assessing attachment quality, does not assess whether the child is attached to the caregiver.

Failure to Develop Specific Attachments

When children do not have an opportunity to develop early primary attachment relationships, they may fail to develop specific attachments to subsequent caregivers or may show odd behaviors with regard to those caregivers. Zeanah and colleagues (2005) have used a coding system developed by Carlson (2002) for assessing the extent to which a child shows attachment behaviors toward a particular figure in the Strange Situation. Ratings are made on the basis of the child's display of behaviors, ranging from typical behaviors shown by children from intact parent-child dyads (at the high end of the scale) to no display of attachment behaviors (at the low end of the scale). This system is important in considering differences among children who spent the early months of their lives in institutional care. In particular, Zeanah and colleagues found that early-institutionalized children displayed less discriminating attachment behaviors than never-institutionalized children. In fact, 100% of the never-institutionalized children showed clear attachment behavior patterns (coded as secure, avoidant, resistant, or disorganized), whereas only 3.2% of the institutionalized children showed clear attachment behaviors.

Indiscriminate Friendliness and Disinhibited Attachment

Related to this failure to develop discriminating attachment relationships are disinhibited attachment and indiscriminate friendliness or indiscriminate sociability. Indiscriminate sociability was first described by Tizard and Hodges (1978); children who display it approach strangers as if they are attachment figures. Rutter and colleagues (2007) provided a multisource assessment of disinhibited attachment at age 11 years, after at least 7½ years in adoptive families. Among Romanian adoptees between 6 and 42 months of age, entering the United Kingdom after having experienced institutional rearing, 26% showed marked disinhibition as assessed by parental report, as compared with 9% of those who had not experienced institutional rearing or who had entered

the United Kingdom below 6 months of age, and 4% in domestic adoptees adopted under the age of 6 months. Investigator ratings showed that the features most strongly associated with disinhibited attachment were socially inappropriate physical contact, a lack of social reserve, an unusual relationship with the examiner, verbal and social violation of conventional boundaries, and a high rate of spontaneous comments. At age 6 years, disinhibited attachment had been associated with a high proportion of disorganized, insecure/other, and unclassifiable classifications, with 41% rated as secure. It was also noteworthy that the majority of the children with disinhibited attachment exhibited problems in several other domains of behavior.

Indiscriminate sociability and disinhibited attachment are seen relatively frequently among children who were previously institutionalized for longer than 6 months of the first 2 years of life (e.g., Chisholm, 1998; Zeanah & Smyke, 2005). Most of the existing evidence suggests that children who were in foster care do not show high rates of indiscriminate sociability

The Meaning of Disinhibited Attachment

Several features of these findings stand out. First, disinhibited attachment constitutes a clinically significant problem that is remarkably persistent many years after adoption for children who were once in institutional care, and almost exclusively so for this population. In the Bucharest Early Intervention Project, Zeanah and Smyke (2005) reported that although inhibited attachment disorders were not disproportionately represented in frequency 18 months after the children were placed in foster families, disinhibited attachment disorders did not remit.

Second, disinhibited attachment is not a variant of attachment insecurity. Rather, it seems to represent an attachment *disorder* that involves a relative failure to develop normal attachment relationships.

Third, although the pattern was strongly associated with institutional deprivation, a substantial proportion of institutionally deprived children did *not* show this pattern. So far, the reasons for the individual differences in response remain obscure. Stevens, Sonuga-Barke, Asherson, Kreppner, and Rutter (2006) have suggested that genetic influences in susceptibility to environmental hazards may be implicated.

Fourth, it seems that the pattern rarely develops if the institutional deprivation does not persist beyond 6 months of age, but it is common with any persistence beyond 6 months. This suggests the possibility that some form of biological programming is involved in disinhibited attachment. The findings call for study of the biological processes that may be involved, but they also raise questions about possible sensitive periods in the development of selective attachment relationships.

Caregiver Commitment

In biologically intact families, commitment is often assumed on the part of the children and parents. It is relatively rare to hear of parents who threaten their children with placement outside the family (e.g., in a juvenile delinquency center, with the gypsies, or on the street), or for underage children to think seriously about leaving home. For foster parents and foster children, however, these issues are often salient. Foster parents have the option of giving the children back to the agency for care. Furthermore, although adoption is intended as a permanent solution, nearly 8% of adoptions are disrupted annually, mostly because parents request the children's removal. Whereas young children form attachment relationships with their new caregivers, some children retain a sense of connection to other parents or to members of another family. These issues are considered in the sections below.

Under typical conditions, we would rarely expect to see a lack of commitment on a parent's part. Humans produce relatively few young and invest an enormous amount of resources in each. There are rare conditions when commitment appears low on the part of biological parents. When children are placed into foster care or with adoptive parents, however, parents' commitment can be variable.

Among some species, infants are adopted, but only under fairly limited conditions. For example, typically only lactating females and biologically related females appear to adopt orphaned or abandoned rhesus macaque infants (M. Gerald, personal communication, February 14, 2004). In general, humans are less under the control of hormonal influences than other species, perhaps partly because of a more highly developed prefrontal cortex. Nonetheless, it is important to remem-

ber that fostering and adopting occur without the usual biological preparedness that accompanies parenting under more typical conditions.

At one end of the continuum, some foster parents appear to think of their foster children as their own, investing emotionally in their children in ways not unlike parents with their birth children. At the other end of the continuum, some foster parents appear to think of themselves as temporary caregivers who should not invest emotionally in their children (Dozier & Lindhiem, 2006).

We have assessed commitment through an interview called the This Is My Baby Interview (Bates & Dozier, 1997) with foster parents. In the interview, a foster mother is asked to describe her child and to indicate how much she would miss the child if he or she were removed from her care, among other things. Differences in commitment are associated with how many children parents have fostered in the past, with the number of children fostered in the past being inversely related to commitment to current children (Dozier & Lindhiem, 2006). Foster parents who have fostered more children are less likely to commit to the children currently in their care than foster parents who have fostered fewer children. Also, commitment differs for children of different ages, with caregivers showing higher levels of commitment to children placed at younger ages.

Dozier and Lindhiem (2006) have suggested that having a committed caregiver is even more important to the child's sense of security than is the caregiver's responsiveness to the child's bids for reassurance. The two constructs of commitment and responsiveness to distress are largely orthogonal. For example, it is possible for a foster mother to be dismissing (and not responsive to child cues), yet highly committed to a child. From an evolutionary perspective, it is critical that the child have a caregiver who will be there to protect him or her under threatening conditions. Although it is optimal if the caregiver is also soothing and responsive, it may be less essential than the caregiver's commitment to the child. Parents who are more highly committed show more delight in their children than parents who are not as highly committed (Bernard & Dozier, 2011). Commitment is associated with whether the relationship endures or is disrupted, but there are probably subtle, as well as more obvious, ways of communicating commitment or its absence. Placements are more likely to be disrupted when caregivers are less committed than when caregivers are more committed (Dozier & Lindhiem, 2006).

Open Adoption and Contact with the Biological Family

When foster children have visitation with birth parents, and/or move back and forth between birth parents' homes and foster homes, issues of "Whose child am I?" sometimes arise. For example, birth mothers may want children to think of them as their mothers, but children often refer to foster mothers as their mothers. The younger the child, the harder it is for the child to hold onto any notion of another parent at all (Piaget, 2000). As children become older, they may be raised by one set of parents while knowing about the existence of another set of parents. A similar set of circumstances faces children who are adopted.

These issues are salient in this era of open adoption, when there is the possibility for both biological parents and adopted children to search for each other. The research undertaken up to now regarding open adoption, although very useful in its own right, has not used attachment measures or assessed attachment issues. The move to open adoption was driven initially by the view that this would be beneficial for a child (Hale & Fortin, 2008). Nonetheless, open adoption has implications for all three groups of participants in what can be considered the *adoption triangle* (Triseliotis, Feast, & Kyle, 2005)—that is, the biological family, the adoptive family, and the adopted individual. What is the effect on the adoptive parents of having to share parenthood with another set of parents? What is the effect on the adopted child if continuing contact with the biological family is not possible in practice? What is the effect on attachment representations when, after an initially closed adoption, contact with the biological family is made after years of no contact? Attachment theory provides no clear guide to what is likely to happen or what should happen. What it does do, however, is highlight how contact or the impossibility of contact is likely to impinge on people's internal working models of themselves and of their relationships with other people.

Howe and Feast (2001) focused primarily on the adopted individual—comparing 394 individuals who had searched for their biological parents with 78 who had not, and who had been sought out and approached on behalf of a birth relative. Of those searchers who found a birth relative, few (7%) were rejected outright, and few (9%) had the contact terminated within a year after only one or two contacts, which was also experienced as a rejection. Most (71%) evaluated the reunion

as emotionally satisfying, and nearly half claimed that it had improved their self-esteem. Few (11%) of the searchers and one-fourth of the nonsearchers felt that the reunion experience had been upsetting. Howe and Feast concluded that adopted individuals who did *not* search were on the whole well integrated into their adoptive families. Those placed transracially were less likely (56 vs. 71% in same-race placements) to report that they felt they "belonged" in their adoptive family.

Triseliotis and colleagues (2005) examined the outcome of contact with respect to all three members of the adoption triangle. Data were derived from a large-scale postal questionnaire, focusing only on adopted children included in the first study. A high participation rate (82%) was achieved. Approximately one-half of the birth mothers were under the age of 20 at the time of the adopted children's birth, and a minority (11%) were 16 or under. Most became pregnant during the 1950s and early 1960s, when social attitudes toward pregnancies outside marriage tended to be very censorious. Most of the girls' parents were initially shocked and upset, but eventually approximately one-third were supportive (despite usually keeping the pregnancies secret). Most women reported that they felt they had no choice about giving up their babies. Emotional support was usually lacking at the time of parting with their children, and most of the biological mothers came to feel lonely and abandoned. Nevertheless, many (70%) of the mothers said that as they looked back, they felt that adoption had been the right decision. Most did not think the experience had affected their capacity to make new relationships (although 14% said that it had). Similarly, some three-fifths did not think parting with their adopted children had affected the quality of their relationships with their other children, but two-fifths thought it had. These findings suggest that a more detailed study of social relationships, including a use of attachment concepts, would be worthwhile.

Regarding the contact with the adopted children many years later, mothers who were sought out were more likely than seekers to report that the contact felt comfortable. In two-thirds of cases, contact was stopped at the initiative of the adopted persons, especially in the case of seeker mothers. For most birth mothers, contact and reunion were happy and satisfying experiences, with about half feeling that their ability to relate to others had been improved by the reunion; however, some (1 in 10) were dissatisfied, and about the same proportion felt angrier since contact than before.

Most adopted people rated their relationships with their adoptive parents as close, but some (nearly 20%) described them as not close. Those who felt that their relationships were close were least likely to feel rejected by their biological parents. In cases in which there was a feeling of rejection, however, this tended to peak in adolescence. Some adopted persons reported a sense of loss. The experience of reunion with their biological mothers was reported by one-third of adopted persons as having enhanced their relationships with their adoptive families, but some (1 in 6) said that it had led to deterioration in these relationships. Eight years after the reunion, about three-fourths were still in contact with the biological relatives. Some (1 in 3) came to look upon their birth mothers as parents, but just over half viewed them as friends or friends/relatives. For the remaining subset (18%), the relationships were distant or their birth mothers felt like strangers. Many (80%) were pleased to have made contact, and where contact had been established, feelings of rejection or loss tended to diminish. Nevertheless, some (10–20%) of adopted people felt that adoption had adversely affected their marriage and social relationships.

Most (nearly 90%) adopting parents had disclosed the adoption when their children were 4 years of age or younger, and most felt that this had been the right time. Most adoptive parents talked (sometimes or often) with their children about the children's birth families, but a minority (1 in 5) felt that their children were reluctant to do this. Almost all adopting parents felt close to their adopted children and felt very happy about their relationship. Over three-fourths of adopters described their children's motivation to search as strong, and most were supportive of it. However, a few (1 in 6) felt frightened and worried. A prominent concern was that their children might be hurt by the contact, but some felt worried that reunion would mean that they would "lose" their children.

Most (70%) adopters reported that their relationships with their children were unchanged by the search and reunion, and for almost everyone else it had been enhanced. Nevertheless, some (1 in 8) said that, especially in the early stages of the search, their relationships were under strain. Overall, most (nearly 70%) reported that the contact experience had been positive, and very few (3%) reported it as clearly negative.

Viewed as a whole, the search and reunion were positive experiences. For an appreciable minority, the experience of parting with their children may have had an adverse effect on their social

relationships. Similarly, for a minority of adopted individuals, there were concerns over some aspects of social relationships. A more detailed study of these variations would benefit from an attachment perspective, but it would be a mistake to ignore the broader social context, and the attachment features would need to be examined alongside other perspectives.

Interventions to Enhance Attachment among Foster and Adopted Children

Harlow found that isolate-reared monkeys engaged in odd, aggressive, and self-destructive behaviors when placed back into their home cages following extended isolation. It turned out that younger monkeys best served as "therapist monkeys" for these isolate-reared monkeys; these younger monkeys allowed close contact while tolerating aberrant behavior without reprisal (Suomi & Harlow, 1972; Suomi, Harlow, & McKinney, 1972). The principle here might be that contact was needed, but in a context that would not result in injury. For children in institutional care, foster care and adoption represent interventions that often meet these two criteria. An interpersonally engaged but tolerant environment appears to result in excellent physical catch-up, as well as reasonable cognitive catch-up for children who had been institutionalized (Bakermans-Kranenburg, Steele, et al., 2011; Gunnar et al., 2000).

Even when provided with the company of "therapist monkeys," Harlow's isolate-reared monkeys continued to show odd behavior. Most did not mate as adults, and most that did mate showed very inappropriate parenting behaviors. Similarly, children adopted from orphanages continue to show anomalous behaviors, especially with regard to social behaviors and inhibitory control. Without nurturing parents, foster children may develop cognitively but have difficulty organizing attachment behaviors (Gunnar et al., 2000). The aspects of functioning that appear problematic, at least for some children, are regulation of neuroendocrine functioning, inhibitory control, and behavioral control (including risk for substance abuse and related problems), as well as disorganized attachment, nondiscriminating attachment relationships, and odd social behaviors (Gunnar et al., 2000). There has been relatively little research investigating how best to alter these behavioral

trajectories. We suggest that interventions need to target the behaviors identified as specifically problematic. In some instances there will be overlap in intervention strategies for foster children, domestically adopted children, and internationally adopted children, and in other instances there will not be. The last two decades have seen an explosion of attachment-based interventions for young children (e.g., Hoffman, Marvin, Cooper, & Powell, 2006). A smaller number of interventions target the needs of children in foster or adoptive care (Dozier, Lindhiem, & Ackerman, 2005; Fisher & Chamberlain, 2000; Juffer, Hoksbergen, Riksen-Walraven, & Kohnstamm, 1997).

Evidence-Based Interventions for Foster and Adopted Children

Several overlapping models of intervention that target attachment issues have been developed for foster and adopted children (Dozier et al., 2005; Lieberman, Ghosh Ippen, & Van Horn, 2006; Spieker, Oxford, Kelly, Nelson, & Fleming, 2012; Zeanah et al., 2001). Programs range from relatively brief interventions (Dozier et al., 2005, Spieker et al., 2012), to longer interventions (Lieberman et al., 2006), to comprehensive change in the nature of how foster care is provided (Zeanah et al., 2001). Some interventions target parent changes in sensitivity almost exclusively (Dozier et al., 2005), whereas others work to change parent reflective functioning (Lieberman et al., 2006; Spieker et al., 2012). These interventions developed explicitly for foster children overlap significantly with interventions for high-risk parents and infants (e.g., Powell, Cooper, Hoffman, & Marvin, 2013). Interventions for foster parents often target the challenges associated with caring for a child who has experienced early adversity (e.g., maltreatment, transitions in care) that affects his or her response to foster parents (e.g., Dozier et al., 2005; Spieker et al., 2012), in addition to more general intervention targets such as sensitivity. Dozier and colleagues (2014) have incorporated intervention components that target specific problems seen among children who experienced institutional care, including indiscriminate sociability and quasi-autistic behaviors.

Although several interventions have been developed that target these populations and are being tested through randomized clinical trials, the evidence base is relatively nascent. The evidence supporting intervention efficacy comes

primarily from trials with high-risk birth parents rather than with foster or adoptive parents. Although preliminary, findings are promising at this point. Dozier and colleagues (2014) reported that foster children randomized to the Attachment and Biobehavioral Catch-Up (ABC) Intervention showed higher rates of security in the Preschool Strange Situation than children assigned to a control intervention. Lewis-Morrarty, Dozier, Bernard, Terracciano, and Moore (2012) found that infants assigned to the ABC condition showed stronger executive functioning in preschool years than children assigned to the control intervention. Spieker and colleagues (2012) saw improvements in sensitivity for parents at postintervention in their randomized clinical trial, although those effects were not sustained 6 months later.

Robust effects were seen in attachment and many other outcomes for children randomly assigned from institutional care to the model of foster care used in the Bucharest Early Intervention Project (Nelson et al., 2014). The model of intervention was comprehensive, including foster parents committing to the care of their children, receiving a stipend that supported intensive involvement with the children, and receiving visits that supported parents' sensitivity.

Harmful Interventions for Foster and Adopted Children

In parallel with these positive developments in evidence-based interventions that target specific needs of foster and adopted children, there have been various coercive interventions claiming to be attachment-based but actually using concepts that are antithetical to attachment theory. These approaches, known as *attachment therapy* or *holding therapy*, lack empirical support and indeed have led to adverse effects, as suggested by Lillienfield (2007), Pignotti and Mercer (2007), and O'Connor and Zeanah (2003). Lillienfield includes holding therapy as one of the "potentially harmful therapies (PHTs)" (p. 53) in his *Psychological Science* review. Holding therapy is included as a Level 1 PHT, classified as "probably produc[ing] harm in some individuals" (p. 59). Several deaths have been associated with the use of this treatment (Pignotti & Mercer, 2007), and no randomized clinical trials that have been conducted support its efficacy (Lillienfield, 2007). Despite claims to the contrary, holding therapy does not provide a

useful basis for further developments in the design of treatments for attachment disorders in adopted or nonadopted children. This treatment is unfortunately often referred to as attachment therapy. It seems critical to differentiate it from treatments derived from attachment theory.

Conclusions

From an evolutionary perspective, it is advantageous that the human attachment system can adapt to a range of caregiving conditions. Children can form attachment relationships to new caregivers when a previous relationship has been disrupted or after the experience of adversity. When new caregivers are nurturing, children can organize their attachment behavior in relation to the new caregivers' availability. Nonetheless, when children experience conditions that are beyond those with which the attachment system is designed to deal, it seems that rigid means of coping (e.g., disinhibited attachment) or a neurobiology that predisposes to later disorder become more likely. Interventions need to target the specific issues with which children struggle most.

Chapter 31

Attachment States of Mind and Psychopathology in Adulthood

K. Chase Stovall-McClough
Mary Dozier

Bowlby (1969/1982, 1973, 1980) proposed a model of development with clearly articulated implications for psychopathology. According to this model, an infant's formation of an attachment to a caregiver is a key developmental task that not only influences the child's representations of self and other but also affects strategies for processing attachment-related thoughts and feelings. Attachment-related events, such as loss and abuse, lead to modifications in these internal representations and affect a child's strategies for processing thoughts and feelings. Bowlby (1973, 1980) suggested that when children develop negative representations of themselves or others, or when they adopt strategies for processing attachment-related thoughts and feelings that compromise realistic appraisals, they become more vulnerable to psychopathology. In this chapter, we consider how the quality of an infant's attachment to his or her caregiver, subsequent attachment-related experiences, and concurrently assessed states of mind with respect to attachment (Main, Goldwyn, & Hesse, 2003) may be related to risk for psychopathology or to psychological resilience in adulthood.

Infant Attachment and Later Psychopathology

When infants' experiences lead to expectations that caregivers will be responsive to their needs,

they develop secure strategies for seeking out their caregivers when distressed or in need, with the expectation that their needs will be met. Insecure strategies vary primarily along the dimension of attempts to minimize or maximize the expression of attachment needs. When children use minimizing strategies, they defensively turn attention away from their distress and from issues of caregiver availability. They therefore have limited access to their own feelings and develop an unrealistic portrayal of parents' availability. When children use maximizing strategies, they defensively turn their attention to their own distress and to issues of caregiver availability. Because they are so "enmeshed" (Main et al., 2003) in issues of caregiver availability, they are unable to appraise accurately whether threats exist and whether caregivers are available. Either of these strategies may leave children at increased risk for psychopathology. Minimizing strategies may predispose a child to externalizing disorders because attention is turned away from the self, without the resolution of negative representations. Maximizing strategies may predispose a child to internalizing disorders because attention is riveted on caregiver availability and negative representations remain painfully alive.

Sroufe (e.g., 1997, 2005; Sroufe, Egeland, Carlson, & Collins, 2005b) have emphasized the importance of the organizational function of the attachment system in integrating affective, motivational, and behavioral components

of experience. In this model, adaptations to early experiences set the stage for negotiating later experiences. Adult psychopathology is placed in a developmental context, with an emphasis on the interactions among prior experience, subsequent adaptation, and current contextual factors (Carlson, Egeland, & Sroufe, 2009). The quality of attachment in childhood can have both a direct impact on adult functioning and be modified by adaptations to caregiving experiences to predict typical or atypical development.

Overview of the Chapter

A number of longitudinal studies have examined links between infant attachment and adult psychopathology (Dutra & Lyons-Ruth, 2005; Englund, Kuo, Puig, & Collins, 2011; Grossmann, Grossmann, & Waters, 2005; Lyons-Ruth, Bureau, Holmes, Easterbrooks, & Brooks, 2013; Shi, Bureau, Easterbrooks, Zhao, & Lyons-Ruth, 2012; Sroufe et al., 2005a, 2005b). In this chapter, we consider evidence from these longitudinal studies and cast our net more broadly to consider associations between attachment-relevant events in childhood (e.g., loss, trauma, and separation from parents) and later psychopathology. In addition, we examine the association between concurrently assessed attachment states of mind as assessed by the Adult Attachment Interview (AAI; George, Kaplan, & Main, 1985; Main et al., 2003) and psychopathology.

We consider specific disorders with regard to the importance of attachment as an etiological factor (with highly heritable disorders less influenced by attachment), and the extent to which disorders represent an internalizing versus an externalizing symptom picture. We start with mood disorders, followed by anxiety disorders. Both of these groups of disorders are heterogeneous with regard to heritability and symptomatology; therefore, it would be surprising if clear findings emerged with regard to attachment-related issues without further specification of parameters. We move from there to a discussion of dissociative disorders. The evidence linking attachment in infancy and attachment-related traumas to later dissociative symptoms and concurrent states of mind with dissociative symptoms converge to form a compelling picture. We consider eating disorders next; these disorders are often comorbid with personality disorders and mood disorders. We then turn our attention to

schizophrenia, a disorder that is highly heritable. From there, we move to a consideration of two of the most prevalent personality disorders: borderline personality disorder and antisocial personality disorder.

For each disorder or group of disorders considered, we begin with a general description of the disorder(s) and the latest evidence regarding genetic involvement. We then discuss attachment theory's contributions to an understanding of the disorder(s). From there we move to a consideration of the empirical evidence linking attachment phenomena to the disorder(s). We include the latest findings and consider them in light of our hypotheses outlined in earlier versions of the chapter in previous editions. Finally, we present the most recent data on links between infant attachment and adult psychopathology, and discuss changes in the state of the field.

Mood Disorders

Unipolar and bipolar mood disorders differ considerably with respect to symptomatology, genetic involvement, course, and the probable role of attachment in their etiology. A large meta-analysis of twin studies found lifetime heritability of major depression to be 37% (Sullivan, Neale, & Kendler 2000). The heritability of major depressive disorder, however, is linearly related to severity, with more severe depression (defined by earlier onset and recurrence) more heritable than less severe depression (Bienvenu, Davydow, & Kendler, 2011). Bipolar disorders are highly heritable, with rates estimated to be as high as 85% (e.g., Bienvenu et al., 2011). There has been little attention paid to the developmental context of bipolar disorder. According to Parry (2010), no studies to date have examined the role of attachment, and few have considered the role of abuse and early trauma. Thus, we focus below on the role of attachment in later depression.

The heterogeneous nature of depression is important to consider in relation to attachment. First, severity seems to be an important dimension to consider (Brown & Harris, 1993), with some suggesting that a "disease-like endogenous" form of the disorder is more heritable than a "neurotic" form driven by environmental and personality vulnerabilities (Bienvenu et al., 2011). Second, the differential reliance on internalizing versus externalizing coping strategies is important, and is

central to states of mind with respect to attachment. Some people with unipolar disorders show predominantly internalizing symptoms, with self-blame and self-deprecation primary. Others show a preponderance of externalizing symptoms, with interpersonal hostility primary. Preoccupied states of mind, which involve a preoccupation with one's own thoughts and feelings, are consistent with internalizing symptoms. On the other hand, dismissing states of mind, which involve a turning away from one's own distress, are consistent with externalizing symptoms.

Attachment and Mood Disorder: Theoretical Links

Bowlby (1980) suggested that three major circumstances are most likely to be associated with the later development of depression. First, when a child's parent dies, and the child experiences little control over ensuing events, he or she is likely to develop a sense of hopelessness and despair in reaction to traumatic events. Second, when a child is unable to form stable and secure relationships with caregivers, he or she develops a model of the self as a failure. Any subsequent loss or disappointment is then likely to be perceived as reflecting that the child is a failure. Third, when a parent gives a child the message that he or she is incompetent or unlovable, the child develops complementary models of the self as unlovable and of others as unloving (Bretherton, 1985). Thus, the child and later the adult will expect hostility and rejection from others when he or she is in need. Cummings and Cicchetti (1990) have suggested that these experiences of having a psychologically unavailable parent are similar to the experience of actually losing a caregiver, in that the child experiences frequent or even chronic losses of the parent. Each of the sets of circumstances specified by Bowlby involves a sense of uncontrollability on the part of the child and is compatible with Seligman's learned helplessness theory of depression (Seligman, Abramson, Semmel, & von Baeyer, 1979).

Children's Attachment-Related Experiences and Later Depression

The circumstances Bowlby proposed as central to the development of depression have received strong empirical support. Insecure attachment (both resistant and avoidant) predicts depression in adolescence (Duggal, Carlson, Sroufe, & Ege-

land, 2001), though to our knowledge those findings have not yet been extended to adulthood. Moreover, several studies provide converging evidence that the death of a parent in early childhood puts an individual at risk for later depression (e.g., Harris, Brown, & Bifulco, 1990; Kivela, Luukinin, Koski, Viramo, & Pahkala, 1998; Nickerson, Bryant, Aderka, Hinton, & Hofmann, 2013; Takeuchi et al., 2003). Harris and colleagues (1990) found that risk for later depression increased when the loss occurred before age 11 and involved the death of (vs. long-term separation from) a parent. Bowlby (1980) suggested that the death of a child's mother may well lead to a sense of total despair, whereas separation from the mother may lead to a belief that events are reversible.

Just as important as the loss itself are the child's subsequent experiences with caregivers (Harris, Brown, & Bifulco, 1986; Kendler, Sheth, Gardner, & Prescott, 2002; Nickerson et al., 2013; Oakley-Browne, Joyce, Wells, Bushnell, & Hornblow, 1995). Harris and colleagues (1986) found that inadequate care following the loss doubled the risk of depression in adulthood, particularly in cases of separation rather than death. More recently, Nickerson and colleagues (2013) found that adverse parenting following the early death of a parent was associated with increased risk for depression, as well as a multitude of other disorders in adulthood.

Attachment States of Mind and Depression

Main and colleagues (2003) have proposed that different attachment states of mind are associated with different patterns of processing attachment-related thoughts, feelings, and memories. Secure *autonomous* transcripts are characterized by coherence; the speaker's representation of attachment experiences is straightforward, clear, and consistent with evidence presented. Insecure *nonautonomous* transcripts fall into several categories, including "dismissing," "preoccupied," "unresolved with respect to loss or trauma," and "cannot classify." A lack of recall, idealization of caregivers, and/or derogation of attachment experiences characterize dismissing transcripts. Preoccupied transcripts are characterized by current angry involvement with attachment figures or by passive speech, such as rambling discourse (Main et al., 2003). The category *unresolved* is used for transcripts in which the speaker experiences lapses in reasoning or lapses in monitoring of discourse regarding a loss or trau-

ma. When an unresolved classification is given, a secondary classification (of autonomous, preoccupied, or dismissing) is also made.

The *cannot classify* category represents a mixture, or shifting, of information-processing strategies that are inconsistent with one another. For example, the individual may describe one parent in a highly dismissing way and relate incidents of distress concerning the other parent in an enmeshed way. The cannot classify category has been associated with high rates of psychopathology (e.g., Allen, Hauser, & Borman-Spurrell, 1996; Hesse, Hobson, Patrick, Maughan, & Main, 2011; Holtzworth-Munroe, Stuart, & Hutchinson, 1997; Riggs et al., 2007), but sample sizes are rarely large enough to examine associations between this category and specific forms of psychopathology. (See Hesse, Chapter 26, this volume, for a more detailed description of the AAI.)

In versions of this chapter in previous editions of this volume, we called attention to the inconsistent findings regarding the association between states of mind and depressive disorders, with some studies reporting depression associated with preoccupied states of mind (Cole-Detke & Kobak, 1996; Fonagy et al., 1996; Rosenstein & Horowitz, 1996), but others reporting depression associated more closely with dismissing states of mind (Patrick, Hobson, Castle, Howard, & Maughan, 1994). Such discrepant findings continue to appear in the literature. Borelli, Goshin, Joestl, Clark, and Byrne (2010) examined self-reported depressive symptoms and attachment state of mind in a sample of incarcerated women, and Ivarsson, Granqvist, Gillberg, and Broberg (2010) looked at attachment state of mind in a clinical sample of adolescents. Similar to Cole-Detke and Kobak (1996), Fonagy and colleagues (1996), and Rosenstein and Horowitz (1996), Borelli and colleagues found depressive symptomatology to be more highly associated with preoccupied states of mind than with secure or dismissing states of mind. On the other hand, Ivarsson and colleagues found that over half of the sample of outpatient depressed adolescents (64%) was classified as dismissing in a forced three-way distribution of secure, insecure/dismissing, and insecure/preoccupied.

Consistent with the point made by Sroufe and colleagues (2005a), we suggest that there may be systematic differences on the internalizing-externalizing dimension in the groups labeled as “depressed” in these studies, and that these may account for the discrepancies in findings. In the Rosenstein and Horowitz (1996) study, ado-

lescents who had been admitted to a psychiatric hospital were separated into three groups: a “pure affective disorder” group, which excluded those with comorbid conduct disorder, a conduct disorder group, and a comorbid group. Thus, adolescents in the pure affective disorder group excluded people who showed externalizing symptoms of conduct disorder but did not exclude those who were comorbid for a more internalizing disorder. They were classified as having preoccupied states of mind significantly more often than those in the comorbid or the conduct disorder group. More specifically, 69% of the pure affective disorder group was classified as preoccupied, whereas 25% of the comorbid group and 14% of the conduct disorder group were classified as preoccupied.

Cole-Detke and Kobak (1996) examined the states of mind of women who reported depressive symptoms, eating disorder symptoms, both types of symptoms, or neither type. The distribution of women who reported only depressed symptoms was relatively even across the three categories of attachment. Although depressed women were classified as preoccupied more often than were women with eating disorders, the majority fell into categories other than preoccupied. Again, the criteria for the depressed group excluded at least some with comorbid externalizing, but not internalizing, symptoms.

In Borelli and colleagues’ (2010) study of incarcerated women residing with their infants, change in depression over the first year of incarceration was assessed. The sample as a whole was rated as primarily nonautonomous, with similar proportions of dismissing and preoccupied states of mind (28% dismissing, 32% preoccupied, and 40% unresolved in a four-way distribution). However, preoccupied states of mind were associated with increases in depression over the first year of incarceration. The sample excluded those incarcerated for violent offenses (and presumably those with externalizing behaviors).

Patrick and colleagues (1994) limited their depressed group to women inpatients without any borderline personality disorder symptomatology, thus excluding some with internalizing symptomatology. They assessed the states of mind of 24 female inpatients with diagnoses of either dysthymia or borderline personality disorder. Women were included in the dysthymic group only if they met none of the criteria for borderline personality disorder. The distribution of states of mind was significantly different for the two groups. All of the women in the borderline group were classified as

preoccupied, as contrasted with 50% of those in the dysthymic group.

In Ivarsson and colleagues' (2010) study of outpatient adolescents with depression ($n = 100$), over half of the sample (64%) was classified as dismissing in a forced three-way distribution. With the five-way classification breakdown (secure, dismissing, preoccupied, unresolved, and cannot classify) 28% were classified as cannot classify and 40% were classified as unresolved. The sample included those with depression and comorbid obsessive-compulsive disorder (OCD), which may account for the high percentage of dismissing states of mind because OCD encompasses extreme efforts to avoid the internal experience of anxiety.

Given that the experience of loss is hypothesized to be a significant vulnerability factor for depression, it follows that people with unipolar mood disorders may be unresolved with respect to loss. In the several studies that have examined unresolved status among depressed people, the results have been inconsistent. In Fonagy and colleagues' (1996) large sample of inpatients, 72% of people with depression were classified as unresolved, compared with 18% in Rosenstein and Horowitz's (1996) adolescent inpatient sample and 16% of Patrick and colleagues' (1994) outpatient sample.

Fonagy and colleagues (1996) found that different subtypes of depression were differentially related to states of mind. Compared with dysthymia, major depression in this study was more often associated with autonomous states of mind. Fonagy and colleagues suggested that these findings could be attributable to the episodic nature of major depression. Major depression may not interfere with the maintenance of coherent states of mind as pervasively as chronic dysthymia does. Another possibility is that major depression is more heritable than dysthymia, so that it takes less unfavorable caregiving for the disorder to emerge.

These various findings point to the importance of diagnostic issues when one is considering linkages between attachment states of mind and mood disorders. Several distinctions among the unipolar mood disorders appear important. Compared with dysthymia, major depression is less frequently associated with autonomous states of mind. Within the categories of major depressive disorder and dysthymia, we suggest that differences in the extent to which disorders are self-blaming (internalizing) versus other-blaming (externalizing) are important in terms of states of mind. A related issue is comorbidity. Although a diag-

nosis of unipolar mood disorder may not provide evidence of the extent to which symptoms are internalizing or externalizing, other comorbid diagnoses (e.g., borderline personality disorder, eating disorders, and particular anxiety disorders such as OCD) may provide such evidence. Several studies have highlighted how important it is to consider comorbid diagnoses in analyses.

Anxiety Disorders

Similar to mood disorders, anxiety disorders are quite heterogeneous. Most, however, are characterized by a combination of anxiety and an effort to avoid the anxiety. When anxiety or fear predominates, the disorder typically involves internalizing symptoms, whereas when avoidance predominates, the disorder typically involves externalizing symptoms. As discussed previously, strategies that maximize the expression of attachment needs are expected to be associated with more internalizing disorders, and strategies that minimize the expression of attachment needs are expected to be associated with more externalizing disorders. The disorder in which fear most clearly predominates is generalized anxiety disorder (GAD). Individuals who have this disorder experience chronic ruminative anxiety regarding at least several life circumstances and there is little ability to stop or avoid the anxiety. Interestingly, however, newer models of GAD have reconceptualized the role of worry in the maintenance of the disorder, suggesting that worry itself serves as a method of *avoiding* conflict, social engagement, and negative internal states (Borkovec, Alcaine, & Behar, 2004; Mennin, Heimberg, Turk, & Fresco, 2002). Panic attacks are also characterized primarily by fear, but avoidance of triggers for panic is an important component of panic disorder. Similarly, phobic disorders (including specific phobia, social phobia, and agoraphobia) are characterized by fear when the individual does not successfully avoid the feared stimulus, but avoidance often predominates. In OCD, fear is experienced to the extent that the individual does not engage in self-prescribed compulsive behaviors. Posttraumatic stress disorder (PTSD) is characterized by vacillation between (1) emotional numbing and efforts to avoid reminders of the trauma, and (2) fear and anxiety associated with reexperiencing the trauma. Underlying this emotional instability is a generalized hypervigilance. It is the vacillation

between avoidance and overwhelming fear that characterizes this disorder.

Comorbidity of anxiety disorders with other diagnoses is common; in particular, anxiety disorders and depressive disorders often co-occur (Hettema, Neale, & Kendler, 2001; Kendler, Heath, Martin, & Eaves, 1987). The estimates of heritability of anxiety disorders vary from study to study, but twin studies suggest between 20 and 40% heritability (Hettema et al., 2001; Hettema, Prescott, Myers, Neale, & Kendler, 2005). A meta-analysis by Hettema and colleagues (2001) found similar heritability across most mood disorders. Furthermore, there is no evidence that one anxiety disorder has a stronger genetic basis than another (Walter et al., 2013).

Attachment and Anxiety Disorders: Theoretical Links

Bowlby (1973) proposed that all forms of anxiety disorders (with the exception of specific animal phobias) are best accounted for by early anxiety regarding the availability of the attachment figure. Several types of family environments were specified as most likely to create a real or perceived threat of parental loss. Included among these are family environments in which a child worries about a parent's survival in the child's absence or about being rejected or abandoned, when the child feels the need to remain home as a companion to a parent, and environments in which a parent has difficulty letting the child go because of overwhelming feelings that harm will come to the child.

Infant Attachment and Later Anxiety Disorders

The Minnesota Study of Risk and Adaptation from Birth to Adulthood (Bosquet & Egeland, 2006; Warren, Huston, Egeland, & Sroufe, 1997) examined the association between attachment in infancy and later anxiety disorders. Anxiety disorders were diagnosed when children were 17½. Infants with resistant attachments were significantly more likely than infants with secure or avoidant attachments to be diagnosed with anxiety disorders as adolescents. Warren and colleagues also assessed whether this relation between resistant attachment and anxiety disorders was attributable to temperamental differences, as indicated by neonatal nurse ratings of reactivity (Terreira, 1960) as

well as the Neonatal Behavioral Assessment Scale (Brazelton, 1973). Even when researchers controlled for differences in temperament, resistant attachments emerged as significant predictors of later anxiety disorders.

In another longitudinal sample of low-risk children, infant attachment security was also found to be associated with anxiety symptoms at age 11. Bar-Haim, Dan, Eshel, and Sagi-Schwartz (2007) found that resistant attachment in particular predicted elevated levels of social phobia, as reported by parents and children, especially for boys. They noted, however, that the symptoms did not reach clinical significance.

Children's Attachment-Related Experiences and Later Anxiety Disorder

Consistent with Bowlby's position, problematic family environments have been linked with anxiety disorders. Brown and Harris (1993) found an increased incidence of early loss of a caregiver and extremely inadequate caregiving in the histories of those with panic disorder compared to those without a psychiatric diagnosis. Faravelli, Webb, Ambonetti, Fonnesu, and Sessarego (1985) found agoraphobia to be associated with a higher incidence of early separation from mothers or parental divorce. In a larger meta-analysis, de Ruiter and Van IJzendoorn (1992) examined the association between early childhood separation anxiety and later agoraphobia. They found that adults with agoraphobia reported more childhood separation anxiety than controls, but were not more likely to suffer from separation anxiety disorder as children. Adults with agoraphobia were also more likely to rate their parents as low on affection and high on overprotection than controls. de Ruiter and Van IJzendoorn argued that this provided indirect support of Bowlby's hypothesized association between ambivalent (resistant) infant attachment and later agoraphobia.

Anxiety disorders in adulthood are also linked with retrospective accounts of negative views of caregiving experiences. Cassidy (1995) examined the cognitive processing characteristics of those with GAD and found they reported more rejection by their parents and role reversal than people without GAD. Similarly, Chambless, Gillis, Tran, and Steketee (1996) found that most people with anxiety disorders described their parents as unloving and controlling. Specific anxiety disorder diagnosis (OCD vs. panic disorder with

agoraphobia) was not differentially associated with parental care (Chambless et al., 1996).

Bandelow and colleagues (2002) compared histories of patients with panic disorder ($n = 115$) and normal controls ($n = 124$). Based on retrospective report, the patients with panic disorder had experienced significantly more traumatic early life events, including parental death and separation, than adults without panic disorder. Such individuals also reported more parental restriction and less love than controls. In a study of adults with social anxiety disorder (social phobia), Bandelow and colleagues (2004) obtained similar results and concluded that, beyond a family history of mental illness, separation experiences in childhood were among the most important contributing factors to adult social anxiety. In these retrospective studies, it is not possible to disentangle the potential biasing effect of concurrent anxiety on recollection of caregiving experiences.

Attachment States of Mind and Anxiety Disorders

In line with findings that resistant infant attachment is predictive of later anxiety symptoms, preoccupied states of mind have been found to be overrepresented in adults with anxiety disorders. Of adolescents with clinically elevated scores on the Anxiety scale of the Millon Multiaxial Personality Inventory (Millon, 1983), 65% had preoccupied states of mind (Rosenstein & Horowitz, 1996). Similarly, Fonagy and colleagues (1996) found that most adults with anxiety disorders were classified as preoccupied in the three-category system. Cassidy (1995) found that, contrasted with people without symptoms of GAD, those with GAD reported greater anger and vulnerability on the Perceptions of Adult Attachment Questionnaire (PAAQ; Lichtenstein & Cassidy, 1991). Feelings of anger and vulnerability are consistent with preoccupied states of mind.

In a few studies, unresolved loss and trauma has been overrepresented in those with anxiety disorders. In a small sample ($n = 18$) of women diagnosed with a variety of anxiety disorders including panic, OCD, and GAD, Manassis, Bradley, Goldberg, Hood, and Swinson (1994) found that all were classified as nonautonomous, with 78% rated as unresolved. Because of the small sample size, it was not possible to analyze relations between specific anxiety disorders and attachment state of mind. Fonagy and colleagues (1996) found

that 86% of the sample of adults with mixed anxiety disorders was classified as unresolved. Brumarui, Obsuth, and Lyons-Ruth (2013) examined 109 adolescents with various DSM-IV Axis I disorders. Comparing those with anxiety disorders (including panic, phobias, PTSD, GAD, and OCD) to those without anxiety disorders (but diagnosed with other DSM IV Axis I disorders), adolescents were rated on a scale of incoherence from 1 to 3 based on AAI classifications. Those with anxiety disorders showed higher levels of overall disorganization or incoherence compared to adolescents without anxiety disorders.

Moving beyond studies that cut across the anxiety disorders, there is some support for the idea that specific anxiety disorders involving primarily avoidance of fear are most often associated with dismissing states of mind. Zeijlmans van Emichoven, Van IJzendoorn, de Ruitter, and Brosschot (2003) examined attachment state of mind among 28 adults with anxiety disorders and 56 adult outpatients without such disorders. In the sample of outpatients, 39% were classified as dismissing, 29% as autonomous, 21% as preoccupied, and 11% as unresolved. Most (86%) of the adults with anxiety disorders were diagnosed with panic disorder and agoraphobia, supporting our contention that anxiety disorders involving mainly avoidance may be best characterized by dismissing states of mind. In a sample comparing adolescents without diagnosed disorders to adolescents with OCD and another group with depression, 80% of those with OCD were classified as dismissing compared to 64% of those with depression.

PTSD is diagnosed in those individuals who exhibit a number of intrusive, avoidant, and hypervigilant symptoms when confronted with either internal or external reminders of traumatic events. Its phenomenological similarity to unresolved trauma and loss, as measured in the AAI, has been noted by several researchers (Fearon & Mansell, 2001; Harari et al., 2009; Nye et al., 2008; Stovall-McClough & Cloitre, 2006). Growing support for the association between PTSD and unresolved loss/trauma supports this idea; however, we have identified only two studies that have examined PTSD and unresolved state of mind regarding the same traumatic event. Stovall-McClough and Cloitre (2006) examined attachment in a sample of 60 women with histories of childhood abuse, 30 of whom were diagnosed with PTSD related to child abuse. Sixty-three percent of those with PTSD were classified as unresolved regarding childhood trauma, compared to 27% of those

without PTSD. Moreover, unresolved trauma on the AAI was associated specifically with PTSD avoidance symptoms, and not with reexperiencing or hypervigilant symptoms. Among Dutch veterans, Harari and colleagues (2009) found that 87% of the veterans with PTSD were unresolved with regard to combat trauma. Additionally, severity of the DSM-IV PTSD symptoms strongly correlated with lack of resolution scores derived from the AAI.

Dissociative Disorders

Dissociative disorders, as the name suggests, are characterized by a dissociation of consciousness and even parts of the self that are usually integrated. Minor dissociative states are commonplace—for example, becoming so absorbed in a conversation while driving as to be unaware of the passing landscape. The dissociative disorders specified in DSM-5 (American Psychiatric Association, 2013) involve dissociation of one's identity (dissociative identity disorder and dissociative fugue), memory (dissociative amnesia), and consciousness (depersonalization/derealization disorder). Transient experiences of depersonalization are seen in about 40% of hospitalized patients (American Psychiatric Association, 2000) and appear to be experienced at some point by many people without elevated clinical symptoms as well. The more serious dissociative disorders have been diagnosed relatively rarely until recently, when there has been a sharp rise in such diagnoses (Johnson, Cohen, Kasen, & Brook, 2006). Waller and Ross (1997) found no evidence for genetic influences in dissociative disorders, but more recent studies suggest a potential link between genetic polymorphisms within the gene *SCN9A* (a gene associated with pain threshold) and dissociative symptoms (Savitz et al., 2008; Tadic et al., 2009).

Attachment and Dissociation: Theoretical Links

Dissociation involves turning away, presumably not volitionally, from some aspect of the environment. Dissociation in the face of trauma clearly has an adaptive function, in that it allows a person to avoid being overwhelmed with the experience. Evolution has predisposed infants and children to experience dissociative states readily when threatened. The cost of experiencing dissociative states

frequently as a child, however, is a sensitized and compromised neurobiology (De Bellis, 2001). This is especially true because children pass through critical periods for the organization of brain systems. Once sensitization has occurred, less is required to evoke dissociative states (De Bellis, 2001). Thus, a child who repeatedly enters dissociative states will more readily enter such states under conditions of mild stress.

When a traumatic event (e.g., a natural disaster, loss, or abuse) is experienced, but the caregiver can provide sensitive care and a sense of protection, the child is not in a position of experiencing “fright without solution” (Main & Hesse, 1990). In these cases, a child can continue to rely on a caregiver for protection. If, however, the caregiver cannot protect the child under conditions that the child experiences as threatening, or if the parent is actually the source of the threat, the child may experience the threat as overwhelming and enter a dissociative state (Main & Morgan, 1996).

Such dissociative states can be seen among some infants in the Strange Situation who are classified as disorganized (see Lyons-Ruth & Jacobvitz, Chapter 29, this volume; Main & Morgan, 1996). For most children, the Strange Situation is distressing, but an organized attachment system orchestrates behaviors with the caregiver. Some infants, however, experience a breakdown of attachment strategies. Abused infants, as well as infants of caregivers who are unresolved with respect to trauma or loss, are likely to show this breakdown in strategies (Carlson, Cicchetti, Barnett, & Braunwald, 1989; Main & Morgan, 1996). Main and Hesse (1990) proposed that frightened or frightening parental behavior leaves these children “frightened without solution.” According to Main and Hesse, as well as Liotti (2004), early experiences with a frightened or frightening caregiver cause a child to develop multiple, incompatible models of the self and the other. In interactions with the caregiver, the child experiences rapid shifts in which the caregiver is at first frightened, then no longer frightened, then caring for the child. With each shift, a different model of self (perpetrator of fright, rescuer, loved child) and of the caregiver (victim, rescued victim, competent caregiver) is operative. These multiple models of the self and other cannot be integrated by young children and are retained as multiple models (Liotti, 2004; Main & Hesse, 1990). These children have an unsolvable dilemma when distressed: They are neither able to go to their caregivers for nurturance nor able to turn away and

distract themselves. Because they experience this continued threat without resolution, they are at risk for entering a minor dissociative state during the Strange Situation and under other threatening conditions.

Liotti (2004) pointed out that disorganized attachment behaviors are phenotypically similar to dissociative states in adulthood, suggesting a possible connection between early trance-like states and later dissociative disorders. Given evidence that the experience of dissociative states in childhood leads to a sensitized neurobiology that predisposes individuals to experiencing later dissociative states, disorganized attachment in infancy and childhood experiences of abuse without caregiver protection may predispose individuals to dissociative states in adulthood (Carlson, 1998).

Infant Attachment and Dissociation in Adulthood

Carlson (1998) and Ogawa, Sroufe, Weinfield, Carlson, and Egeland (1997) examined the association between disorganized attachment in infancy and dissociative symptoms during childhood and adolescence in the Minnesota longitudinal study. Of the original sample, 35% of the infants were classified as disorganized/disoriented at 12 months, and 43% were classified as disorganized at 18 months. Infant disorganization was associated with higher teacher ratings of dissociative symptoms both in elementary and high school, and in adulthood (Carlson, 1998). Furthermore, disorganized/disoriented behavior in the Strange Situation predicted the self-report of more dissociative symptomatology at age 19 (Carlson, 1998) and into adulthood (Sroufe, Egeland, Carlson, & Collins, 2005a). Thus, two sets of raters converged in pointing to symptoms of dissociation for adolescents who were assessed as disorganized/disoriented in infancy, and the relations persisted over time. Ogawa and colleagues (1997) found that, combined with indices of maternal emotional availability, disorganized attachment accounted for 34% of the variance in later dissociative symptoms. In addition, no associations emerged between disorganized/disoriented attachment and any of the variables assessing endogenous vulnerability, such as prenatal difficulties, difficulties during childbirth, or maternal drug and alcohol use (Carlson, 1998; Ogawa et al., 1997).

Dutra and Lyons-Ruth (2005) obtained similar findings in their longitudinal study. Fifty-

six late adolescents who had participated in the Strange Situation as infants were administered the Dissociative Experiences Scale. Measures of parent–infant affective communication, quality of care, parental psychopathology, and maltreatment history were also administered at several time periods. The strongest predictors of adolescent dissociative symptoms were disorganization of attachment during infancy, disrupted affective communication with the mother, and maternal neglect.

Children's Attachment-Related Experiences and Later Dissociative Disorders

As noted earlier, Main and Hesse (1990) proposed that disorganized or disoriented behavior in the Strange Situation results from the caregiver behaving in a frightened or frightening manner toward the child. This caregiver, who is often unresolved with respect to attachment, is unable to protect the child adequately from later threats, or may even perpetrate threats. Thus, it seems that a child who is disorganized in infancy may be at increased risk for later abuse because of the caregiver's qualities. Children who have formed disorganized attachments to caregivers in infancy and are later repeatedly abused may be particularly susceptible to later dissociative disorders (Liotti, 2004). In fact, the incidence of abuse among people with dissociative disorders is extremely high, with figures as high as 97% reported in some studies (e.g., Putnam, 1991).

Main and Hesse (1990) proposed an intergenerational model of the transmission of dissociative symptoms. They suggested that unresolved loss and trauma are the underlying causes of parents behaving in frightening or frightened ways with their children. Indirect support for this idea is suggested by the finding that unresolved loss on the AAI is associated with levels of absorption as measured by Tellegen's Absorption Scale (Hesse & Van IJzendoorn, 1998). Losses require some time to resolve, according to Main and colleagues (2003). Very recent losses are not considered in the scoring of unresolved status in Main and colleagues' system because lack of resolution in such cases is normative. Even recent losses can have disorganizing effects on parental behavior, however. Therefore, it follows that a parent's experience of the death of someone close may make disorganized attachment and even later dissociative states

in a child more likely. Indeed, Liotti (2004) found that 62% of adults diagnosed with dissociative disorders had mothers who had lost a close relative within 2 years of their children's birth. In a follow-up study, Pasquini, Liotti, Mazzotti, Fassone, and Picardi (2002) compared a sample of patients with dissociative disorders to clinical controls. Patients whose mothers had suffered a loss or other traumatic life event within 2 years of the patients' births had an increased risk of 2.6 for a dissociative disorder diagnosis.

Attachment States of Mind and Dissociative Disorders

Several studies have examined unresolved attachment status and the presence of dissociative symptoms in patients and other high-risk samples. West, Adam, Spreng, and Rose (2001) found that adolescent inpatients with higher dissociation scores were classified as unresolved or cannot classify in the AAI more often than were adolescent inpatients with lower dissociation scores. In a study by Riggs and colleagues (2007), psychiatric inpatients with unresolved trauma showed more dissociative symptomatology than inpatients without unresolved trauma. And finally, in a sample of pregnant adolescents, Madigan, Vaillancourt, McKibbin, and Benoit (2012) found higher self-reported dissociative symptoms in adolescents with an unresolved attachment classification than in those without an unresolved classification.

Although, to our knowledge, there are no published studies documenting the distribution of attachment classifications among adults with dissociative disorders per se (rather than dissociative symptoms more generally), Steele (2003) reported that the AAI was routinely administered to patients at the Clinic for Dissociative Studies in London. When it was administered to people diagnosed with dissociative identity disorder, the transcripts were characterized by multiple organizational strategies. More specifically, separate identifiable personalities appear to be linked with their own personal histories and strategies for managing the affect and content elicited by AAI questions. Thomson and Jaque (2012) examined the association between unresolved trauma and loss and dissociation in a sample of artists. Among artists who reported pathological levels of dissociation as seen in dissociative disorders (e.g., dissociative amnesia and depersonalization/derealization), 53% were classified as unresolved on the AAI.

Eating Disorders

Eating disorders include anorexia nervosa and bulimia nervosa. *Anorexia nervosa* is characterized by maintaining a body weight that is dangerously low, accompanied by distorted body image and fears of becoming fat. *Bulimia nervosa* is characterized by binge eating, accompanied by behaviors intended to compensate for the bingeing, such as purging and taking laxatives. Typically these disorders emerge in adolescence, particularly at stressful times, such as college entry. The vast majority (90%) of those diagnosed with eating disorders are women (American Psychiatric Association, 2000). Many women with eating disorders are also depressed, with rates of reported comorbidity as high as 75% (Mitchell & Pyle, 1985).

Attachment and Eating Disorders: Theoretical Links

Bowlby (1973) suggested that a child feels inadequate and out of control if given the message that he or she will have difficulty functioning independently or is unlovable. As discussed previously, children who receive such messages may feel their own anxiety exquisitely—developing GAD or agoraphobia, for example. If these children have developed an avoidant strategy of turning their attention away from their own distress, however, they may be at increased risk for developing externalizing symptoms. Cole-Detke and Kobak (1996) suggested that young women who develop eating disorders might be attempting to control their world through eating behavior that directs attention away from their own feelings of distress.

Children's Attachment-Related Experiences and Later Eating Disorders

Much of the evidence linking early attachment-related experiences to eating disorders relies on retrospective accounts of parenting availability. The findings that emerge are complicated but relatively consistent. First, women with anorexia nervosa typically describe both of their parents negatively (e.g., Palmer, Openheimer, & Marshall, 1988; Ratti, Humphrey, & Lyons, 1996; Rowa, Kerig, & Geller, 2001; Vidovic, Juresa, Begovac, Mahnik, & Tociljkj, 2005; Wade, Treloar, & Martin, 2001; Wallin & Hansson, 1999; Woodside et al., 2002).

Second, fathers are often described as emotionally unavailable and rejecting (Cole-Detke & Kobak, 1996; Rhodes & Kroger, 1992). Third, mothers are described as domineering, overprotective, and perfectionistic (Minuchin, Rosman, & Baker, 1980; Woodside et al., 2002). Finally, parents appear to act in ways that thwart efforts at independence (Ratti et al., 1996). Kenny and Hart (1992) found that women with eating disorders described their parents as generally unsupportive of their independence.

Thus, a picture generally emerges of an overcontrolling, perfectionistic mother who communicates lack of support for her daughter's autonomy striving; an emotionally rejecting father; and a daughter who feels rejected, controlled, and inadequate. Although sexual abuse has been suggested as a causal factor for eating disorders, the preponderance of evidence suggests that such abuse is not strongly related to the development of either anorexia nervosa or bulimia nervosa (e.g., Carter, Bewell, Blackmore, & Woodside, 2006; Pope, Mangweth, Negrao, Hudson, & Cordas, 1994; Welch & Fairburn, 1994).

Attachment States of Mind and Eating Disorders

Several studies have examined the association between AAI states of mind and eating disorders, with somewhat contradictory results. As reviewed previously, Cole-Detke and Kobak (1996) used the self-reports of a sample of college women for the assessment of eating disorders. The methodology yielded information about preoccupied, dismissing, and autonomous states of mind, but not about the unresolved or cannot classify categories. The breakdown of states of mind differed significantly for women reporting eating disorders, depression, a combination of the two, or neither. Women who reported eating disorders only were most frequently classified as dismissing. Women who reported a combination of eating disorders and depression were most frequently classified as preoccupied (similar to women who reported only depression). Similarly, Ward and colleagues (2001) found that the overwhelming majority (95%) of patients were classified as nonautonomous on the AAI, and that 79% were classified as dismissing. Barone and Guiducci (2009) found an overrepresentation of nonautonomous attachment states of mind (90%) among adults with eating disorders compared with adults without eating disorders. More specifically,

dismissing states of mind appeared to characterize those with eating disorders (47% for the eating disorders group vs. 20% for the comparison group). Unresolved states of mind also differentiated those with eating disorders, 27% of whom were classified as unresolved, compared to only 7% of the comparison group.

In contrast, Fonagy and colleagues (1996) found that 64% of people with eating disorders were classified as preoccupied. When the four-category system was used, 13 of the 14 individuals with eating disorders were classified as unresolved with respect to loss or trauma. Those with eating disorders did not differ significantly from those with other psychiatric disorders in the breakdown of state-of-mind classifications. In the Cole-Detke and Kobak (1996) study, over half (61%) of the women reporting eating disorders also reported depression, and were therefore not included in the "pure" eating disorder group. If a similar proportion of people in Fonagy and colleagues' study were comorbid for depression, the majority of the remaining "pure" eating disorder group might have been classified as dismissing, thus matching Cole-Detke and Kobak's results.

Consistent with the patterns of family interaction described earlier, Cole-Detke and Kobak (1996) and Ward and colleagues (2001) have argued that women with eating disorders are attempting to control their worlds through their eating behavior, and that the type of control exerted is externally oriented. This type of control is chosen because women with eating disorders do not have the ability to examine their own psychological states, and they cope instead by diverting their distress to focus on their own bodies. Cole-Detke and Kobak have therefore proposed that eating disorders allow the diversion of attention away from attachment-related concerns, and toward the more external and more "attainable" goal of body change.

Further differentiation between eating disorders may also be useful in considering the role of attachment states of mind. Primarily restrictive behavior, as seen in anorexia, may be associated with dismissing states of mind, whereas eating disorders characterized by primarily bingeing and purging may be associated with preoccupied states of mind. Dias, Soares, Klein, Cunha, and Roisman (2011) provide preliminary support for this hypothesis. In a sample of eating disordered patients, AAIs were rated using Kobak's continuous Q-sorting method (Kobak, 1993). The large majority of the clinical sample was classified as

nonautonomous (70%), with hyperactivation of attachment differentiating the purging patients from the restrictive patients.

Schizophrenia

The various types of schizophrenia are the disorders often associated with the greatest level of dysfunction. They are characterized most especially by *psychosis* (i.e., loss of touch with reality), as manifested often in delusions or hallucinations. The schizophrenias have high heritability (e.g., Thompson, Watson, Steinhauer, Goldstein, & Pogue-Geile, 2005). For example, the concordance for monozygotic twins is usually estimated at about 50%, as opposed to 15% for dizygotic twins (Gottesman, 1991). Even in adoption studies, when the influence of the environmental effects associated with biological parents is minimized, the influence of biological parents appears more predictive of the development of schizophrenia than the influence of adoptive parents (Gottesman, 1991). The mechanism for the transmission has not been clearly specified as a single-gene or single-chromosome locus. Many researchers are now exploring what seems the more likely explanation that multiple genes are involved, and that the involvement of specific genes will be variable across the schizophrenias (Baron, 2001; Gottesman, 1991).

Children's Attachment-Related Experiences and Later Schizophrenia

The family environment variable that has been most widely suggested as causal in the etiology of schizophrenia is "expressed emotion" (Goldstein, 1985). High levels of expressed emotion are characterized by familial overinvolvement and/or criticality. Communication deviance and expressed emotion assessed in the families of adolescents with mild to moderate clinical disturbances predicted schizophrenia and schizophrenia spectrum disorders (schizoid, schizotypal, and paranoid personality disorders) 15 years later (Goldstein, 1985). Even though these results suggest that parental behavior is important in the onset of schizophrenia, it is also plausible that the parents' behaviors reflected sensitivity to different premorbid behaviors of their children who later developed schizophrenia. For example, Walker,

Grimes, Davis, and Smith (1993) found that in home videotapes taken years before the onset of schizophrenia, the children who later developed schizophrenia could be reliably differentiated from their siblings who did not develop schizophrenia.

Attachment States of Mind and Schizophrenia

Only a handful of studies have examined the distribution of AAI classifications among individuals with schizophrenia or other psychoses. Dozier and colleagues have examined states of mind among individuals with schizophrenia (Dozier, Cue, & Barnett, 1994; Tyrrell, Dozier, Teague, & Fallot, 1999). Tyrrell and colleagues (1999) found that 89% of individuals with schizophrenia were classified as dismissing when unresolved status was not considered, but 44% were classified as unresolved when that category was included. (The insecure cannot classify category was not used in these studies.) MacBeth, Gumley, Schwannauer, and Fisher (2010) examined attachment states of mind in a sample of patients recovering from their first episode of psychosis. In this study, 26% of the patients were classified as autonomous and 62% were classified as dismissing (62%). The four-way classification breakdown revealed that 29% of the sample fell into the unresolved category.

We argue, however, that these results tell us little about factors predisposing individuals to schizophrenia. First, we suggest that findings of higher rates of unresolved status among people with schizophrenia should be interpreted with caution. Indeed, schizophrenia, characterized most especially by thought disorder, involves "lapses in monitoring of reasoning and discourse" (Main et al., 2003., p. 97)—the characteristics that define unresolved status. Thus, people with thought disorder may appear unresolved with respect to loss or abuse *because* of their thought disorder. Second, we suggest that the failure to find many autonomous transcripts among those with schizophrenia may reflect the deleterious effect of schizophrenia on the brain. The lack of coherence associated with formal thought disorder is inconsistent with a coherent transcript. Although we urge caution in thinking of states of mind as preceding psychopathology when measured concurrently, we suggest that differences in states of mind are important in how relationships are approached and how treatment is used. Indeed, in a review of studies examining attachment in those with psychotic disorders,

an autonomous state of mind was related to better service engagement and follow-through than was a nonautonomous state of mind (Gumley, Taylor, Schwannauer, & MacBeth, 2014).

Borderline Personality Disorder

People with borderline personality disorder have a notably unstable sense of self (American Psychiatric Association, 2000, 2013). Similarly, representations of others are undeveloped and unstable; that is, others are idealized at times and devalued at other times. A central issue is the fear of abandonment by an idealized other. Because the unstable sense of self is dependent on validation from the idealized other, the threat of abandonment is experienced as potentially devastating. This instability of internal representations is often associated with emotional volatility. In particular, strong feelings of anger and dysphoria can be readily precipitated by subtle suggestions of rejection. Thus, a number of contributing factors create conditions in which interpersonal relationships are likely to be intense and tumultuous. Such factors also point to probable attachment-relevant influences on the etiology of borderline personality disorder (Agrawal, Gunderson, Holmes, & Lyons-Ruth, 2004).

Although the prevalence of borderline personality disorder in the general population is about 6% (Torgersen, Kringle & Cramer, 2001), the prevalence among people receiving treatment is much greater—about 15% among outpatients and 50% among outpatients diagnosed with personality disorders (Widiger, 1993). Thus, people with borderline personality disorder are relatively more likely than others to seek treatment; this is not surprising given that “crying out for help” is characteristic of the disorder.

Among personality disorders, studies investigating heritability among twins have found rates as low as 30% when personality traits are measured with standardized interview methods (Kendler et al., 2008) and as high as 70–80% when using self-report methods (Coolidge, Thede, & Jang, 2001). The heritability of borderline personality disorder specifically is also found to vary across self-report and interview-based measures. Torgersen and colleagues (2012) suggest that when the two methods of assessment are both taken into account in the same study, error variance between methods is eliminated, producing a more accurate estimate. In a large twin study using both self-report and in-

terview-based measures, Torgersen and colleagues (2000) established a heritability rate of 67% for borderline personality disorder among twins, suggesting a significant genetic influence. A predisposition toward emotional sensitivity, poor emotion regulation, and both internalizing and externalizing behavioral tendencies are likely the underlying traits (e.g., Crowell, Beauchaine, & Linehan, 2009; Torgersen et al., 2000).

There is growing evidence to support the diathesis-stress model of borderline personality disorder with early environmental factors interacting with genetic influences to increase the risk for the disorder. To test this model directly, Belsky and colleagues (2012) examined the interactions among a number of environmental and family history characteristics in a longitudinal study of over 1,000 pairs of same-sex twins followed from birth until age 12. The twin study estimated the heritability of borderline traits at age 12 to be about 66%, consistent with Torgersen and colleagues (2012). As predicted, both environmental adversity (harsh early parenting and maternal negative expressed emotion) and inherited risk (a family history of psychiatric illness) independently predicted borderline personality traits at age 12. The diathesis–stress model was also supported. Children with harsh early experiences were more likely to show borderline traits at age 12 if they also had a family history of psychiatric illness than were those children with harsh early experiences without a family psychiatric history. The authors concluded that both “acted as a more virulent risk factor in the presence of the other” (Belsky et al., 2012, p. 261).

Attachment and Borderline Personality Disorder: Theoretical Links

Main and Hesse (1990) have suggested that the experience of trauma in the absence of a supportive caregiver predisposes individuals to develop either borderline or dissociative pathology. As described previously, Main and Hesse have proposed that a child cannot integrate the various qualities of a caregiver into single models of self and other when the caregiver behaves in a frightened or frightening way; thus, unintegrated models are maintained. This formulation is consistent with the organizational model of the developing self and borderline personality disorder suggested by Carlson and colleagues (2009). Early traumatic experiences overwhelm children’s ability to regu-

late emotions and organize internal models of self and other, leading eventually to a breakdown in these capacities.

Borderline pathology is generally associated with exaggeration of symptomatology and negative affect, as well as a “preoccupation” with concerns about current and previous relationship difficulties. The readiness to report distress is consistent with maximizing the expression of attachment needs, seen in infants with resistant attachment and in adults who are preoccupied with respect to attachment. Internalized models of caregivers as incompetent or inconsistently available, and of the self as inconsistently valued, seem as central to a diagnosis of borderline personality disorder as to a classification of preoccupied attachment (Agrawal et al., 2004).

Children’s Attachment-Related Experiences and Later Borderline Personality Disorder

The evidence for problematic family conditions in the development of borderline personality disorder is compelling. Early abuse in particular is often seen in the histories of people diagnosed with borderline personality disorder (Brown & Anderson, 1991; Carlson et al., 2009; Herman, Perry, & van der Kolk, 1989; Ogata et al., 1990). Sanders and Giolas (1991) found evidence of higher rates of documented abuse histories in the hospital records of patients with this disorder than in the histories of other patients. Thus, these results do not appear to reflect a reporting bias only. In addition, people with borderline personality disorder report high rates of prolonged separations from caregivers during their childhoods (Zanarini, Gunderson, Marino, Schwartz, & Frankenburg, 1989), especially from their mothers (Soloff & Millward, 1983). They also report emotional neglect when their caregivers were physically present (Patrick et al., 1994; Zanarini et al., 1989). Liotti and Pasquini (2000) found a 2.5-fold increase in the risk for borderline personality disorder for individuals whose mothers had suffered a loss within 2 years of their birth, and a 5.3-fold increase for those with early maltreatment.

Since the previous *Handbook* was published, there is growing evidence pointing to a multiterminated model of borderline personality disorder that takes into account both genetic or endogenous characteristics and early environmental factors (including caregiving experiences) (Belsky et al., 2012; Carlson et al., 2009). With regard to

infant attachment and its relationship with adult borderline personality disorder, the findings are mixed. To our knowledge, only two longitudinal studies have examined the association between infant attachment quality and later borderline symptoms. Lyons-Ruth, Yellin, Melnick, and Atwood (2005) reported on the development of borderline personality disorder features in a group of 56 high-risk infants in early adulthood. Early attachment status, including attachment disorganization, did not predict later borderline personality disorder symptoms, as measured by a psychiatric interview. Rather, early maltreatment and disrupted parent–infant communication were associated with a greater likelihood of developing borderline symptoms. In a study exploring the etiology of borderline personality disorder from a developmental psychopathology perspective, Carlson and colleagues (2009) examined the influence of early environmental variables, including infant attachment and early “endogenous” variables such as medical issues and representations of the self measured in middle childhood and early adolescence. Although infant disorganization, maternal hostility, abuse, family disruptions, and maternal stress predicted adulthood borderline personality disorder symptoms, only maternal hostility at age 3 continued to predict borderline symptoms after researchers controlled for the early endogenous variables. The influence of disorganized attachment on risk for borderline personality disorder was mediated by disturbances in self-representations measured at 12 years.

Attachment States of Mind and Borderline Personality Disorder

A number of researchers have reported on the association between attachment state of mind, as measured by the AAI, and the incidence of diagnosed borderline personality disorder in clinical samples (Barone, 2003; Barone, Fossati, & Guiducci, 2011; Diamond, Stovall-McClough, Clarkin, & Levy, 2003; Fonagy et al., 1996; Patrick et al., 1994; Rosenstein & Horowitz, 1996; Stalker & Davies, 1995; Stovall-McClough & Cloitre, 2003). Using the three-way classification system, Fonagy and colleagues (1996) found that 75% of people with borderline personality disorder had preoccupied states of mind, and that half of those with preoccupied states of mind fell into the rarely used subgroup “fearfully preoccupied with respect to trauma” (E3). In Patrick and colleagues’ (1994) study, all women with borderline personality disorder were classified as preoccupied, and 10 of the

12 were classified as E3. When the four-way classification system was used, 89 and 75% of people with borderline personality disorder were classified as unresolved in the Fonagy and colleagues and Patrick and colleagues studies, respectively. In a study of inpatient adolescents, Rosenstein and Horowitz (1996) found that the majority of those diagnosed with borderline personality disorder (64%) were also classified as preoccupied on the AAI. This study did not include the unresolved category. Barone (2003) examined attachment status in a sample of 80 subjects, 40 of whom were diagnosed with borderline personality disorder and 40 of whom were nonclinical controls. Using the four-way attachment classification system, he identified only 7% of those with borderline personality disorder as autonomous, whereas 23% were preoccupied, 20% were dismissing, and 50% were unresolved. This distribution was significantly different than that found in the control group, where 62% were identified as autonomous, 10% as preoccupied, and only 7% as unresolved.

Recent reviews suggest that, indeed, preoccupied and unresolved attachment states of mind appear to be the most commonly identified attachment classification in those with borderline personality disorder (Bakermans-Kranenburg & Van IJzendoorn, 2009; Barone et al., 2011). Looking more closely at subgroups within borderline personality disorder, Barone and colleagues (2011) divided a large sample of therapy-seeking participants who were diagnosed with borderline personality disorder into four subgroups based on their DSM-IV Axis I diagnoses: (1) mood disorders, (2) drug use/abuse disorders, (3) alcohol use/abuse disorders, and (4) eating disorders. Three-way analyses revealed that preoccupied states of mind distinguished those with mood disorders (52%) from the other three groups, whereas dismissing states of mind best characterized those with drug (57%) and alcohol use disorders (55%) as well as eating disorders (60%). Unresolved states of mind did not differentiate the four groups but was found in 28% of the sample.

Antisocial Personality Disorder

Antisocial personality disorder is characterized by a consistent disregard for the rights and feelings of others and for the basic laws of society (American Psychiatric Association, 2000, 2013). Characteristics of antisocial personality disorder include deceitfulness, impulsivity, irresponsibility, irritability,

and lack of remorse. The links between childhood and adolescent conduct disorder and later adult antisocial personality disorder have been noted in numerous studies (e.g., Blair, Peschardt, Budhani, Mitchell, & Pine, 2006). Indeed, one of the criteria for antisocial personality disorder is the presence of earlier conduct disorder.

Attachment and Antisocial Personality Disorder: Theoretical Links

Bowlby (1973) proposed that when children experience separations from parents, and when parents threaten abandonment, children feel intense anger. Ordinary but stressful separations are often met with anger, which is functional in communicating to the parents the children's feelings about the separation. When prolonged separations are combined with frightening threats, however, Bowlby suggested that children are likely to feel a dysfunctional level of anger toward parents, often involving intense hatred. Initially, the anger may be directed toward the parents. Because that may prove dangerous in maintaining the relationship with the parents, however, the anger is often repressed and directed toward other targets (Bowlby, 1973).

Children's Attachment-Related Experiences and Later Antisocial Personality Disorder

Prolonged separations from primary caregivers (as the result of divorce or separation rather than death), fathers' antisocial or deviant behavior, and mothers' unaffectionate, neglectful care are associated with antisocial personality disorder (McCord, 1979; Robins, 1966). Robins found that parental desertion, divorce, or separation was associated with the diagnosis of antisocial personality disorder. Zanarini and colleagues (1989) found that 89% of people with antisocial personality disorder had experienced prolonged separations from a caregiver at some point in childhood. Given that loss by death was not associated with later antisocial personality disorder, however, it does not seem to be simply the absence of a caregiver that is important (Robins, 1966). In a prospective longitudinal study, McCord (1979) found that antisocial personality disorder is a likely outcome only when mothers are also unaffectionate and do not provide adequate supervision, and when fathers are deviant.

Attachment States of Mind and Antisocial Personality Disorder

Most of the empirical evidence suggests that antisocial personality disorder is associated with unresolved and dismissing states of mind (Allen et al., 1996; Frodi, Dernevik, Sepa, Philipson, & Bragleslo, 2001; Levinson & Fonagy, 2004; Rosenstein & Horowitz, 1996). Allen and colleagues (1996) assessed states of mind in adolescent psychiatric inpatients and a control group of high school students. Criminality and use of “hard drugs” were then assessed approximately 10 years later. The most impressive finding was that ratings from the adolescents’ attachment interviews predicted criminality 10 years later, even after researchers accounted for previous psychiatric hospitalization. In particular, derogation of attachment and lack of resolution of trauma predicted criminal behavior. In *derogation of attachment*, a rarely occurring feature of dismissing attachment, the person derogates attachment figures or attachment experiences. Among the sample of psychiatric inpatients in the Allen and colleagues study, 15% of the interviews were categorized as cannot classify because they met criteria for multiple, incompatible categories. This group of people reported the most criminal behavior, followed by people classified as dismissing and unresolved. Post hoc analyses revealed that the cannot-classify (termed *unclassifiable* at that time) group showed higher levels of criminal behavior than the autonomous and preoccupied groups, and that the dismissing group showed significantly higher levels than the autonomous group. Similarly, Hesse and colleagues (2011) examined the incidence of cannot classify and secondary dismissing (Ds2) classifications in a small sample of male prisoners ($n = 19$). Eleven of the men were classified as psychopaths based on the Psychopathy Checklist—Revised (PCL-R; Hare, Hart, & Harpur, 1991). All were classified as cannot classify regardless of the nature of their offense, but derogation of attachment did not appear to distinguish the psychopathic prisoners from those who were not classified as psychopaths. A secondary analysis, however, found that those incarcerated for crimes involving murder or violent bodily harm ($n = 9$) were more likely to fall in the rare Ds2 subcategory than were the men incarcerated for other offenses.

Rosenstein and Horowitz (1996) found that among adolescents with conduct disorder only, six of seven were classified as dismissing, and none was classified as unresolved. Among adolescents

with comorbid conduct disorder and mood disorder, half were classified as dismissing, and nearly half were classified as unresolved with respect to loss or trauma. Fonagy and colleagues (1996) obtained very different results for a combined group of people with antisocial and paranoid personality disorders, however. When the three-category system was used, more were classified as preoccupied and autonomous than as dismissing. When the four-category system was used, most were classified as unresolved.

Findings have been relatively consistent when researchers have considered violence rather than antisocial personality disorder. In a study examining the association between attachment status and propensity toward domestic violence, Holtzworth-Munroe and colleagues (1997) administered the AAI to maritally distressed violent men ($n = 30$) and nonviolent men ($n = 30$). Men with histories of domestic violence were more likely than nonviolent men to be classified as nonautonomous, and 37% were rated as cannot classify. Babcock, Jacobson, Gottman, and Yerington (2000) conducted a study with a group of maritally distressed men with a history of domestic violence ($n = 23$) and those without such a history ($n = 13$). Similar to Holtzworth-Munroe and colleagues’ (1997) findings, domestically violent men were more likely to be rated as nonautonomous. Moreover, the dismissing category was associated with higher scores on an antisocial scale than were other categories. Only 9% of the domestically violent men could not be classified on the AAI—a lower rate than that reported by Holtzworth-Munroe and colleagues, but higher than that seen in the general population.

Summary: Current State of Theory and Research

Attachment in Infancy: Links to Adult Psychopathology

Since we last visited these issues, it remains the case that the only clear connections between infant attachment and adult psychopathology are between disorganized attachment and dissociative symptoms in adolescence and early adulthood (Carlson, 1998; Sroufe et al., 2005a) and between resistant attachment and anxiety disorders in adolescence (Warren et al., 1997). These associations are compelling for a number of reasons. First, the “phenotypic similarity” of the phenomena is strik-

ing when one considers the link between disorganized attachment and dissociative symptoms (Liotto, 2004; Main & Morgan, 1996) and between resistant attachment and anxiety (Cassidy, 1995). Second, the caregiving experiences predictive of disorganized and resistant attachment are similar to the caregiving experiences predictive of dissociative symptoms and anxiety symptoms, respectively. More specifically, the occurrence of attachment-related trauma, especially abuse, is known to be associated with both disorganized attachment (Carlson et al., 1989) and dissociative disorders (e.g., Putnam, 1991). This connection between abuse and later dissociation may be accounted for partially by the development of a sensitized neurobiology when a child experiences frightening events from which escape is not possible. Similarly, unavailable or inconsistently available caregiving appears predictive of both resistant attachment and symptoms of anxiety (Cassidy, 1995). Carlson (1998) has suggested that a child who frequently becomes hyperaroused (rather than disorganized) when threatened with an unavailable caregiver develops a sensitized neurobiology that predisposes him or her to later anxiety.

Finally, the categories of adult attachment that parallel infant disorganized and resistant attachment are characterized by behaviors consistent with the predicted symptomatology (Sroufe et al., 2005a). Adults who are unresolved with respect to loss or trauma are characterized by a “lapse in reasoning or in the monitoring of discourse” when discussing loss or trauma (Main et al., 2003, p. 97). Similarly, the discourse of adults who are preoccupied with respect to attachment is affected by anxiety that may be either more diffuse (e.g., similar to the anxiety associated with GAD; Cassidy, 1995) or more focused (e.g., similar to the anxiety associated with a phobic disorder). Thus, the categories of adult attachment that parallel infant disorganized and resistant attachment are themselves characterized by some level of dissociation and anxiety, respectively.

Attachment States of Mind: State of the Field

Following the publication of this volume in 2008, a meta-analysis was conducted to examine the distribution of AAI classifications among both clinical and nonclinical groups (Bakermans-Kranenberg & Van IJzendoorn, 2009). Drawing from studies published over the past 25 years, over 10,000 AAIs were included in the study.

Two robust findings emerged with regard to attachment states of mind and adult psychopathology. First, psychiatric disorders are nearly always associated with nonautonomous states of mind and/or unresolved status (Bakermans-Kranenberg & Van IJzendoorn, 2009). Cutting across all clinical samples, 76% ($n = 1,956$) of the AAIs were classified as nonautonomous, compared to 42% of nonclinical samples. A large percentage (43%) of the AAIs in the clinical samples were classified as unresolved or cannot classify, whereas only 18% of the interviews from the nonclinical group fell into these categories. What these findings mean in terms of the causal connection between attachment state of mind and psychiatric disorders remains unclear. Only the Allen and colleagues (1996) study provided evidence that ratings of derogation and lack of resolution of abuse can predict problematic behaviors (in particular, criminal behavior and hard drug use) in a high-risk sample. Some of the longitudinal studies now being conducted with high-risk samples will address the association between states of mind and the emergence of different psychiatric disorders more comprehensively.

The second finding highlighted by Bakermans-Kranenberg and Van IJzendoorn's (2009) meta-analysis is the connection between dismissing-preoccupied states of mind and externalizing-internalizing disorders. Meta-analytic results supported connections we had proposed in previous versions of this volume; namely, that externalizing disorders such as conduct disorder and antisocial personality disorder are associated with dismissing states of mind, and disorders characterized by internalizing symptoms, such as borderline personality disorder, are associated with preoccupied states of mind. Further support for this distinction was provided by the meta-analysis, which included studies of violent behavior separated into those studies involving violence against the family, the self, and society. Violence against the family was associated with preoccupied states of mind, whereas violence against society (criminal behaviors) and violence against the self (e.g., drug abuse and eating disorders) were associated with dismissing states of mind.

There are exceptions to this rule, however. Individuals with anxiety and depression tend to show a mixed picture with regard to attachment. At least one study including antisocial personality disorder appears to show a preponderance of preoccupied states of mind, contrary to our hypothesis (Fonagy et al., 1996). Bakermans-Kranenberg

and Van IJzendoorn's (2009) meta-analysis, which included both adolescent and adult criminal samples, suggested that in addition to dismissing states of mind, preoccupied states of mind are also identified in externalizing/conduct disorder samples more often than autonomous states of mind. We suggest that the comorbidity of samples is critical to consider in such cases. Diversity of symptom pictures within a disorder may also contribute to inconsistent findings. For instance, both depression and anxiety are heterogeneous disorders, subsuming both those who are more self-focused (i.e., internalizing) and less self-focused (i.e., externalizing). Eating disorders, too, consist of both restricting symptoms requiring a tuning out of internal hunger/pain signals and purging behaviors resulting from an overreaction to internal feelings of satiation.

The Metaphor of the Branching Railway Lines: New Directions

The research we have examined in this chapter provides growing support for Bowlby's (1973) model of the "branching railway lines." In this model there are no circumstances, including the quality of early caregiving or the experiences of loss or abuse, that fully constrain development. Nonetheless, certain developmental pathways become more or less likely with experience because there develops within a child an organized system for coping with his or her experiences (Sroufe et al., 2005a). Ways in which early attachment experiences may place children at risk for later psychopathology, however, still need to be tested. Large longitudinal studies are best suited to assessing how early attachment experiences place children at risk for later psychopathology, but such studies are expensive in terms of both time, money, and other resources. Indeed, such studies span full careers, and in the best-case scenarios are even then handed on to the next generation of researchers. Several longitudinal studies have focused on attachment experiences early, following participants throughout life. An example is the Minnesota Longitudinal Project, begun when Alan Sroufe and Byron Egeland were junior faculty members at University of Minnesota's Institute of Child Development and still being conducted by a second generation of faculty at the Institute. The Minnesota Longitudinal Project is extraordinary, most especially for the care with which the investigators set out to examine salient tasks at each point

in development. But, surely, these are challenging studies to undertake that require an impressive research infrastructure, ongoing support for the research, and a long-term commitment on the part of the research team.

Efforts to integrate theory and research findings from multiple disciplines including developmental psychology, clinical psychology, and cognitive neuroscience are on the rise; such research is certainly needed to more fully develop our understanding of "psychopathology as an outcome of development" (Sroufe, 1997, p. 251). Neuroscience in particular is a promising area for exploring the brain mechanisms involved in problematic adaptations to parental behavior and understanding why some children suffer adverse consequences while others demonstrate apparent resilience. Researchers have begun to uncover possible mechanisms by which environmental stress such as parental maltreatment may affect gene expression leading to later psychiatric symptoms and disorders. Also, study of gene \times environment interactions have highlighted the potential role of the dopamine receptor gene (*DRD4*) and a particular allele (7-repeat allele) that appears to drive the dopaminergic networks of the brain. Children with the *DRD4* 7-repeat allele have been found to be particularly susceptible to both positive and negative parenting environments (Bakermans-Kranenburg, Van IJzendoorn, Caspers, & Philibert, 2011). The presence of these so called "risk genes" or "susceptibility genes" (Bakermans-Kranenburg et al., 2011) are involved in strong interaction effects enabling researchers to better understand why some children appear to be differentially vulnerable to their environments (see Bakermans-Kranenburg & Van IJzendoorn, Chapter 8, for further discussion of this topic). These represent examples of future research in the area.

Intervention studies will be important in the next generation of understanding the effects of attachment on later development. To the extent that attachment quality can be experimentally manipulated, claims of causal effects of caregiver availability and attachment quality on developmental outcomes can be made. In a number of randomized clinical trials, interventions targeting parental sensitivity have been shown to affect attachment quality (e.g., Bernard et al., 2012; Cicchetti, Rogosch, & Toth, 2006). If these experimental studies can be extended longitudinally, claims that early attachment affects later psychopathology can be made with greater confidence than has been allowed in the past.

Chapter 32

Prevention and Intervention Programs to Support Early Attachment Security

A Move to the Level of the Community

Lisa J. Berlin
Charles H. Zeanah
Alicia F. Lieberman

The opportunity to revisit the topic of attachment-based interventions for this third edition of the *Handbook of Attachment* comes at a particularly exciting time for several reasons. First, supporting early child development is a prominent goal among practitioners and policymakers. Galvanized by large studies linking early adversity to diverse negative outcomes (e.g., Edwards, Holden, Anda, & Felitti, 2003), concerns about young children's exposure to "toxic stress" are being widely voiced (e.g., Bornstein, 2013; Shonkoff, 2010). Simultaneously, and informed in large part by attachment theory and research, supportive parenting is increasingly recognized as a crucial buffer to toxic stressors (Shonkoff, 2010; Tough, 2012). President Barack Obama's 2014 State of the Union address called for the expansion of services that support early child development and early parenting.

Another reason to be especially enthusiastic about attachment-based interventions concerns the depth of the evidence base. Rigorous evaluations are increasingly demonstrating lasting and diverse positive effects of several attachment intervention programs. Moreover, attachment inter-

ventions are increasingly moving from university-based trials to community-based implementation, creating the possibility for attachment-based programs to play a sustained role in the broader provision of social services to children and families.

We begin by reviewing the implications of attachment theory and research for attachment-based intervention. We then review the four attachment-based intervention programs with the strongest evidence base: Child-Parent Psychotherapy, the Attachment and Biobehavioral Catch-up program, the Video-Feedback Intervention to Promote Positive Parenting program, and the Circle of Security program. We next describe several efforts to translate attachment interventions from university research-driven endeavors to community-based programs. We conclude with a set of recommendations for sustaining the "real-world" implementation of attachment-based interventions. Throughout, we highlight progress in attachment-based interventions since our previous version of this *Handbook* chapter (Berlin, Zeanah, & Lieberman, 2008) and offer suggestions for the continued development of the field.

Implications of Attachment Theory and Research for Attachment-Based Intervention

The Attachment “Transmission Gap” and Infants’ Differential Susceptibility

As we have previously discussed at length (Berlin et al., 2008), attachment theory and research have direct implications for intervention. Van IJzendoorn’s (1995) “transmission model” and his identification of a “transmission gap” concisely summarize this theory and research. According to the transmission model, a parent’s internal working models of attachment drive parenting behaviors, which in turn shape the quality of the child’s attachment to that parent. Parents’ internal working models influence parenting behaviors by guiding the parent’s responsiveness to the child’s needs (Main, 1990). The parent’s sensitive responsiveness fosters emotional security, whereas less supportive parenting is characterized by partial or inconsistent responsiveness.

Through two meta-analyses, Van IJzendoorn (1995; deWolff & Van IJzendoorn, 1997) provided strong support for direct links between (1) parents’ internal working models and their sensitive parenting behaviors, (2) parents’ internal working models and their child’s attachment to them, and (3) sensitive parenting behaviors and child attachment. Sensitive parenting behaviors, however, accounted for a relatively small proportion of the association between parental internal working models and child attachment (Van IJzendoorn, 1995). Thus, sensitive parenting did not appear to be the principal mediator of the effects of parental working models on child attachment. This “transmission gap” was subsequently replicated in several other investigations (for reviews, see Atkinson et al., 2000, 2005; Madigan et al., 2006) and is still not well understood.

We (2008) previously discussed several emerging areas of research helping to clarify the transmission gap and its implications for intervention. Of these, Belsky’s differential susceptibility framework (Belsky & Pleuss, 2009) has been especially valuable. According to this framework, individuals are differentially susceptible to rearing influences. Moreover, individuals are differentially susceptible “for better *and* for worse,” meaning that some highly sensitive and often temperamentally irritable infants both suffer more in response to early adversity and also benefit more from early

support (Bakermans-Kranenburg & Van IJzendoorn, 2007; Belsky, Bakermans-Kranenburg, & Van IJzendoorn, 2007).

Differential susceptibility may be due, in part, to genes that regulate dopamine in the brain, as illustrated by a recent meta-analysis (Bakermans-Kranenburg & Van IJzendoorn, 2011). For example, a 2006 study found that infants with a dopamine receptor polymorphism (*D4DR* 7-repeat allele) whose mothers had unresolved losses or traumas were at increased risk for attachment disorganization (Van IJzendoorn & Bakermans-Kranenburg, 2006). Moreover, infants with this 7-repeat allele whose mothers did not have unresolved losses or traumas exhibited significantly less disorganization than infants without the 7-repeat allele, regardless of whether these less susceptible infants had mothers who were resolved or unresolved with respect to loss or trauma. Another inquiry illustrated that children with the *D4DR* 7-repeat allele whose mothers treated them less sensitively at 10 months were reported to have more externalizing behavior problems at age 3 than children without the 7-repeat allele, regardless of their mothers’ sensitivity (Bakermans-Kranenburg & Van IJzendoorn, 2006). Furthermore, children with the 7-repeat allele whose mothers treated them more sensitively during infancy had the lowest externalizing behavior problem scores. Other research examining gene–environment interactions as predictors of attachment-related phenomena has pointed to polymorphisms of serotonin transporter genes (e.g., Cicchetti, Rogosch, & Toth, 2011; Drury et al., 2012; Spangler, Johann, Ronai, & Zimmermann, 2009). For further discussion of attachment, genetics, and differential susceptibility, see Bakermans-Kranenburg and Van IJzendoorn (Chapter 8, this volume).

Taken as a whole, the growing evidence of gene–environment interactions as predictors of attachment-related phenomena implies that one reason for the transmission gap may be that the transmission model is more relevant to some (more susceptible) children than to others. By extension, the implications of the transmission model for attachment programs may also need to be considered in the context of the differential susceptibility approach (Bakermans-Kranenburg & Van IJzendoorn, 2015). Much about the transmission gap and about differential susceptibility remains to be specified. Understanding of both will likely draw on attachment intervention work guided by the transmission model.

Implications of the Attachment “Transmission Model” for Attachment-Based Intervention

As we have previously described (Berlin et al., 2008), the attachment transmission model suggests two points of intervention: the parent’s internal working models and parenting behavior(s). In keeping with Bowlby’s (1980, 1988) proposal that new attachments are one of the factors most likely to alter internal working models, we have emphasized the importance of the intervener serving as a secure base for the parent. As we describe further later in this chapter, the relationship between the intervener and the parent plays at least some role in all the attachment-based interventions we review.

Prevention and Intervention Programs to Support Early Attachment Security: The Evidence Base

In this section we review the four attachment-based intervention programs that have amassed the strongest evidence bases: Child–Parent Psychotherapy, the Attachment and Biobehavioral Catch-up program, the Video-Feedback Intervention to Promote Positive Parenting program, and the Circle of Security program. In so doing, we describe key intervention targets and processes, as well as the latest evaluation findings. We also revisit three questions identified in our earlier work as requiring clarification. The first question stems from evidence that different services fit some families better than others: *What works for whom?* The second question refers to mechanisms of therapeutic change: *What drives program success?* The third question concerns the criteria for positive outcomes: *What is program success?*

Child–Parent Psychotherapy

Child–Parent Psychotherapy (CPP) is a dyadic intervention based on infant–parent psychotherapy, a psychoanalytic treatment for infants under age 3 and their parents. In this intervention, the metaphor of “ghosts in the nursery” is used to describe the intergenerational transmission of unresolved childhood conflicts from the parent to the infant (Fraiberg, 1980). The principal goals are to help the parent (1) reconnect with the pain, fear, anger,

and helplessness evoked by frightening childhood experiences and (2) understand his or her current negative feelings toward his or her infant as a re-enactment of unresolved conflicts about his or her own parents or other important childhood figures resulting from these frightening experiences. The therapist’s empathic guidance is considered the essential ingredient for helping the parents explore their past, practice new parenting behaviors, and free their child from engulfment in the parents’ conflicted childhood experiences.

Lieberman and Van Horn (2005, 2008) expanded this model to CPP, a manualized, 12-month intervention for children between birth and 5 years of age. CPP incorporates Bowlby’s emphasis on the importance of external reality as a source of traumatic stressors and other adverse influences that may have a dual impact on the child and on parental perceptions and behaviors toward the child. It does this while also retaining an appreciation for the role of the parents’ unresolved childhood experiences in shaping their working models of attachment and their relationship with the child (Lieberman & Van Horn, 2008). CPP simultaneously targets the parent’s pathogenic perceptions and behaviors, and the child’s mental health symptoms, and aims to support attachment security primarily as a mechanism for promoting the child’s mental health.

The initial CPP assessment of the dyad includes a structured questionnaire about child and parent exposure to traumatic experiences, an evaluation of safety concerns and concrete needs, and an exploration of the parents’ culturally based caregiving values and practices. The assessment ends with a feedback session in which the parent is engaged in co-creating a treatment plan that includes psychoeducation about the impact of trauma and adverse experiences on the child and the parent.

CPP sessions are conducted jointly with the parent(s) and the child. The CPP therapist uses play and unstructured interactions as vehicles to promote a goal-corrected partnership, translate the motivations and feelings of the child and the parent toward each other, address trauma reminders, and reframe mutual negative attributions. When this therapeutic focus on the present is not sufficient to promote improvement, the CPP therapist guides the parent into an exploration of her or his childhood experiences that are being reenacted in relation to the child. CPP therapists also provide case management and connect the family to relevant community services when concrete problems

of living interfere with the parent's ability to create a safe family environment.

CPP efficacy is supported by five randomized trials. Lieberman, Weston, and Pawl (1991) randomly assigned 59 newly immigrated, impoverished, and highly stressed Latina mothers and their insecurely attached 1-year-olds to 1 year of weekly, 90-minute, home-based CPP or to a control group. When the children were 2 years old, the CPP group had higher scores on observed maternal empathy and dyadic goal-corrected partnership, and lower levels of children's avoidance, resistance, and anger toward their mothers. The Attachment Q-Sort did not show group differences, a finding attributed by the authors to insufficient training of the assessors in using this measure. Within the CPP group, a measure of "level of therapeutic process" predicted attachment security, maternal empathy, initiation of interaction and involvement, dyadic goal-corrected partnership, and lower child avoidance.

CPP was also found to foster attachment security in infants and preschoolers from maltreating families (Cicchetti, Rogosch, & Toth, 2006; Toth, Maughan, Manly, Spagnola, & Cicchetti, 2002). In a randomized trial with 137 infants, those receiving CPP between ages 12 months and 24 months were significantly more likely to be securely attached at 26 months than control infants receiving services as usual. A 1-year follow-up study found higher rates of attachment security (according to Schneider-Rosen, Braunwald, Carlson, & Cicchetti's [1985] coding scheme) among CPP 3-year-olds compared to controls (Stronach, Toth, Rogosch, & Cicchetti, 2013). A subsequent follow-up study revealed that by age 3, the CPP children were showing increasingly higher (normal) production of morning cortisol, a hormonal index of stress regulation that often shows atypical patterns in traumatized children (Cicchetti, Rogosch, Toth, & Sturge-Apple, 2011). The control infants' morning cortisol production declined over time to atypically low levels. Thus, in this case, CPP appeared to prevent hormonal dysregulation. There were not significant group differences in maternal sensitivity when children were 26 months old or in mother-reported behavior problems at age 3. There was also no evidence of any genetic moderators of the efficacy of the intervention (Cicchetti, Rogosch, & Toth, 2011).

Interestingly, immediately postintervention, there were no group differences in attachment between the CPP group and a group receiving a home-based psychoeducational parenting inter-

vention (Cicchetti et al., 2006). At follow-up, however, CPP 3-year-olds were more likely to be securely attached than children in the comparison group (Stronach et al., 2013). Similar findings emerged from a randomized trial of 87 maltreated preschoolers (Toth et al., 2002).

CPP also fostered attachment security in toddlers of depressed mothers (Cicchetti, Toth, & Rogosch, 1999; Toth, Rogosch, Manly, & Cicchetti, 2006). At age 3, the CPP group had higher IQ scores than the control group (Cicchetti, Rogosch, & Toth, 2000). No CPP effects were found on maternal depression, and maternal depression did not moderate intervention effects.

A final randomized trial included 75 preschoolers exposed to marital violence and other traumatic stressors (Lieberman, Van Horn, & Ghosh Ippen, 2005). Compared to case management plus community treatment as usual, those who received weekly CPP for 1 year showed fewer mother-reported behavior problems and traumatic stress symptoms and were less likely to meet criteria for traumatic stress disorder. Mothers reported significantly fewer symptoms of posttraumatic stress disorder (PTSD)-related avoidance (Lieberman et al., 2005). A 6-month follow-up study reexamining 50 of these dyads showed that children in the CPP group maintained their lower behavior problems relative to the control group, and their mother reported significantly fewer psychiatric symptoms (Lieberman, Ghosh Ippen, & Van Horn, 2006). A data reanalysis comparing children with four or more traumatic events and children with fewer than four traumatic events showed that CPP effects were stronger for children and mothers who had experienced more risk (Ghosh Ippen, Harris, Van Horn, & Lieberman, 2011).

In summary, in keeping with its overarching concerns with children's mental health, CPP has demonstrated largely positive effects on both attachment-specific and broader mental health outcomes. Three of four randomized trials with high-risk families tested and found effects of CPP on attachment security in infants, toddlers, or preschoolers. In the one study in which there were no program effects on attachment security, there were positive effects on relevant maternal and child behaviors such as maternal empathy and child avoidance (Lieberman et al., 1991). In some, but not all, subsequent studies demonstrating effects on attachment security, there were also effects on maternal sensitivity (e.g., Cicchetti et al., 2006). In some, but not all, studies CPP demonstrated positive effects on child behavior prob-

lems. CPP has shown sustained effects on attachment security, maternal mental health, and child behavior problems (Lieberman et al., 2006; Stronach et al., 2013). Finally, CPP has shown positive effects on hormonal (cortisol) regulation (Cicchetti, Rogosch, Toth, & Sturge-Apple, 2011). This body of findings is important because CPP is attachment-informed rather than attachment-derived and addresses the child–parent relationship broadly, rather than focusing more narrowly on attachment behaviors. The fact that CPP’s effects on attachment security are as powerful as they are speaks to the centrality of attachment in child–parent relationships.

As we discuss later in this chapter, CPP has been broadly disseminated worldwide, and it is increasingly being implemented in community settings. Given its duration and intensity, CPP requires extensive resources. Current and future efforts for program development center on mechanisms for ensuring fidelity and long-term sustainability, often within the context of broad-based social service systems (e.g., Van Horn et al., 2012).

Attachment and Biobehavioral Catch-up

Developed by Dozier and her colleagues to promote attachment security and biological regulation in children who have experienced early adversity, the manualized Attachment and Biobehavioral Catch-up (ABC) program consists of 10 home-based sessions delivered by a trained parent coach (Dozier, Lindheim, & Ackerman, 2005). Each session includes mother and child together and addresses a specific topic. Each session also includes a review of video-recorded mother–infant interactions, starting with stock Strange Situation clips and moving to video feedback specific to the dyad, both to reinforce supportive parenting behaviors and to facilitate gentle suggestions for alternatives.

The ABC program has undergone continual refinement during the past several years. It now emphasizes explicit parent coaching in reference to three behavioral targets: (1) nurturance; (2) following the child’s lead; and (3) reducing frightening caregiving behavior. Two sessions are devoted to the topic of “overriding” one’s own parenting history and/or non-nurturing instincts. In addition, parent coaches provide frequent “in-the-moment” comments in response to opportunities that they observe for the parent to provide nurturance or to follow the child’s lead. The parent coach explicitly

connects the parent’s ongoing behaviors to these behavioral targets and to the infant’s responses and/or longer-term developmental benefits. Comments are deliberately disproportionately positive. For example, if the parent coach notices the mother hugging her distressed toddler, the parent coach will immediately praise the mother for providing nurturance and note how helpful it is for her child (e.g., “Great job cuddling him after he fell down. . . . See how he is calming down so quickly in your arms. . . . You are teaching him that you are there for him . . .”). An ABC parent coach is expected to make at least one comment per minute during every session. The quantity and content of a parent coach’s in-the-moment commenting has become the focal point of ABC training, supervision, and monitoring.

Two large randomized trials have provided strong evidence of program efficacy. Both have compared the ABC program to a 10-session, home-based control intervention that targets cognitive and language development. The first randomized trial included 96 foster infants and their foster mothers. Following intervention, the ABC foster mothers showed greater pre- to post-intervention improvements in sensitive parenting behaviors than control foster mothers (Bick & Dozier, 2013). The ABC foster infants demonstrated more secure attachment behaviors and less avoidance than the control foster infants, according to the Parent Attachment Diaries (Dozier et al., 2009). Within ABC recipients, foster mothers who began the ABC program with autonomous (secure) states of mind with respect to attachment according to the Adult Attachment Interview also received higher coder-rated score for understanding of intervention concepts and “reflective functioning” (insight and self-awareness) than foster mothers who began ABC with nonautonomous states of mind (Bick, Dozier, & Moore, 2012).

A follow-up analysis of cortisol production revealed that, compared to the control group, children in the ABC group exhibited more normal patterns of cortisol production and that this pattern did not differ significantly from the pattern observed in a comparison group of 104 children who had never been in foster care (Dozier et al., 2006; Dozier, Peloso, Lewis, Laurenceau, & Levine, 2008). Moreover, ABC foster mothers of toddlers reported fewer behavior problems than control foster mothers (Dozier et al., 2006). Another follow-up study examined 37 of the original participants’ cognitive flexibility and theory of mind (perspective-taking) skills between the ages

of 4 and 6 (Lewis-Morrarty, Dozier, Bernard, Terracciano, & Moore, 2012). Findings again favored the ABC children, who demonstrated stronger cognitive flexibility and theory-of-mind skills than control children, and cognitive flexibility and theory-of-mind skills equal to those of 24 never-fostered comparison children.

A second randomized trial targeted 212 custodial biological mothers and their infants or toddlers (age two or younger) receiving child protective services after being identified as being at risk for child neglect (Bernard et al., 2012). Analysis of postintervention Strange Situations for 120 infants and toddlers (mean age 19 months) revealed that ABC children were significantly less likely to be disorganized and more likely to be securely attached than controls (Bernard et al., 2012). Observation of 117 toddlers' problem-solving abilities during a challenging tool task with their mothers indicated that ABC toddlers displayed less sadness and anger than controls (Lind, Bernard, Ross, & Dozier, 2014).

In keeping with its original goals, the ABC program has demonstrated positive effects on both biological and behavioral outcomes. Specifically, a postintervention study including 101 participants found that children in the ABC group exhibited higher morning levels of cortisol and more normal diurnal patterns of cortisol production (i.e., higher morning levels followed by lower evening levels), whereas control children showed a flatter pattern across the day (Bernard, Dozier, Bick, & Gordon, 2014). A follow-up study including 125 preschoolers revealed strikingly similar findings, with the ABC preschoolers again exhibiting higher morning levels of cortisol and more normal diurnal patterns of cortisol production approximately 3 years after the end of the ABC intervention (Bernard, Hostinar, & Dozier, 2015).

Finally, analysis of parent coaches' in-the-moment comments is beginning to illuminate the mechanisms underlying ABC program effects. Two different, relatively recent studies indicated that coders' ratings of the frequency and content of parent coaches' in-the-moment comments predicted positive changes in observed parenting behaviors (Meade & Dozier, 2012; Meade, Dozier, Weston-Lee, & Neely, 2014).

In summary, the ABC program has demonstrated consistently positive short-term effects on attachment-specific outcomes, including child security and caregivers' sensitive behaviors, long-term effects on child behaviors such as cognitive flexibility, and short- and longer-term effects on

hormonal (cortisol) regulation. The program's combined features of manualization, a short duration, and substantive intensity make it an especially appealing candidate for community-based implementation outside of controlled evaluation studies. As we discuss later in this chapter, increasingly ABC is in fact being broadly disseminated and folded into child- and family-serving systems such as child welfare services. It is important to note that parent coaching according to ABC requires considerable skill. Parent coaches work relatively independently, must address session-specific intervention topics with caregivers while simultaneously observing and commenting on ongoing caregiving behaviors, and must be dexterous users of video recordings. As will be discussed further, the process of ABC adoption by community-based providers requires attending carefully to all of these demands.

With respect to the evaluation and thorough "unpacking" of the mechanisms underlying both attachment-based interventions and attachment relationships, we (2008) previously noted that there are no attachment-based intervention studies with both pre- and postintervention assessments of maternal state of mind with respect to attachment, parenting behaviors, and child attachment security. This is still the case, though with the exception of preintervention measure of child attachment security and postintervention measures of maternal states of mind (Adult Attachment Interviews), Dozier's ABC database contains all of the other components noted and therefore is currently the most comprehensive attachment intervention database.

Video-Feedback Intervention to Promote Positive Parenting

Juffer, Bakermans-Kranenburg, and Van IJzendoorn (2008) have developed and evaluated several versions of the Video-Feedback Intervention to Promote Positive Parenting (VIPP), which is a home-based program that includes four to six sessions of approximately 90 minutes each. Trained interveners focus on promoting parental sensitivity through interveners' presentation of written materials and review of in-home, videotaped infant-parent interactions. Using an approach called "speaking for the child," interveners aim to help the parent notice the infant's signals, interpret them accurately, and respond promptly and appropriately. Video reviews highlight "sensitivity chains" in which the parent's sensitive responsiv-

ity is met with a positive reaction from the infant (Juffer, Bakermans-Kranenburg, & Van IJzendoorn, 2014).

Multiple randomized trials support program efficacy. VIPP has typically been contrasted with a light control “intervention,” such as weekly phone check-ins with the parent. Positive effects of the program have been concentrated in improvements in sensitive caregiving behaviors. For example, one randomized trial targeted 81 first-time mothers preliminarily classified as having insecure states of mind with respect to attachment (Klein Velderman, Bakermans-Kranenburg, Juffer, & Van IJzendoorn, 2006a). VIPP mothers received home visits between their infants’ seventh and 10th months. When their infants were 11 and 13 months old, VIPP mothers were rated as significantly more sensitive than no-treatment control mothers. Interestingly, the intervention had stronger effects on increasing maternal sensitivity for mothers of temperamentally “highly reactive” infants. There were no significant intervention effects on infant–mother attachment at 13 months. Among the highly reactive infants who received VIPP, there was a significant association between pre- to posttest change in maternal sensitivity and infant attachment security. This association was not significant among the less reactive infants who received VIPP. Together these findings lend support to Belsky’s differential susceptibility framework by illustrating stronger intervention effects for the highly reactive and presumably more sensitive and susceptible infants, as well as greater susceptibility among these infants to their mothers’ evolving parenting behaviors.

In a follow-up study conducted when these children were of preschool age, children who had received VIPP during infancy were less likely to meet clinical criteria for externalizing behavior problems (Klein Velderman et al., 2006b). These effects were not mediated by earlier maternal sensitivity. In addition, there were no program effects on maternal sensitivity or on Attachment Q-Sort scores at this time, nor any evidence of moderation of program effects by infant reactivity.

Another randomized trial with approximately 130 adoptive parents found some positive effects on attachment security of an enhanced version of VIPP (VIPP-R), in which the duration of the home visits was expanded to 3 hours in order to include discussion of parents’ childhood attachment experiences (Juffer, Hoksbergen, Riksen-Walraven, & Kohnstamm, 1997; Juffer, Rosenboom, Hoksbergen, Riksen-Walraven, & Kohnstamm,

1997). Among adoptive families without—but not with—birth children, those who had participated in VIPP-R evinced a higher proportion of securely attached infants compared to the control group. Follow-up analyses of both types of adoptive families indicated positive effects of VIPP-R (but not VIPP) on attachment organization (i.e., fewer infants classified disorganized; Juffer, Bakermans-Kranenburg, & Van IJzendoorn, 2005) and on children’s behavior problems at age 7 (Stams, Juffer, Van IJzendoorn, & Hoksbergen, 2001).

Another version of the program, Video-Feedback Intervention to Promote Positive Parenting and Sensitive Discipline (VIPP-SD), emphasizes both parental sensitivity and positive disciplinary practices for children showing early signs of externalizing problems (Mesman et al., 2007). In a randomized trial of 237 families selected on the basis of their 1- to 3-year-old child’s high scores for externalizing behaviors, 1 year after completing treatment, program mothers exhibited significantly more sensitive disciplinary attitudes and behaviors than control mothers (van Zeijl et al., 2006).

Two follow-ups of this study have examined the dopamine receptor polymorphism (*D4DR* 7-repeat allele) as a moderator of the effects of VIPP-SD. The first examined the *D4DR* 7-repeat allele as a moderator of program effects on 157 children’s externalizing behavior problems, as reported by their mothers, an outcome for which there was not a main effect in the original study with all 237 families (Bakermans-Kranenburg, Van IJzendoorn, Pijlman, et al., 2008). As expected, the children with the *D4DR* 7-repeat allele were differentially susceptible to the intervention such that VIPP-SD reduced behavior problems only for these children (VIPP-SD did not have an effect for children without the *D4DR* 7-repeat allele). This effect was especially pronounced in VIPP-SD families whose mothers showed more improvement in their use of sensitive discipline. A second follow-up study investigated the *D4DR* 7-repeat allele as a moderator of program effects on 130 children’s daily cortisol production (Bakermans-Kranenburg, Van IJzendoorn, Mesman, Alink, & Juffer, 2008). Again, the children with the *D4DR* 7-repeat allele were differentially susceptible to the intervention, such that VIPP-SD reduced daily—and particularly morning—production of cortisol for these children only.

The VIPP program continues to undergo development and expansion. For example, VIPP has been implemented for mothers with eating disor-

ders (Stein et al., 2006) and with children with autism spectrum disorders (Poslawsky et al., 2015). A randomized trial of VIPP-SD in Portugal including 42 poor, high-risk families with toddlers found positive effects on observed mother–child interactions, harsh discipline, and mother-reported family environment (Negrão, Pereira, Soares, & Mesman, 2014; Pereira, Negrão, Soares, & Mesman, 2014). Another randomized trial of VIPP-SD targeting 76 Turkish minority families in the Netherlands revealed positive effects on maternal sensitivity and (reduced) intrusiveness (Yagmur, Mesman, Malda, Bakermans-Kranenburg, & Ekmekci, 2014). Finally, an initial randomized trial with 120 home-based child care providers has demonstrated positive effects on care quality of the newly developed Video-Feedback Intervention to Promote Positive Parenting and Child Care (VIPP-CC; Groenveld; Vermeer, Van IJzendoorn, & Linting, 2011).

In summary, VIPP is the briefest attachment-based intervention considered here. It has typically been provided to lower-risk families than those targeted by CPP, ABC, or the Circle of Security, and it emphasizes preventing or reducing children's behavior problems. Although brief, the program is precisely targeted, and it has shown positive effects on sensitive caregiving behaviors and child outcomes, especially externalizing behavior problems. VIPP's effects have been more pronounced for more temperamentally reactive infants (Klein Velderman et al., 2006a) and for those carrying the *D4DR* dopamine receptor polymorphism (e.g., for cortisol production; Bakermans-Kranenburg, Van IJzendoorn, Mesman, et al., 2008). It is also important to note that with the exception of an earlier, more intensive version of the program (VIPP-R) delivered to adoptive families, program effects on infant–mother attachment security have not been obtained. VIPP has been multiply adapted not only to focus on sensitive discipline but also for child care providers and special needs children. As we later discuss, VIPP is also being implemented in multiple community-based settings.

Circle of Security

The Circle of Security (COS) program is an attachment-based intervention that has undergone tremendous development in the past several years (see Powell, Cooper, Hoffman, & Marvin, 2014). Whereas the evidence base for this program is more limited than that supporting the other three attachment programs, several versions of the program have been evaluated and have demonstrated

positive effects. All versions of the program implement core components of the COS approach that include a trained intervener in either a group or individual meeting who teaches the parent(s) attachment theory and research, and helps them to reflect on their own histories and parenting behaviors. The centerpiece of the program content is the COS graphic, a remarkably simple yet comprehensive pictorial depiction of attachment theory's key constructs about (1) children's needs for both intimate connection and autonomy, and (2) parenting behaviors that support these needs. The COS also focuses on children's cues, emphasizing that children sometimes “miscue” their parents about their true needs.

To guide the intervener's approach to parenting behaviors, COS includes consideration of parents' “core sensitivities” regarding separation, esteem, and safety. In addition, the COS program uses the innovative concept of “shark music” to help parents think about why specific child behaviors that are not actually dangerous might *feel* threatening to parents and elicit negative responses (i.e., activate a parent's “shark music”). All versions of the COS program emphasize video review with parents. The Circle of Security Interview (COSI) taps parents' working models of attachment and can be used to guide the intervener's understanding of the parent's core sensitivities and parenting challenges.

Three separate evaluations attest to the promise of the COS program. The first evaluation used a pre- and posttreatment design to evaluate 65 dyads in a 20-week, group-based version of the program (Hoffman, Marvin, Cooper, & Powell, 2006). Trained group leaders delivered the intervention in 75-minute weekly sessions to groups of six to eight parents of Head Start or Early Head Start toddlers or preschoolers. Preintervention Strange Situations and COSI's were administered for research purposes and to help individualize program foci. Comparisons of pre- and postintervention Strange Situations revealed significant decreases in both insecure and disorganized classifications. At baseline, 80% of the children were classified as insecure and 60% were disorganized. Postintervention, 46% of the children were classified as insecure, and 25% were disorganized.

The second evaluation consisted of a randomized trial including 220 low-income mothers with firstborn, temperamentally irritable infants (Cassidy, Woodhouse, Sherman, Stupica, & Lejuez, 2011). Dyads were randomly assigned to a four-session, home-based version of the COS pro-

gram or to a psychoeducational control intervention. Interestingly, although there were no main effects of the intervention, infants subclassified as “highly irritable” in the COS group were more likely to be securely attached than highly irritable controls. Mothers’ self-reported attachment styles also moderated the intervention’s effects. For highly irritable infants only, when mothers were more secure, there was an effect of COS participation on (increased likelihood of) infant attachment security at age 1, whereas when mothers were less secure, there was no COS effect. For highly irritable infants with more dismissing mothers, there was a positive effect of COS on attachment security, whereas when mothers were less dismissing (and more preoccupied), there was no effect. Moreover, within the control group, highly irritable infants with more dismissing mothers were significantly less likely to be secure than moderately irritable infants with more dismissing mothers. As Cassidy and her colleagues noted, these findings are consistent with Belsky’s differential susceptibility framework. They illustrate not only a targeted benefit of the intervention for the highly irritable and presumably more sensitive and susceptible infants, but also increased challenge (i.e., attachment insecurity) for these same infants under less beneficial conditions (i.e., in the absence of the intervention and when their mothers also reported more dismissing attachment styles).

The third evaluation of the COS program consisted of an evaluation of COS groups provided as a supplemental treatment to mothers and their infants in a jail-diversion program (Cassidy et al., 2010). This study is discussed in greater detail in the following section addressing the wider dissemination of attachment-based interventions.

In summary, COS is the newest attachment-based intervention considered here. It derives most directly from attachment theory and in fact teaches parents and caregivers attachment theory in the course of the intervention. It is the only attachment-based intervention considered here that does not include the child or allow for opportunities to practice new parenting behaviors during the intervention sessions. Initial studies of the COS program indicate positive effects on infant or toddler attachment security. The program requires further evaluation, however, especially in the context of rigorous randomized trials. The one existing randomized trial demonstrated positive effects on infant attachment security, although these effects were limited to highly irritable infants. Interestingly, at the same time, effects were also moder-

ated by maternal attachment style, such that when high infant irritability and maternal attachment style combined to increase infants’ risk for developing attachment insecurity, the program significantly reduced that risk. As we discuss further, dissemination of COS has vastly outpaced program evaluation. The next steps for this program center on the development of the most recent, unified, and highly scalable version of the program and, concurrently, on strengthening its evidence base.

Summary

Each of the four programs just reviewed is directly informed by attachment theory and research. CPP has the longest history and the most intensive approach, with the program typically lasting at least 1 year and targeting parents’ internal working models and parenting behaviors. Moreover, CPP also invests heavily in the relationship between the intervener (therapist) and parent; the “level of therapeutic process” developed in this relationship has been found to magnify program outcomes (Lieberman et al., 1991).

The other three programs provide between four and 20 individual or group sessions. Although significantly shorter and more narrowly focused than CPP, these three programs also aim to promote parental reflection and to help parents make explicit connections between their own histories and what parenting behaviors they do and do not want to replicate. The three newer programs all incorporate video review to enhance parental reflection. Moreover, like CPP, the ABC, VIPP, and COS program approaches all consider the intimate and often delicate nature of attachment intervention work. All attend carefully to the nature of the interaction between the intervener and the parent, and to the model of relating that the intervener provides. For example, in the ABC program, more challenging in-the-moment comments are not provided during earlier sessions but rather are reserved for later sessions, after a supportive foundation has been laid. Similarly, the early sessions of both the VIPP and COS programs emphasize building the relationship between the intervener and the mother.

The evaluations of these four interventions demonstrate that attachment-based interventions can indeed support the development of attachment security and can reduce the risk of developing or maintaining attachment insecurity. Positive effects have emerged from multiple rigorous randomized trials conducted with participants with

varying levels of risk, both within and outside the United States. Especially—but not exclusively—with respect to attachment-specific outcomes, attachment-based interventions have consistently outperformed not only light or no-treatment control conditions but also more didactic and/or cognitively focused interventions of equal duration and intensity. As detailed in our review, increasingly attachment-based interventions are demonstrating long-term effects on attachment security (e.g., Stronach et al., 2013) and other socio-emotional outcomes such as behavior problems (e.g., Klein Velderman et al., 2006b).

Attachment-based interventions are also increasingly demonstrating effects on biological outcomes. Four studies have reported intervention effects on children's cortisol production (Bakermans-Kranenburg, Van IJzendoorn, Mesman, et al., 2008; Bernard et al., 2014; Cicchetti, Rogosch, Toth, & Sturge-Apple, 2011; Dozier et al., 2006). These effects are somewhat inconsistent, however. For example, Bakermans-Kranenburg, Van IJzendoorn, Mesman, and colleagues (2008) found that VIPP-SD reduced morning production of cortisol for the intervention children with the *D4DR* 7-repeat allele. Both Cicchetti, Rogosch, Toth, and Sturge-Apple (2011) and Bernard and colleagues (2014) found that attachment-based intervention raised the production of morning cortisol. These inconsistencies may well reflect variation in these studies' samples—especially with regard to prior risk exposure—and/or to variation in intervention approach. Regardless, one task for future research is to help clarify such apparent discrepancies. Analyzing biological outcomes elucidates not only the mechanisms underlying the associations between increased maternal sensitivity and young children's self-regulation but also the connections between biological and behavioral processes writ large.

Key Questions

In 2008, we highlighted three questions within the field of attachment-based intervention: (1) What works for whom? (2) What drives program success? And (3) What is program success? Recent progress in the field has helped to address these questions. With regard to what works for whom, there is evidence of stronger effects for dyads with more secure mothers and/or with children at higher risk, especially those who are more temperamentally and/or genetically sensitive (susceptible). For example, Bick and her colleagues

(2012) found that foster mothers with autonomous states of mind demonstrated better understanding of intervention concepts and more reflective functioning during intervention sessions. Cassidy and her colleagues (2011) found that highly irritable infants with more secure mothers (compared to those with less secure mothers) derived positive effects from COS. Furthermore, Ghosh Ippen and her colleagues (2011) discerned stronger effects of CPP for children who had experienced more traumatic events, and both Cassidy and colleagues' study and several evaluations of the VIPP program (Bakermans-Kranenburg, Van IJzendoorn, Mesman, et al., 2008; Bakermans-Kranenburg, Van IJzendoorn, Pijlman, et al., 2008; Klein Velderman et al., 2006a) found stronger intervention effects for "highly irritable," "highly reactive," and/or genetically more vulnerable children (with the *D4DR* 7-repeat allele). More vulnerable infants with less secure mothers also experienced greater benefits in some cases (Cassidy et al., 2011; Klein Velderman et al., 2006a). Taken together, these findings help to illuminate what works for whom and may also inform the tailoring of intervention approaches. Infants who are more temperamentally and/or genetically sensitive might be prioritized for attachment-based interventions, for example. Program providers might also consider the *fit* between a parent's attachment security and his or her child's emotional reactivity.

With respect to what drives program success, Dozier and her colleagues have made important strides by specifying the components of the intervener's behavior toward the mother (i.e., more frequent and more targeted in-the-moment comments) that increase the mother's sensitive parenting behaviors (Meade & Dozier, 2012; Meade et al., 2014). The in-the-moment comments are designed to provide explicit feedback to parents as they practice ABC target behaviors in their typical parenting environments. Notably, the ABC program approach is consistent with the findings of a 2008 meta-analysis of "parent training" programs indicating that one of the intervention components associated with larger program effects was the requirement for parents to practice new skills with their children during training sessions (Kaminski, Vale, Filene, & Boyle, 2008).

At the same time, much remains to be understood more generally about how attachment-based interventions with as few as four sessions can induce such important changes in human development. Bakermans-Kranenburg, Van IJzendoorn,

Mesman, and colleagues (2008) have discussed the merits of briefer attachment-based interventions, including (1) precise, short-term goals, and (2) relative ease of adherence to program requirements for typical interveners. The use of video feedback, which is an important component of ABC, VIPP, and COS, also deserves mention. Video review may be especially conducive for attachment-based intervention because it concretely facilitates the observation of parent-child interaction, which in turn may stimulate parental reflection (Juffer & Steele, 2014). Moreover, the coviewing of video between the intervener and parent may increase their therapeutic alliance and galvanize the action of “putting feelings into words . . . [that] has often been described as fundamental to the therapeutic process” (Steele et al., 2014, p. 409).

We further suggest the importance of considering how rewarding it is for both parent and child to be harmoniously in step with one another. For example, it was notable to us that CPP reduced psychiatric symptoms among mothers (Lieberman et al., 2006) because CPP does not focus on maternal mental health per se. CPP’s focus on the mother-child relationship may have improved maternal mental health through the mothers’ increased satisfaction with their relationships with their children and/or through mothers’ own increased reflective capacities. In addition, to the extent that attachment-based interventions increase children’s biological and behavioral self-regulation, they often make parenting easier and more enjoyable. Last, more harmonious parent-child interactions may be so rewarding that they quickly perpetuate themselves. As Bakermans-Kranenburg, Van IJzendoorn, and Pijlman (2008, pp. 816–817) note, “the children’s reinforcement of their parents’ successful interactive behaviors may partly explain the long-term effects of relatively brief interventions. . . . The process of feedback may continue after the intervener leaves the home.”

Finally, with respect to defining program success, Shonkoff (2010) has urged those concerned with supporting early childhood development to articulate common short- and long-term goals. Attachment-based interventions are in many ways more specific than other early interventions in identifying sensitive parenting behaviors and/or child attachment security as the key outcomes to target. As attachment-based interventions move from more tightly controlled research endeavors to more widely and often more loosely implemented

initiatives, considering the criteria for intervention success remains an important task.

Community Implementation of Attachment-Based Interventions

The impressive evidence supporting attachment interventions has helped to galvanize policy initiatives for early child development. It has also increased demand from practitioners in many spheres for services to support early attachment security. Increasingly, community-based agencies are seeking to integrate attachment-focused protocol into ongoing, broad-based social services. This trend bodes well for the long-term sustainability of attachment-based programs. As Greenberg (2005) argued a decade ago, transforming new evidence-based interventions into widespread practice requires integrating the interventions into existing systems. In this section we describe several different examples of recent or ongoing community implementation initiatives.

Community Implementation of CPP

Facilitated in part by the National Child Traumatic Stress Network, CPP has now been implemented in 30 states in the United States and in Israel and Sweden (Substance Abuse and Mental Health Services Administration, n.d.). One interesting example is provided by the Florida Infant Mental Health Pilot Program, funded by the Florida state legislature (Osofsky et al., 2007). Participants were 57 mothers with infants or young children who had been investigated or substantiated for child maltreatment. The principal treatment was CPP. Notably, during and immediately after 25 CPP sessions, there were no further maltreatment reports for participants. There were also some positive changes in observed maternal and child behaviors. Building on these findings, the national advocacy organization Zero to Three established the Safe Babies Court Teams Project, which provides similar court teams in five other states (Zero to Three, 2014). One study has indicated that children served by the Court Teams achieved a permanent placement sooner than comparison children, and that Court Team children were more likely to reach permanency with a member of their biological family (McCombs-Thornton & Foster, 2012).

Another example of community-based implementation of CPP is a 2009 initiative in which

CPP was one of three interventions integrated into a wraparound foster care program for a diverse population of 216 three- to 18-year-olds (Weiner, Schneider, & Lyons, 2009). CPP was provided to children 6 years old and younger who had experienced a moderate or severe trauma and who had a caregiver willing to participate in the program. Pre- to posttreatment analyses revealed positive effects on ongoing clinical assessments of children's traumatic stress symptoms and "behavioral and emotional needs" for African American, Hispanic, and biracial (but not white) children.

A final example is provided by the Building Healthy Children program, an ongoing multi-pronged initiative for high-risk families that includes CPP as one component (Paradis, Sandler, Manly, & Valentine, 2013; Toth & Gravener, 2012). The program is being provided collaboratively by the Mt. Hope Family Center and the Departments of Social Work and Pediatrics at the University of Rochester. Services are integrated into children's medical homes, and funding is provided by the county Department of Human Services and the United Way. The program focuses on low-income young mothers (age 20 or younger) with two or fewer children under the age of 3. Eligible families are enrolled into a randomized trial in which CPP is one of three home-based interventions provided to families depending on a baseline needs assessment. Control families receive community services as usual. The program includes active, culturally sensitive outreach and careful coordination across multiple service sectors. In 2013, the program had enrolled approximately 500 (program and control) families, provided CPP to 56 (11%) of the dyads, and retained 85% of all families by the target child's third birthday. Initial findings from health and developmental assessments included greater compliance with well-child visits and avoidance of child welfare services in the program group (Paradis et al., 2013). Upcoming outcome assessments will include observer-sorted Q-Sets assessing infant-parent attachment and maternal behavior in the home.

Community Implementation of the ABC Program

The ABC program has been implemented in several locations in the United States and abroad, including Germany and Australia. One recent pilot randomized trial tested the feasibility and efficacy of supplementing services as usual for new mothers in residential substance abuse treatment with

ABC (Berlin, Shanahan, & Appleyard Carmody, 2014). Findings were promising: Mothers who were randomly assigned to receive supplemental ABC home visits scored higher than control mothers on observational ratings of sensitive parenting behaviors.

An ongoing project located in Hawaii is examining ABC as one component of community-based child welfare services (Meade et al., 2014). Initial analyses have examined 78 families with infants or toddlers referred to child protective services. Families received ABC from one of nine trained child welfare staff members. Initial findings have indicated pre- to posttreatment increases in observed maternal sensitivity and positive regard, as well as decreases in observed intrusive parenting behaviors.

Finally, in another ongoing project, Berlin, Jones Harden, and their colleagues are conducting a randomized trial to examine home-based Early Head Start services for low-income families with and without ABC. Initial findings have indicated strong feasibility and acceptance of this model by both mothers and Early Head Start staff. Qualitative maternal interviews have highlighted the unique benefits of receiving ABC in addition to Early Head Start home visits (Denmark, Aparicio, Berlin, & Jones Harden, 2014). Outcome assessments will include observed maternal sensitivity and measures of both mothers' and children's cortisol production.

Community Implementation of VIPP

Since 2000, VIPP has been offered to all adoptive parents in the Netherlands. It is also used on a regular basis by several Dutch organizations providing clinical services to youth. In Flemish Belgium, VIPP is being implemented with foster parents countywide (M. J. van IJzendoorn, personal communication, January 14, 2015). These initiatives have not been formally evaluated.

Community Implementation of the COS Program

The COS program has been implemented in multiple locations in the United States and abroad, including Canada, Australia, New Zealand, Africa, Asia, Europe, and South America. Moreover, several U.S. states are incorporating COS into their service systems. For example, in New Mexico, COS is provided to families receiv-

ing child protective services. In Nebraska, one region has set a goal of 80% of the parents of birth- to 3-year-old children receiving COS by 2017. The Minnesota Department of Human Services is providing COS training to adult mental health service providers. New York City's Department of Health has launched COS services throughout the city's five boroughs. In Norway, COS is being implemented with foster and adoptive parents nationwide. In Australia, COS is widely used and underpins a cross-agency collaborative for children between birth and age 8 (G. Cooper & K. Hoffman, personal communication, January 28, 2015).

Whereas COS dissemination has far outpaced evaluation, one evaluation of a jail-diversion program for pregnant women and new mothers with a history of substance abuse who were involved in the criminal justice system yielded positive findings (Cassidy et al., 2010). A prenatal-early infancy version of COS was created for this program and provided by doctoral-level therapists in 20 weekly group sessions as a supplement to the program's other services (e.g., substance abuse treatment, trauma treatment, job training). Analysis of postintervention Strange Situations for twenty 12-month-old infants illustrated rates of attachment security (70%) and disorganization (20%) characteristic of low-risk samples.

Most recently, a new version of COS was developed deliberately for purposes of program scalability (Circle of Security International, n.d.). The Circle of Security Parenting (COS-P) consists of eight sessions led by a trained group leader. COS-P can also be provided on an individual basis. This version of the program uses standard video clips to teach basic tenets of attachment theory and research and to promote parental reflection. As of 2015, COS-P had been translated into nine languages, over 6,000 providers had been trained in this model, and randomized trials were under way to test it.

Community Implementation of Attachment-Based Interventions for Maltreated Children

The Tulane Infant Team and Family Resource Center in New Orleans, Louisiana, draws on multiple attachment-based interventions to serve children and families involved with child protective services within a six-parish (county) region. The program is supported through contracts with the state and private foundations. The Family Resource Center provides basic interventions to 200

children and their parents per year, and the Infant Team provides targeted interventions to children younger than 5 years old and their parents. This work involves collaboration with legal, child welfare, educational, health, and mental health systems to provide attachment theory- and research-based assessments and treatments to young children. The Infant Team sometimes provides simultaneous intervention to the child and foster parent, who must co-construct a new attachment relationship, and to the child and birth parents, with whom the child has disrupted and usually disturbed relationships. Treatment plans are individualized and may include CPP, ABC, and COS.

Following their placement in foster care, approximately half of the children treated by the Infant Team are returned to their parents or relatives, and about half are freed for adoption following voluntary or involuntary termination of parental rights (Zeanah et al., 2001). Although randomized assignment to the program is not possible, Zeanah and his colleagues (2001) have studied outcomes for maltreated children in the 4 years following the intervention to the 4 years that immediately preceded the intervention. They found that the intervention led to a 68% reduction in recidivism for the same child. In addition, they found a 75% reduction in maltreatment recidivism for children born subsequently to the same mother. Ten years later, both child and maternal recidivism rates were essentially unchanged from the original evaluation (Larrieu, 2014). In addition, a 5-year follow-up of graduates of the intervention demonstrated few differences between maltreated children who had received the intervention and age- and gender-matched peers who had never been maltreated (Robinson et al., 2012). Taken as a whole, these findings illustrate the value of translating attachment based interventions to community-based services for maltreated young children and their caregivers.

Summary

Multiple attachment-based programs with increasing evidence of efficacy are increasingly being implemented in community settings, explicitly outside of controlled research trials and with an eye toward integrating attachment-based intervention protocol into comprehensive social service systems. Results so far are promising, both in terms of broadening the reach of attachment theory- and research-based interventions and in terms of demonstrated positive effects. At the same time,

it is important to bear in mind that evaluations of these community-based efforts are often not as rigorous as the randomized trials that initially demonstrated program efficacy. For example, as Toth and Gravener (2012, p. 134) noted, "it is unclear what impact CPP has on the attachment relationship when applied in a community setting." The attachment outcomes from the ongoing Building Healthy Children initiative should clarify this question, however. In another example, Berlin and her colleagues (2014) not only implemented a rigorous (pilot) randomized trial but also provided expert ABC parent coaches to the agency with whom they partnered. Sustaining the integration of ABC into residential substance abuse treatment will require agency staff becoming ABC parent coaches, as is being done in the ongoing ABC project with child welfare staff in Hawaii. Thus, going forward, an important task will be rigorous evaluations of attachment-based interventions as *they are being implemented in the community*. Finally, we note that evaluating attachment interventions within broader service agencies provides a unique opportunity to examine program effects on non-attachment outcomes. For example, the COS/jail-diversion program demonstrated preliminary success in terms of infant attachment outcomes. Program successes in terms of maternal substance use and criminal recidivism can also be examined, as can the interplay among direct and indirect program impacts.

Implementing and Sustaining Attachment-Based Programs in Community Settings

In light of the increasing community implementation of attachment-based interventions and in the interest of supporting their long-term sustainability, here we discuss three sets of issues: (1) *fidelity and quality control*; (2) *family culture and belief systems*; and (3) *community collaboration*. First, the replication of positive intervention effects requires careful attention to fidelity and quality control. Both CPP and ABC have been implemented in community settings through the learning collaborative model, which focuses on high-quality implementation at the community level. Developed by Ebert and her colleagues at the National Center for Child Traumatic Stress, the learning collaborative model is based on previous work conducted

by the Institute for Healthcare Improvement. The model also incorporates Fixsen and Blase's (2008) concepts of "implementation drivers" to promote fidelity and sustainable practice. *Implementation drivers* refer to the key components of the infrastructure required to support practice, organizational, and systems change (see also Blome, Bennett, & Page, 2010, for a related discussion of organizational dynamics). Moreover, sustainability planning is incorporated into the initial stages of program implementation.

The learning collaborative model involves the development of multiple partnerships and takes a data-driven approach. The model includes the assessment of organizational readiness for change, involvement of senior administrative staff, and careful attention to fidelity. Intervention developers and expert consultants help to initiate the collaboration. Multilevel teams including intervention trainers, trainees, supervisors, and agency administrators work together for a specifically defined time punctuated by frequent meetings and incremental process evaluations. Initial studies of learning collaboratives point to positive outcomes including community-based practitioners' sustained use of high-fidelity practices and increased organizational capacity for implementing and sustaining such practices (Ebert, Amaya-Jackson, Markiewicz, Kisiel, & Fairbank, 2012).

The learning collaborative approach has guided numerous community implementations of CPP, including implementation of CPP within wraparound foster care and within the Safe Babies Court Teams Project (i.e., Weiner et al., 2009; Zero to Three, 2014). The CPP development team also recently released a package of fidelity instruments designed to measure fidelity to process and content. Specific procedures are prescribed for the assessment and engagement phase of treatment, with the later phase of treatments tailored to the needs of the dyad (Ghosh Ippen, Van Horn, & Liberman, 2012).

The learning collaborative approach has also guided community implementations of the ABC program with multiple child-serving agencies in North Carolina (Appleyard Carmody, Dozier, Amaya-Jackson, Murphy, & Alvord, 2013). The ABC manual prescribes specific content for particular sessions, and there are specific fidelity requirements. These requirements center on both the frequency and foci of the parent coach's in-the-moment commenting (e.g., one comment per minute, focusing on the program's

target parenting behaviors). These concrete fidelity markers inform not only training and supervision practices but also parent coach selection processes. For example, Dozier and her colleagues have used a screening instrument that includes asking prospective parent coaches to make in-the-moment comments in response to video clips of mother–child interaction. A study of 16 prospective parent coaches found that the quality of their in-the-moment comments during screening predicted the quality of their commenting during actual ABC sessions (Meade, Blackwell, Roben, & Dozier, 2013).

With regard to *family culture and belief systems*, the developers of CPP have long emphasized the importance of attending to the role of culture in defining nuclear and extended family dynamics, acceptable help-seeking behaviors, and family–community relationships, all factors that inevitably influence the alignment of an attachment intervention’s aims and any family’s uptake of that intervention (e.g., Lieberman & Van Horn, 2008). Initial qualitative findings from Berlin and her colleagues’ ongoing randomized trial of Early Head Start plus ABC support this point (Denmark et al., 2014). Because over 80% of study participants are Latinas who were not born in the United States, mothers were queried specifically about the fit between their culture(s) and ABC program objectives. Mothers highlighted the value of having Latina parent coaches, especially when addressing the program’s behavioral target of following the child’s lead, which, while appealing, ran counter to many mothers’ own upbringings.

With regard to *community collaboration*, we emphasize here the importance of communication and support among multiple stakeholders for strong implementation and sustainability of attachment-based programs in the community. Stakeholders often include multiple parties from different disciplinary backgrounds and professional cultures, and with differing agendas and constraints (e.g., university-based researchers, community practitioners, agency administrators, local funders). A lengthy trust-building period is often required, as is a demonstrated willingness to compromise. One example of an area in which to compromise is the selection of outcome measures. In our experience, whereas university-based researchers pursue numerous and often nuanced program outcomes, community agency personnel and local funders are most interested in basic public health and child welfare indicators, such as rate of children in foster

placements, or rates of children referred for special needs services, both of which have large financial implications for local and state governments. An early-stage discussion of outcome measures could incorporate plans for both types of data. In short, as Toth and Gravener noted (2012, p. 135), both implementation and sustainability require “commitment across systems and the ability to recognize and build on the strengths of diverse organizations.” We encourage both researchers and practitioners interested in the community implementation of attachment-based interventions to attend carefully to such commitments.

Conclusion

Our revisiting of the topic of attachment-based interventions for this third edition of the *Handbook of Attachment* has both illustrated significant progress and led to a number of suggestions for the continued development of the field. Whereas virtually all attachment interventions are based on the transmission model, Belsky’s differential susceptibility framework has been especially valuable for improving understanding of mechanisms of influence in early attachments and variation in intervention effects. Four attachment-based intervention programs have amassed a strong evidence base: CPP, the ABC program, the VIPP program, and the COS program. The evidence indisputably demonstrates the effects of attachment interventions on both promoting the development of attachment security and preventing or altering attachment insecurity, in addition to other outcomes. Three of these four programs are being implemented in community settings, often in the context of broad-based social service systems. The learning collaborative approach, enacted to date with the CPP and ABC programs, offers one promising avenue toward ensuring and sustaining high-fidelity, community-based program implementation. The impressive evidence supporting attachment interventions has helped to galvanize policy initiatives for early child development. Maintaining a “place at the table” among such initiatives for attachment-based interventions will require continued careful attention to fidelity, family culture and belief systems, and community collaboration. At the same time, rigorous research must continue to elucidate the role of early attachments in human development and how best to support them.

Chapter 33

Attachment and Adult Psychotherapy

Theory, Research, and Practice

Arietta Slade

Attachment theory evolved from John Bowlby's (1969/1982, 1973, 1980, 1988) elegant and parsimonious conceptualization of the nature and function of human attachment. His influence on the field of developmental psychology became apparent in the 1960s, largely as a result of the work of his colleague and friend Mary Ainsworth (Ainsworth, Blehar, Waters, & Wall, 1978; for reviews, see Karen, 1998; Slade & Holmes, 2013). However, despite the fact that Bowlby was a psychoanalyst and psychotherapist, his work was largely ignored by clinicians and clinical researchers for decades. Writing in 1988, Bowlby expressed his dismay at this state of affairs:

It is a little unexpected that, whereas attachment theory was formulated by a clinician for use in the diagnosis and treatment of emotionally disturbed patients and families, its usage hitherto has been mainly to promote research in developmental psychology. Whilst I welcome the findings of this research as enormously extending our understanding of personality development and psychopathology, and thus as of the greatest clinical relevance, it has none the less been disappointing that clinicians have been so slow to test the theory's uses. (pp. ix–x)

The reasons behind what Bowlby rightly described as the failure of clinicians to embrace his

work are complex (see Holmes, 1993, 1995), and to a large extent this situation has changed considerably over the past 25 years. Beginning in the early 1990s, but particularly in the last 15 years, researchers and clinicians working from a variety of perspectives have (to paraphrase Bowlby) *tested the theory's uses* in a number of ways. Thus, whereas there was hardly any research on attachment and psychotherapy in 1990 (save Mary Dozier's groundbreaking study, published that year), there is today a considerable research literature in this area. Likewise, whereas in 1990 it would have been fair to say that most clinicians were largely unaware of attachment theory, and even less aware of its relevance to their work, it is equally fair to say that the situation is largely reversed today. And yet, as I hope to make clear in this chapter, there is still a great deal of work to be done to truly realize Bowlby's vision.

When I set out to prepare this chapter, my goal was primarily to update the one I had written for the 2008 *Handbook of Attachment*. However, perhaps because I had reviewed a number of classic articles in attachment theory, research, and clinical practice for a collection compiled with Jeremy Holmes (Slade & Holmes, 2013), I now read the literature through a different lens. What I began to see was that many tests of attachment theory's use

in psychotherapeutic research and practice over the last 25 years have been limited in significant ways.

On the *research* side, this has been—until very recently—reflected in the relative absence of outcome measures sensitive to the dynamically meaningful and theoretically predictable differences among secure, avoidant, preoccupied, and unresolved/disorganized patients¹ in their patterns of relating and of regulating affect (for reviews, see Daniel, 2006; Mikulincer, Shaver, & Berant, 2013; Steele, Steele, & Murphy, 2009), particularly within the often emotionally arousing context of psychotherapy. These differences are of utmost importance clinically because the course and outcome of treatment, as well as the technical demands for treating secure, avoidant, preoccupied, and unresolved/disorganized patients, are quite distinct (Holmes, 2001; Slade, 2000; Wallin, 2007). However, these differences are evident only as trends in the research literature, the net result being that the only clear and unsurprising conclusion is that insecure attachment (both the patient's and the therapist's) makes for a more problematic course in psychotherapy. Fortunately, as I describe below, Sarah Daniel, Alessandro Talia, and their colleagues (Daniel, 2006, 2009, 2011, 2014; Talia et al., 2014) have begun to publish work that transcends these trends in crucial ways, moving the study of attachment and psychotherapy research to what they refer to as “the level of the relation” (Talia et al., 2014). As I outline below, this refers to the impact of attachment organization on the dynamic relationship between patient and therapist, specifically the ways the patient's discourse elicits, maintains, or disrupts emotional proximity with the therapist.

On the *clinical* side, these limitations have been manifest in a surprising lack of depth in the way attachment constructs are applied to the clinical enterprise. On the face of it, attachment is a dominant construct in the theory and practice of psychotherapy today (there were 4.3 million results of a Google search of “attachment and psychotherapy”). This would include not only dynamic psychotherapy, but also more behaviorally oriented therapies (e.g., attachment is an important concept in Linehan's [1993] dialectical behavior therapy, or DBT). But what many clinicians mean by the term *attachment* and what Bowlby and his followers mean by it are quite different. The vast majority of clinicians use the term *attachment* as a way of talking about the early mother-child relationship. Although this is to a certain extent

accurate, using the term in this way robs it of the evolutionary, motivational contexts that were so central to Bowlby's thinking. For Bowlby, the term *attachment* referred to a dynamic relational system that is activated by threat, shaped by interaction with the caregiving environment, and powered by the instinct to survive, on multiple levels (Slade, 2014). Thus, the assumption that *attachment* is shorthand for *relationship* is both incorrect and incomplete. There are other clinicians who do in fact describe patients in terms of their purported attachment organizations, but often these simply become another form of diagnosis uncoupled from a discussion of more dynamic processes and outcomes. I would think of these as *flirtations* with attachment rather than the love affair that would be implied by over 4 million Google hits.

At the same time, there is a core group of writers who eschew the generic use of the term *attachment*, and who write about psychotherapy and about their adult patients in ways that are deeply *attachment informed*. This work began to take shape in the 1980s, when Mary Main's work (Main, Kaplan, & Cassidy, 1985) captured the imagination of the psychoanalytic establishment, and “attachment” returned to its original home after years of exile. In 1987, Larry Aber and I gave a talk to a predominantly psychoanalytic audience on the clinical implications of attachment theory (Slade & Aber, 1992). The large auditorium was packed, with more than a few psychoanalytic luminaries in the audience. Nevertheless, the questions at the end of the day suggested that curiosity and acceptance were still very far apart. “How could a 30-minute procedure tell us anything about the complexity of a child's internal life?” (This from clinicians who were fully prepared to accept the validity of another, relatively brief, procedure, the Rorschach.) “What about the drives?” “What about the unconscious?” And most memorably, “What does Mary Main think about sex?” Over the next decade, however, this resistance, which was initially focused on the nondynamic nature of classification, began to give way, and attachment theory slowly began to take hold of the imaginations of clinicians working from a psychodynamic perspective.

The most prolific and influential of these is certainly Jeremy Holmes (1997, 1998, 2001, 2004, 2009, 2014), who—as Bowlby's biographer—has been studying attachment since he began his psychiatry training in the 1960s. Others in this group include Sarah Daniel (2009, 2014), Morris Eagle (2013), Peter Fonagy and his colleagues Mary

Target and Anthony Bateman (2001; Bateman & Fonagy, 2009; Fonagy & Target, 1996), Karlen Lyons-Ruth (Lyons-Ruth, 1999, Lyons-Ruth, Dutra, Schuder, & Bianchi, 2006), Pat Sable (2000), Howard and Miriam Steele (2008), David Wallin (2007), and myself (1999, 2004a, 2004b, 2014). Sue Johnson's work (2008) on attachment processes in couple therapy also belongs in this group (see Brassard & Johnson, Chapter 35, this volume). A number of important additional contributions to the literature on attachment-informed psychotherapy practice have been compiled in three volumes published in the last decade: Oppenheim and Goldsmith (2007); Steele and Steele (2008), and Obegi and Berant (2009).

It is important to note that none of these clinicians see attachment classifications as *defining* patients. From a clinical perspective, classifications are less relevant than the dynamics that underlie them and the defenses that these evoke; that is, thinking about attachment "*informs* rather than *defines* intervention and clinical thinking, and offers a broad and far-reaching view of human functioning that has the potential to change the way clinicians think about and respond to their patients, and the way they understand the dynamics of the therapeutic relationship" (Slade, 2008, p. 763, emphasis added).

This review and critique is organized around the questions that have dominated the research and clinical literatures, albeit in different ways. The first question is whether a *patient's* attachment organization or style affects the process and outcome of treatment. That is, does the patient's attachment affect the nature of the therapeutic alliance, the transference, the capacity to engage in the process of psychotherapy, or symptom remission? The second question is whether the *therapist's* attachment organization or style affects the process and outcome of treatment, and the third is whether treatment should be tailored to a patient's attachment organization. The final question is whether attachment organization or style can be changed by psychotherapy. Here, attachment is the *target* of change (rather than the predictor of change).

Each of these questions is based on a single key assumption: Psychodynamic psychotherapy—by virtue of its emphasis on the therapeutic relationship and on discovering or recovering memories and affects from the past and in the present—inherently activates an individual's attachment system. It requires that the patient form a relationship with the "stronger and wiser" thera-

pist (which will have multiple levels of meaning and functions), that the patient remember elements of his or her early experiences with parents or caregivers, and that the patient confront intense and presumably negative feelings in relation to both past and present experiences with significant others. Each of these circumstances would be expected to trigger attachment-related patterns of defense and affect regulation in the patient (and, as we shall see, the therapist), even if (as in some behavioral therapies) transforming these is not an explicit goal of treatment.

I write this chapter not only as an attachment theorist and researcher, trained in both the Strange Situation (Ainsworth et al., 1978) and the Adult Attachment Interview (AAI; George, Kaplan, & Main, 1996), but also as a dynamically oriented psychotherapist with 40 years' experience working with a broad array of patients, teaching assessment and psychotherapy, and supervising clinicians at all levels of experience. Although I am reasonably acquainted with other forms of therapy, and—like most experienced therapists—do at times incorporate various adjunctive methods in my work, my lens is (primarily) long-term work with patients that assumes a link between past experience and present psychological organization.

I begin with a background section laying out the historical contexts for the study of attachment and psychotherapy. This will be followed by an exploration of research and clinical "answers" to each of the four questions posed earlier. Because of the complex nature of both the research and clinical literatures in this area, I focus here primarily on research. In the concluding sections, I suggest directions for future integrative research and practice.²

Attachment Theory: Dynamics and Classifications

Bowlby introduced attachment theory over the course of 30 years, beginning with his paper on juvenile thieves in 1944. By 1980, when the final volume of his trilogy was published, attachment theory had evolved as a complex motivational and dynamic theory of development and personality (Bowlby 1969/1982, 1973; see Cassidy, Chapter 1, this volume). Attachment theory was from the start deeply grounded in evolutionary theory and, as such, Bowlby viewed much of human development in light of the individual's instinct to sur-

vive. He described a number of key biological systems designed to ensure this. Of these, he saw the attachment-behavioral system as primary, in that it establishes the social relationships essential both to immediate survival in infancy and to the proper functioning of other key biological systems—the exploratory system, the affiliative system, the sexual/reproductive system, and the caregiving system. Bowlby described these systems as *inherently dynamic*, each being in a state of “activation” or relative “deactivation.” Thus, for example, when a child needs care (either because of external threats, illness, or exhaustion), the attachment-behavioral system will be activated, and the child will signal a “stronger and wiser” caregiver, and (in whatever way development to that point allows) seek proximity. When the child feels safe, or the immediate needs are met, the attachment system will be relatively “deactivated,” and the child will feel free to explore the environment, again in whatever way is developmentally possible. At the same time, it is important to note that—for critical evolutionary reasons—the attachment system itself is never fully deactivated; rather, attachment *behavior* is deactivated (Bowlby, 1969/1982).

Equally crucial in Bowlby’s thinking was another dynamic construct, that of adaptation. He believed that an individual will *adapt* in whatever way is necessary to ensure safety, and to maintain the relationships that are key to emotional and physical survival. Thus, if a mother cannot tolerate her infant’s needs, the infant will learn to express them in ways that she can tolerate. Finally, Bowlby saw the relationship between caregiver and infant as *dynamic*, in that the infant’s response shapes that of the mother, who in turn shapes that of the child, and so on. This dynamic interaction is ultimately *internalized* by the child, and forms what Bowlby called “internal working models of attachment.” Mary Main and her colleagues (1985) aptly link internal working models to the dynamic “attempts and outcomes” (p. 75) of the child’s search for safety. Thus, *relational* patterns, including both sides of the relationship (Sroufe & Fleeson, 1986) are internalized.

These ideas, grounded in dynamic systems theory and ethology, gave rise to the idea of attachment *patterns*. Over time, Bowlby suggested that individuals—as a function of their lived experience in their primary relationships—are likely to develop *characteristic* ways of responding to their internal experience, and *characteristic* ways of seeking care and closeness from important others. These are typical *ways of being in relation* to

significant others, and of ensuring that vital relationships can be maintained and one’s relative safety is ensured. In this way, attachment patterns serve *particular interpersonal functions* with respect to attachment: to maintain closeness and allow for autonomy (security); to maintain distance (avoidance); to ensure negative proximity (preoccupation); or to preserve safety in the face of interpersonal danger (unresolved/disorganized). Insecure organizations also serve defensive functions, in that they protect the individual from feelings or thoughts that might threaten the attachment relationship (Bowlby, 1969/1982).

Bowlby’s work laid the foundation for the tripartite classification system formalized by Mary Ainsworth’s study of mother-infant attachment (Ainsworth et al., 1978) and Mary Main’s study of adult attachment (Main et al., 1985), both of which outlined three major “organized” patterns: secure, avoidant/dismissing, and resistant/preoccupied. Some years later, disorganized infant and unresolved adult patterns were introduced (Main & Hesse, 1990; Main & Solomon, 1990).³

The study of classifications led to a subtle shift away from Bowlby’s original dynamic model. Whereas dynamic and interpersonal functions are clearly *implied* in each of the organized and disorganized patterns (indeed, Main calls them “states of mind”), researchers and even clinicians often refer to attachment classifications or styles as if these are static attributes of an individual. This tendency persists despite the fact that both the Ainsworth and Main classification systems are based on evaluation of a range of dynamic and interrelated processes that are triggered by the activation of the attachment system. For example, in the Strange Situation, it is not proximity seeking per se that is crucial for classification, but when, how, and why it occurs. It is the *pattern* of proximity seeking relative to other behaviors that is relevant to classification. Likewise, in the AAI, incoherence occurs in particular ways and in response to particular questions; these distinctions are key to scoring. It is the *pattern* and type of incoherence that reveal meaningful differences among insecure organizations. Each pattern serves distinct, interpersonal, and defensive functions that are triggered when the attachment system is activated. Thus, it is crucial to remember that attachment classifications and styles refer to dynamic interpersonal processes, and not static internal (trait-like) characteristics. *It is the dynamic nature of attachment orientations that offers the promise of change through psychotherapy.*

Attachment and Psychotherapy: A Look from Both Sides

Issues of Method

There are two distinct strands of research in studies of attachment and psychotherapy: one relies on paper-and-pencil assessments of attachment style or orientation, while the other relies on in-depth assessment of attachment organization using the AAI. While these two methods are in some sense complementary, they are not one and the same. This makes it more difficult to compare findings across studies and adds another layer of complexity to an already multifaceted field.

The bulk of research on attachment and psychotherapy process and/or outcome assesses adult attachment using one or more of a set of related instruments to measure “global” attachment style: the Relationship Styles Questionnaire (RSQ; Griffin & Bartholomew, 1994) and the Experiences in Close Relationships scale (ECR; Brennan, Clark, and Shaver, 1998). The RSQ gave rise to the ECR, and both are brief, self-report questionnaires that can be administered in under 20 minutes, yielding a score on two dimensions: anxiety and avoidance. An individual’s “attachment style” refers to the degree to which attachment-related anxiety or avoidance is a prominent feature of expectations regarding close relationships. Although both dimensions can be analyzed continuously, both can also be scored categorically. Individuals who score high on avoidance and low on anxiety are considered “avoidant”; those who score high on anxiety and low on avoidance are considered “anxious”; and individuals high on both dimensions are described as “fearful avoidant.” The key difference between the anxiety and avoidance dimensions concerns the strategies subjects report using to manage a variety of attachment-related threats. Whereas the psychotherapy research literature includes studies based on other questionnaire or Q-sort assessments of attachment style, the RSQ and ECR are by far the most prevalent instruments in this area.

These instruments, and the picture they yield, are distinct from the assessment of “attachment organization” using the AAI (George et al., 1996). This is an hour-long, 16-question, in-depth interview that leads to a verbatim transcript for scoring. It takes an experienced coder an average of 2 hours to score each AAI. The AAI yields attachment classifications of secure-autonomous;

insecure-dismissing; insecure-preoccupied; and a fourth classification, insecure-unresolved. This fourth classification can either be scored as a second classification in a forced three-way solution (i.e., secure, dismissing, or preoccupied individuals can also be unresolved in relation to loss or trauma, with “U” scored as a secondary classification), or as a classification in its own right in a four-way solution. While this is an enormously rich instrument that has tremendous face validity for clinicians, it is important to note that the AAI is used almost exclusively to yield attachment categories, and therefore does not distinguish among *degrees* of avoidance, preoccupation, or disorganization. Although severity is to some extent reflected in subclassifications, these have never been used in psychotherapy research. The absence of an assessment of degree is unfortunate because if we think of attachment classifications as manifestations of different ways of managing intense, attachment-related affects, and of defending against those that might threaten vital relations, the flexibility and or rigidity of any defense is crucial. There are the “wounded well” who use organized insecure defenses in reasonably successful ways, in contrast to the deeply disturbed, who rely on them in rigid and primitive ways.

Although it might seem that measures of attachment style and organization assess similar aspects of “attachment,” and that results would appear be comparable across studies, the results of a recent meta-analysis (Roisman et al., 2007) indicate that, in fact, these measures converge only slightly, suggesting that they are measuring distinct phenomena and should not be conflated. Psychotherapy researchers working with large samples have understandably tended to use the RSQ and ECR because of their ease of administration and scoring, and the analytic flexibility that is afforded by a continuous rather than categorical measure. These instruments also permit the evaluation of dynamic change. Yet these instruments lack the potential for deeper examination of attachment-related psychological processes that is provided by the AAI. The fact that the increasingly complex research literature on attachment and psychotherapy is based on two quite different measures, with much conceptual but little methodological overlap, complicates the interpretation of many findings and makes the translation of research for clinicians even more difficult.

A related issue of method is that studies of patients in very diverse settings and with dramatically different levels of functioning and

psychopathology (college counseling centers, inpatient units, residential treatment centers) are often lumped together for the purpose of meta-analysis. Not only are these groups quite different from one another, but also it is likely that attachment orientations or organizations manifest themselves in different ways depending on overall level of functioning. In this context, the degree of avoidance, preoccupation, or disorganization becomes especially crucial. Going forward, more nuanced thinking about both levels of psychopathology, as well as the interrelationship between psychopathology and attachment processes, is necessary.

I now turn to an examination of the four questions outlined earlier. I ground these questions in the 2001 report of the American Psychological Association Division 29 Task Force on Empirically Supported Treatments (Ackerman et al., 2001). These American Psychological Association guidelines are directly relevant both to general questions of contemporary psychotherapy research and practice, and to the particular importance of attachment processes in psychotherapy.

Does a patient's attachment organization or style affect the process and outcome of treatment?

In 2001, the American Psychological Association Division 29 Task Force on Empirically Supported Treatments concluded that “the therapy relationship makes substantial and consistent contributions to psychotherapy outcome independent of specific type of treatment” (Ackerman et al., 2001, p. 495). This is entirely consistent with the belief held by most experienced therapists that the *therapeutic* relationship with a patient is essential to successful outcomes, and that the corrective emotional experience provided by the therapist is itself a potent agent for change.

Attachment theory would, of course, predict that the capacity to form a trusting relationship with a therapist will be determined, at least in part, by the patient's attachment organization. Attachment theory would also predict—particularly for insecure individuals—that the vulnerability and therefore the threat inherent in forming a therapeutic relationship is likely to activate the attachment system in a variety of ways, revealing distinct patterns of defense and interpersonal relatedness.⁴ Indeed, activation of the attachment system within the confines of good psychotherapy

is a *sine qua non* of a successful treatment because it offers the possibility for change, adaptation, and thus transformation.

Mary Dozier's 1990 study was one of the first to examine the impact of attachment on psychotherapy. She assessed the attachment organization of 40 individuals with schizophrenic or bipolar mood disorders using Kobak's Q-set methodology for scoring the AAI (Kobak, Cole, Ferenz-Gillies, & Fleming, 1993), which yields ratings of deactivation–activation, as well as security–anxiety (and in this sense is conceptually similar to the RSQ and ECR). She then collected clinician ratings of patient compliance, help seeking, self-disclosure, and general treatment use. She found that clinician ratings of treatment compliance were associated with the secure dimension of attachment, whereas patients who were more avoidant were less likely to seek help from their therapists, less likely to comply with treatment, and less likely to make productive use of treatment. More preoccupied patients were more likely to self-disclose than those scoring high on the avoidance dimension. This pioneering study confirmed attachment theory's assumptions about the value of a secure orientation in promoting a helping relationship. Also, because many of the outcomes were designed to detect theoretically meaningful differences in the behavior and attitudes of avoidant and preoccupied patients, the study also offered the first hints as to how these two insecure organizations might differentially affect process and outcome in psychotherapy.

Patient Attachment and the Working Alliance

Psychotherapy researchers have long used measures of what is termed the *working* or *therapeutic* alliance to assess the strength of the patient–therapist relationship. Following Dozier (1990), the first wave of research on attachment and psychotherapy focused on the relation between an individual's global orientation to attachment and the strength of the working alliance, using a range of attachment assessments, including the AAI and ECR (and its variants), as well as other questionnaire-based measures of attachment style. A recent meta-analysis of 17 of these studies (Diener & Monroe, 2011) indicates that a patient's attachment style (only one study used the AAI) predicts the quality of the alliance. Patients with secure attachment styles are more likely to have stronger alliances, whereas those with insecure attachment

styles are likely to have weaker alliances. Neither attachment anxiety nor attachment-related avoidance (as variously measured) differentially predicted the weakness of the alliance. None of the moderation analyses were significant, including those assessing the effects of treatment type, alliance measure, attachment measure, or treatment length. The one difference that did emerge is that patient ratings of the alliance were more strongly correlated with patient attachment style than were therapist ratings of alliance; this presumably reflects the fact that patients are likely influenced by their attachment style in rating their connection to and relationship with the therapist. The effect size of the relation between attachment and working alliance was small to medium ($r = .17$) (Diener, Hilsenroth, & Weinberger, 2009; Diener & Monroe, 2011).

These results confirm the notion that a sense of security allows for closeness in relationships and promotes exploration, curiosity, and reflection, and that insecurity, by contrast, inhibits the development of a healing partnership. But is this anything but a confirmation of what most clinicians and psychotherapy researchers already know—that healthier, more flexible patients do better in treatment, no matter what kind of treatment they receive? And that more rigid, defended, chaotic, or disorganized patients are more difficult to connect with and help? A measure that assesses alliance in a linear way (e.g., all poor alliances are grouped together) at a single point in time is unlikely to reveal anything about the nature of these poor alliances and how therapists might tailor their work to the *particular* weaknesses associated with *particular* forms of attachment insecurity. Given that the bulk of patients in clinical samples are insecure (Van IJzendoorn & Bakermans-Kranenburg, 2009), the need for more nuanced answers is great.

Of the many investigations of attachment and therapeutic alliance conducted over the past 20 years, only two involved investigation of differences between avoidant and preoccupied patients in *patterns* of alliance. Eames and Roth (2000) studied the link between attachment organization and patterns of treatment rupture, and found that preoccupied patients reported more frequent ruptures, whereas dismissing patients reported lower rates of rupture. These patterns are consistent with theoretical predictions that preoccupied patients would be likely to engage with their therapists in more intense and volatile ways, and that dismissing patients would be more

affectively constrained and perhaps less engaged (again in line with their defensive strategies for regulating interpersonal relationships). Parenthetically, this study used a rupture-and-repair methodology that—despite being widely used in psychotherapy research (Safran & Muran, 2003)—has rarely been used in research on attachment and psychotherapy. Because this method permits the identification of specific moments of emotional arousal and defense, its rarity in the attachment literature is unfortunate.

Kanninen, Salo, and Punamaki (2000) examined changes in alliance over time and found that whereas secure patients reported few shifts in therapeutic alliance over the course of treatment, there was a steep drop in therapeutic alliance ratings for preoccupied patients in the middle of therapy, with a steep rise at the end of therapy. Dismissing patients, by contrast, showed a drop in alliance ratings at the end of therapy. Thus, patterns of change in the alliance distinguished avoidant and preoccupied patients.

By focusing on the dynamics of the alliance—of rupture or of change—these two studies allowed researchers to track differences between avoidant and preoccupied patients in their response to the emotional context of treatment and the therapeutic relationship in distinct, theoretically predictable, and clinically significant ways. Preoccupied patients in particular—in a way that is entirely consistent with Ainsworth's observations of insecure/resistant infants (Ainsworth et al., 1978)—appear to be intensely engaged with the therapist but then resist this closeness over the course of treatment.

Patient Attachment and Psychotherapy Outcomes

Several studies have examined whether attachment organization or styles differentially predict outcomes, as measured by reduction in symptoms. In a recent meta-analysis, Levy, Ellison, Scott, and Bernecker (2011) compared results across 14 studies, all of which assessed symptom remission in light of attachment style at the start of treatment; of these, nine studies used the RSQ or ECR, and the rest used a variety of other paper-and-pencil attachment assessments. The results of this meta-analysis indicated that patients scoring high in attachment anxiety showed least remission in symptoms, whereas patients rated as high in attachment security had the most positive outcomes.

Attachment avoidance appeared to be minimally related to treatment outcome. The findings of this meta-analysis again reflect a trend that recurs throughout the research literature, which is quite consistent with theory, namely, that avoidant individuals tend to look less affected by therapy and the therapeutic relationship on a number of fronts, whereas preoccupied individuals tend to have more stormy and intense courses of therapy, and do less well overall.

A small number of studies do suggest that shifts in attachment avoidance may sometimes occur. In one of the studies included in the meta-analysis, Muller and Rosenkranz (2009) studied outcomes of an 8-week group treatment for PTSD, and described treatment outcome as moderated by change in attachment orientation, such that the lessening of both attachment anxiety and attachment-related avoidance over the course of treatment were associated with decreases in overall symptomatology. Thus, if a treatment is successful in lowering avoidance, symptoms may lessen. Fonagy and colleagues (1996) used the AAI to measure the relation between attachment and outcome in a sample of psychiatric inpatients receiving psychoanalytic psychotherapy ($N = 85$). These researchers found that dismissing patients were more likely to show changes in the Global Assessment of Functioning Scale on the DSM-IV than were those who were preoccupied or unresolved/disorganized. In another study that was included in the meta-analysis, McBride, Atkinson, Quilty, and Bagby (2006) likewise found that depressed patients who scored high on avoidant attachment did better than their anxiously attached (i.e., more preoccupied) peers.

Although these results are hardly conclusive, they do align with the view that individuals with preoccupied attachments have the worst outcomes in therapy, whereas the picture is more mixed and ambiguous for those who are avoidant in their attachments. This general trend, indicating a bumpier course in treatment (more ruptures, shifting alliances) and likely poorer outcomes for patients who are preoccupied and unresolved/disorganized is consistent with the finding that these classifications are often linked with borderline personality disorder (BPD) and other severe personality disorders (see Westen, Nakash, Thomas, & Bradley, 2007, for a review), and require treatment that is targeted specifically to their diagnosis (Bateman & Fonagy, 2009; Levy et al., 2006; Linehan, 1993).

The Patient's Attachment to the Therapist

In 1995, research on attachment and psychotherapy took a new turn when Brent Mallinckrodt and his colleagues introduced a method for assessing the quality of the patient's *attachment to the therapist* (Mallinckrodt, Gantt, & Coble, 1995), as distinct from the patient's more general or global attachment organization or style (as measured by the AAI or ECR). The Client Attachment to Therapist Scale (CATS) is a 36-item self-report measure that distinguishes among secure, avoidant-fearful, and preoccupied-merged attachment to the therapist. It is important to note that this three-category model collapses the ECR avoidant and fearful dimensions into a single category, complicating comparison with other measures. In later research, Mallinckrodt and colleagues (2005) documented the specific contribution that the patient's attachment to the therapist makes to the working alliance, over and above global attachment style. In general, this measure is only modestly correlated with global attachment style or organization (Mikulincer et al., 2013), suggesting that global insecurity does not necessarily preclude forming a secure attachment to the therapist, presumably because the therapist defies the patient's expectations of relationships.

ATTACHMENT TO THE THERAPIST AND THE WORKING ALLIANCE

In their initial research, Mallinckrodt and his colleagues (1995) found that secure attachment to the therapist on the CATS predicted a strong working alliance; this finding has been replicated in a number of subsequent studies (see Mikulincer et al., 2013). In related work, Gelso and his colleagues (Fuertes et al., 2007; Marmarosh et al., 2009) found that patients' positive feelings about the real relationship with the therapist were correlated with secure attachment to the therapist and a stronger working alliance. Once again, these results shed little light on the differential impact of avoidant and preoccupied attachment to the therapist on the clinical process.

Several of the findings in Mallinckrodt and his colleagues' (1995) original study do, however, point to important differences in these two insecure groups. Consistent with prior research, they found that avoidant attachment to the therapist was associated with a poor alliance. Interestingly, they also found that patients whose attachment to the therapist was judged to be preoccupied rated

their alliance with the therapist as strong, as did those with secure attachments. This finding raises a crucial question: Are these apparently equally “strong” attachments the same?

Research by Woodhouse, Schlosser, Crook, Ligiero, and Gelso (2003) raised a similar set of questions. These researchers examined the relation between a patient’s attachment to his or her therapist and therapist ratings of the patient’s negative and positive transference, namely, the patient’s tendency to project his or her own interpersonal expectations and childhood fantasies onto the therapist. Avoidant/fearful attachment to the therapist was unrelated to any aspect of transference. And, contrary to their predictions, there was no connection between a patient’s secure attachment to the therapist and the positive transference. Rather, secure attachment was related to both the negative transference and the overall amount of transference. In other words, secure attachment to the therapist allowed room for a powerful and even negative transference to emerge. Most important, however, and consistent with the findings of Mallinckrodt and colleagues (1995), preoccupied/merged attachment to the therapist was *also* strongly correlated with negative transference and amount of transference.

In both studies, secure and preoccupied attachment patterns look superficially alike; both types of patients feel connected to the therapist and have powerful feelings about him or her. But to return again to the question of dynamics, although we would expect patients with both secure and preoccupied attachments to the therapist to have intense feelings during the treatment, particularly negative ones, *the meaning and interpersonal function of these feelings would be entirely different.* The securely attached patient would feel free to express negative feelings about the therapist without fear of retribution, and would expect appropriate coregulation. The preoccupied patient would know of no other way to experience closeness than through heightened negative affect (Cassidy, 1994) and efforts to control these feelings through resistance. Thus, the outcomes are different for the two groups, despite some apparent similarities in their experience of the transference. In other words, it is quite likely that the *fate* of both negative transference and overall transference would differ for secure and preoccupied patients; also, we would expect the patients’ capacity to reflect on the meaning of the transference to differ considerably, as would the flexibility and/or intractability of transference feelings.

ATTACHMENT TO THE THERAPIST AND THE DEPTH OF ENGAGEMENT

Two studies (Romano, Fitzpatrick, & Janzen, 2009; Saypol & Farber, 2010) have linked secure attachment to the therapist to the capacity to explore significant issues in psychotherapy, whereas avoidant attachment to the therapist was linked to less self-disclosure and meaningful exploration. Related to this work is a recent study by Janzen, Fitzpatrick, and Drapeau (2008), in which reports of emotionally charged moments, even after a short period in therapy, were linked to increases in avoidant patients’ experience of security in relation to the therapist, and appeared to enhance their feeling that the therapy was helpful. Avoidant patients appear to be more likely to engage when their concerns about closeness are somehow addressed. Thus, as in the Eames and Roth (2000) and Kanninen and colleagues (2000) studies described earlier, these researchers attempted to focus on transformational moments within the therapy and to link these in a meaningful way to attachment. For clinicians, these shifts are where attachment issues reveal themselves dramatically and where change is most likely to occur.

As I hope I have made clear, despite the fact that a number of researchers have examined the relation between a patient’s attachment orientation and the process and outcome of psychotherapy, the only clear outcome to emerge thus far is that secure patients do better in psychotherapy and insecure patients do more poorly. The small number of studies that *have* detected meaningful differences among secure, avoidant, and preoccupied patients—in their patterns of response to the therapist and to the therapeutic process—have typically relied on more novel methodologies that allow for the assessment of change in the alliance over time, patterns of rupture, the study of critical incidents, and so forth. These kinds of methodologies allow researchers to examine *dynamic relational processes* in the treatment, namely, what happens when the attachment system is activated (via ruptures, critical incidents, etc.), either over the course of a single session or over the course of a treatment. It is in these contexts that we are most likely to see attachment defenses triggered and change is most likely to occur. When does change happen and in what context? Can these changes be understood in light of attachment? One-time assessments using linear outcome measures (e.g., the working alliance, self-disclosure) make it difficult to detect the patterns that reveal the “coher-

ence of individual development” (Sroufe, 1979). Unless outcomes are considered in relation to each other (i.e., as patterns), it is very difficult to detect differences between avoidant and preoccupied strategies.

The Clinical Perspective

In rather sharp contrast to the relative ambiguity of the research literature regarding the differential effects of avoidant and preoccupied ways of relating and being, there is a small body of writing about the clinical utility of attachment theory and classification in thinking about and organizing psychotherapeutic material. In myriad ways, attachment processes are seen as providing vital clues to understanding shifts in alliance, degrees of engagement, the evolving attachment to the therapist, and an individual’s capacity to change. Although few clinicians routinely administer the AAI (but see Steele & Steele, 2008) or are indeed trained in either the AAI or the Strange Situation procedure, the distinctions among avoidant, preoccupied, and unresolved/disorganized patterns have enormous face validity for clinicians. As I have described elsewhere (1999, 2000, 2007, 2014), thinking about and listening for attachment dynamics and themes helps me find metaphors and language that are experience-near for patients, encompass the nature of both defenses and treatment ruptures, make sense of relational patterns, and provide an imaginative picture of early experiences of seeking and receiving care. The differences among the narratives of avoidant, preoccupied, and unresolved/disorganized adults are striking (also see Daniel, 2009, 2014; Holmes, 1997, 1998, 2004, 2009), and alert the clinician in powerful ways to moments when the attachment system is activated or deactivated. These moments also tell us a great deal about an individual’s vulnerability to threat and defense (Slade, 2014), and as such offer significant opportunities for change and reorganization.

Although rarely the focus of research, the unresolved/disorganized category has been particularly meaningful to clinicians and provides a useful entrée into thinking about the long-term sequelae of unresolved fear and trauma. Giovanni Liotti (2004) has been making important contributions in this area for over 20 years. His suggestion that disorganized attachment in infancy might well lead to dissociative processes in adults inspired Main and Hesse (1990) to study the link between maternal frightened and frightening behavior and

infant disorganization. Karlen Lyons-Ruth has also been a major contributor in this area, tracking the long-term sequelae of atypical maternal behavior, and in particular the multiple clinical and developmental consequences of the “hostile–helpless” diathesis in setting the stage for severe pathology in later life (see Holmes, 2004; Lyons-Ruth & Jacobvitz, Chapter 29, this volume; Slade, 2007;). Of particular note is Lyons-Ruth and colleagues’ astute observation regarding the complexities of working with patients who are unresolved/disorganized in relation to attachment:

The resolution of discrete traumatic events in treatment may come about more quickly than the resolution of long-standing patterns of role-reversal, disorientation, and disrupted forms of affect communication in the transference. Among dissociative young adults, current research suggests that disrupted communication patterns with attachment figures tend to be a subtle and implicit part of dyadic interaction from a very early age, and therefore, may be extremely difficult for the patient to articulate until forms of a healthier and more genuine implicit and explicit dialog around heightened affective experiences are worked out in the therapeutic relationship. (p. 82)

This observation makes it clear why these difficulties, which are challenging to track in clinical work, present major challenges for researchers.

Does the therapist’s attachment organization affect the process and outcome of treatment?

The second conclusion of the American Psychological Association Division 29 Task Force is as follows: “Practice and treatment guidelines should explicitly address therapist behaviors and qualities that promote a facilitative therapy relationship” (Ackerman et al., p. 495). Thus, the task force not only placed particular importance on the therapy relationship, but it also placed the responsibility for the formation and maintenance of this relationship squarely on the shoulders of the therapist. As is clear from the previous sections, we know that the bulk of patients will be insecure, making it likely that they will struggle in some way or other to form a solid alliance and working relationship. This makes the therapist’s capacity to build relationships despite the challenges of a patient’s insecurity all the more important. From an attachment perspective, not only is the patient’s

attachment organization relevant to outcome, *so is the therapist's*. Therapists who are able to provide a secure and safe base for their patients, to remain emotionally present and compassionate while managing complex and potentially intense affects within a therapy session, are likely to be those who best facilitate their patients' development.

Again, it was Mary Dozier who opened the door to studying how therapists' attachment organization affects outcomes (Dozier, Cue, & Barnett, 1994). Dozier assessed the attachment organization of the 18 case managers who had provided treatment to the patients described in her 1990 study. She coded the clinician AAIs using Kobak and colleagues' (1993) Q-set; the patients' AAIs had also been classified using this method. Dozier found that a therapist's security predicted her ability to "respond therapeutically to the individual needs of her clients" (Dozier et al., 1994, p. 798). A number of studies have since confirmed that security in the therapist is correlated with the strength of the working alliance and patients' experience of being helped by the therapy (for reviews, see Daniel, 2006; Mikulincer et al., 2013).

But Dozier's research took the issue of therapist attachment one crucial step further: She examined how therapist attachment style *interacts* with that of the patient (here, again, we see her dynamic and deeply attachment-informed perspective). What she found was that secure therapists are able to work flexibly with patients, regardless of their attachment style, whereas insecure therapists are more inclined to get sidetracked by the patient's defenses and respond to them in non-therapeutic ways. In particular, whereas insecure therapists responded to what was *apparent or manifest* in patient communications, secure therapists were able to recognize and respond to *underlying* (and presumably more disruptive) feelings and needs. Thus, secure therapists responded to dependency needs in dismissing patients, and were more autonomy promoting with preoccupied patients. Insecure therapists, by contrast, were much more likely to "perceive greater dependency needs and intervene more intensively with clients who are preoccupied than they are with those who are dismissing" (Dozier et al., 1994, p. 798). In other words, insecure therapists are likely to heighten and magnify patient defenses rather than explore the needs that are *provoking* attachment-related defenses, presumably because of the ways the patient activates their own defenses and anxieties. Dozier and colleagues' (1994) findings have been replicated and expanded in studies published over

the past 15 years (Petrowski, Nowacki, Pokorny, & Buchheim, 2011; Romano, Janzen, & Fitzpatrick, 2009; Tyrrell, Dozier, Teague, & Fallot, 1999). As we shall see, study of the interaction between patient and therapist attachment has important implications for the question of how therapists should respond to signs of avoidance and anxiety in their patients.

Unlike the literature on attachment and both therapy process and outcome, this literature quite explicitly outlines the differences between the ways avoidant and preoccupied patients defend themselves against their needs for closeness and autonomy within the activating context of psychotherapy. These differences are found to have differential effects on therapists, who, like their patients, defend against affect and relatedness within the activating context of psychotherapy in theoretically predictable ways. Thus, the literature on the therapist's attachment classification is inherently a much more dynamic research literature, with much clearer implications for clinical training, supervision, and practice.

The Clinical Perspective

With the exception of Holmes (1998, 2001) and Wallin (2010), clinical writers have had surprisingly little to say about how a therapist's attachment organization or style affects the process and outcome of psychotherapy. This omission is particularly striking given that the notion of countertransference has its roots in classical psychoanalytic theory. The importance of countertransference is implicit in the directive to young clinicians to pursue both personal treatment and supervision, yet explicit consideration in case studies of the impact of the therapist's own defenses and anxiety has been notably absent from the clinical literature (even relational psychoanalysis, with its intersubjective focus, seems to skirt these issues). Given the highly robust research finding that the therapist's attachment style has an effect on both process and outcome, and provides explicit evidence for the *relational nature* of attachment processes, this omission is particularly unfortunate.

Should psychotherapy be tailored to the patient's attachment organization?

For reasons that should by now not be surprising, the American Psychological Association Division 29 Task Force on Empirically Supported

Psychotherapy concluded in 2001 that “current research on [attachment] is insufficient for a clear judgment to be made on whether customizing the therapy relationship to these [attachment] characteristics improves treatment outcomes” (Ackerman et al., 2001, p. 496). However, evidence gathered since then suggests that there may well be value—once the therapeutic relationship has been established—in tailoring the treatment process to the patient’s predominant attachment style or organization. In particular, research suggests that there is value in responding “against” the patient’s attachment style, and that the ability to do so is likely a reflection of the therapist’s own attachment organization. Much of this research is attachment-informed in the sense that it is based on the assumption that avoidant and preoccupied patients have “typical” ways of defending against and regulating affect and relationships, and that these patterns or styles of relating have distinct implications for practice.

Researchers originally suggested that therapists are inclined to respond with more cognitive interventions (interpretations and suggestions) with dismissing/deactivating patients, and with more affective interventions (reflection of feelings, empathy) to more preoccupied/hyperactivating patients (Rubino, Barker, Roth, & Fearon, 2000). However, these linear trends do not obtain when the therapist’s attachment organization is taken into account. As described earlier, Dozier and colleagues (1994) reported that secure case managers are less likely than insecure case managers to become enmeshed with hyperactivating patients or to shut down in concert with their deactivating patients. Secure therapists are inclined to adopt styles that are noncomplementary to those of their patients. In a later study of patient–therapist interaction, Tyrrell and colleagues (1999) reported similar findings. Even though therapists in this sample were all classified as secure, those who were *less* dismissing/deactivating were able to form stronger alliances with patients who were *more* dismissing/deactivating. These same researchers also reported that more dismissing patients did better with more preoccupied/hyperactivating clinicians. Petrowski and colleagues (2011) likewise reported that patients scoring high on attachment anxiety found therapists with higher attachment avoidance more helpful, suggesting that the containment provided by a more avoidant therapist was therapeutic, as compared with the hyperactivating strategies that might be used by a therapist whose attachment style was anxious.

One of the conclusions that can be drawn from this work is that secure therapists are more able than their insecure peers to respond in a non-complementary way to a patient’s defenses, presumably because they are themselves less likely to respond defensively with patients and less likely to be dysregulated by the content of sessions. Gentle challenges to the patient’s attachment organization have the effect of softening rather than provoking characteristic defensive styles, thereby enhancing flexibility and change (see Daniel, 2006). In a fascinating article supporting this research, Daly and Mallinckrodt (2009) presented data (based on detailed interviews with experienced therapists) to support the notion that more experienced clinicians (regardless of their orientation) are able to move “in” and “out” of attachment style with a patient over the course of treatment. Noting that most studies of attachment and psychotherapy are carried out with inexperienced therapists in training clinics, Daly and Mallinckrodt suggested that in the early stages of therapy, when the relationship and alliance are just getting established, experienced clinicians are likely to respond “in style” to patient defenses. This makes patients feel more understood and mirrored. As therapy progresses, however, and the relationship is more secure, experienced therapists move toward responding in ways that are “out of style,” pushing more dismissing patients to express intolerable emotions and become more engaged in relation to the therapist, and pushing more preoccupied patients to contain powerful emotions, function more autonomously, and deintensify transference manifestations and expectations. Although Daly and Mallinckrodt did not study these patterns in relation to therapist attachment style, it seems likely that therapists become more flexible and sensitive to both manifest defenses and latent affect as they become more experienced. It may be that experience—at least to some extent—will override therapists’ own attachment-related anxiety and defenses, such that they are able to respond more therapeutically to a range of patients and clinical situations. This kind of flexibility is much more difficult for inexperienced therapists, who, unfortunately, most often serve as the therapists in psychotherapy research.

The Clinical Perspective

Most, if not all, dynamically oriented clinicians adjust what they do in treatment on the basis of the patient’s defenses, psychic organization, and

interpersonal functioning. Again, the clinical attachment literature documents this in many ways; in work with avoidant patients, therapists must find ways to engage them emotionally, and “break” their rigid stories (Holmes, 1998). The therapists of preoccupied patients must help them contain and regulate intense emotions by creating meaningful narratives and (following Talia et al., 2014) derive comfort from the contact they seek. The “strategies” for doing this are not unique to an attachment perspective; the softening of defenses and the containment of pain is the essential work of psychotherapy. But when the question is framed in terms of whether to respond “in” or “out” of style (see Holmes, 1998; Slade, 1999), it is, in effect, framing therapeutic action in attachment terms. Here, I think it is clear that challenging the patient’s defenses is likely what will be most useful, and that either the “secure” and/or experienced therapist (and experience, of course, makes most professionals feel safe) is in the best position to do this.

Can psychotherapy change attachment orientations?

The literature reviewed up to this point addressed the impact of attachment organization on therapy process and outcomes. A small number of studies have come at this question in a different way, examining whether attachment status itself can be changed by psychotherapy: Rather than assess the impact of attachment on psychotherapy, they assess the impact of psychotherapy on attachment. Change in attachment status itself becomes the target of treatment.

In their study of 35 nonpsychotic inpatients, Fonagy and colleagues (1995) gave the AAI to patients upon admission for intensive inpatient treatment and on follow-up, 1 year postdischarge. The authors reported that whereas all patients were insecure at the start of treatment, 40% were secure upon discharge. Unfortunately, the distribution of classifications before and after treatment is not reported, so it is difficult to assess who changed and in what way. Clearer evidence for the utility of the AAI as an outcome measure emerged in a large-sample randomized clinical trial conducted by Levy and his colleagues (2006). This group compared the effectiveness of transference-focused psychotherapy (TFP) with that of DBT and modified psychodynamic supportive psychotherapy in treating individuals with BPD. They re-

ported that in a sample of 60 outpatients following 1 year of treatment, TFP (but not DBT or supportive psychotherapy) led to a significant increase in the number of individuals classified as secure in relation to attachment. These results suggest that a treatment that works directly on the patient’s feelings about the therapist may be particularly suited to changing attachment organization. However, Diamond, Stovall-McClough, Clarkin, and Levy (2003) reporting on a subsample of Levy and colleagues’ (2006) larger sample, examined changes in attachment status in 10 patients receiving TFP. Here the shifts described in the Levy and colleagues study did not obtain. Only two of the nine subjects who were insecure on intake shifted to secure. The rest either stayed the same or shifted to other insecure categories.

In third study, reported by Stovall-McClough and Cloitre (2003), 18 women with posttraumatic stress disorder (PTSD) diagnoses were treated using either exposure therapy or skills training. At intake, 72% were classified as unresolved/disorganized with regard to trauma, and only 11% of the sample was judged secure. Over half of patients who were unresolved/disorganized (62%; $n = 8$) shifted from the unresolved/disorganized status following treatment, and 50% of the total sample was secure at termination.

To date, these appear to be the only studies that have examined change in AAI status as a function of treatment. As a whole, especially given the relatively small sample sizes, they provide at best only modest support for the idea that AAI status can change in psychotherapy, and even less evidence that therapy can bring about shifts from insecure to secure status. Thus the question remains whether it is reasonable to assess treatment outcome or establish the empirical basis for one treatment over another using change in AAI classification as a criterion measure. Attachment classifications are overt manifestations of deep structures that take time to change, even in the most successful of treatments. As Everett Waters and his colleagues pointed out (Waters, Hamilton, & Weinfeld, 2000), stability in attachment classifications is the rule rather than the exception, with negative life events being most clearly associated with instability. Thus, to return to one of the themes of this chapter, it is probably much more useful to assess change in a more dynamic and nuanced way.

One way to do this would be to assess change in attachment dimensions, but even here the results are modest and mixed. Two studies have

examined the impact of psychotherapy on attachment style, which is potentially a way to study change in a more dynamic way. Travis, Bliwise, Binder, and Horne-Meyer (2001) reported findings similar to those of Diamond and colleagues (2003), namely, that while a significant proportion of patients shifted attachment styles, the number who shifted to a secure style was not significant. In a more recent study, Muller and Rosenkranz (2009) examined changes in attachment style over the course of an 8-week intensive group psychotherapy treatment for PTSD. They reported that the treatment group (as opposed to the waiting-list controls) was more likely to move from an insecure to secure style of attachment. Attachment anxiety decreased from admission to discharge to follow-up, whereas changes in attachment avoidance were more difficult to detect.

The Clinical Perspective

Most clinical writers suggest that when treatment is going well, anxiety diminishes, avoidance softens, and psychological organization improves. And, indeed, the clinical attachment literature, which includes many case studies, routinely documents shifts in attachment processes and dynamics over the course of treatment, with many patients moving from insecure-unresolved/disorganized to insecure-organized to secure modes of regulating affect and being “in relation” to significant others. These changes are typically observed rather than measured, but from a clinical perspective, these are meaningful and observable transformations.

New Directions: Narrative Processes, and a “Move to the Level of the Relation”

As mentioned early in this chapter, I view recent work by Sarah Daniel, Alessandro Talia, and their colleagues as leading the way toward a paradigm shift in attachment-informed research and clinical practice (Daniel, 2009, 2014; Talia et al., 2014). Recall that from Bowlby’s perspective, attachment classifications and styles refer to dynamic relational processes, and not static internal (trait-like) characteristics. These processes are the explicit focus of Daniel and Talia’s research, which uses novel methods and approaches to measure both dynamic patterns of attachment activation and their relational functions within a treatment context.

In 2006, Daniel published a remarkably detailed, comprehensive, and integrated review of the literature on adult attachment patterns and individual psychotherapy. Several years later, she published an exploratory study examining the relation between adult attachment insecurity and narrative processes in psychotherapy. As Mary Main’s work makes so explicit, assessing the *quality* of narrative processes is at the heart of attachment classification. And, as Holmes and I have both pointed out elsewhere (Holmes, 1998, 2001; Slade 1999, 2014), narrative patterns within the context of a single psychotherapy session provide crucial information about defensive structures and other features of attachment organization, as well as crucial opportunities for intervention and transformation. In her 2011 study, Daniel coded three key elements of narrative processes in psychotherapy: verbal productivity, narrative initiative, and topic segments. These were subdivided on the basis of semantic content into those focusing on external, internal, or reflexive processes. The participants, who were evaluated within the context of a randomized clinical trial of cognitive-behavioral and psychoanalytic treatments for bulimia, were assessed on the AAI prior to treatment. Later, their in-session discourse was coded along the dimensions described earlier. Daniel reported significant differences between dismissing and preoccupied patients in their verbal productivity during psychotherapy sessions, with preoccupied patients talking more and taking more speech turns per session than their dismissing counterparts, who were more likely to pause during sessions. Likewise, preoccupied patients were more likely to initiate narratives in therapy. Type of treatment, cognitive-behavioral therapy (CBT) or psychoanalytic psychotherapy (PPT), had no apparent effect on these patterns. Differences in content were less clear, and interacted with treatment type, leading Daniel to suggest the need for more “fine-grained” analysis of discourse patterns, and for the inclusion of secure and unresolved/disorganized patients in future research.

Several features distinguished Daniel’s early work from other research on attachment and psychotherapy, and indeed from other adult attachment research. Main and her colleagues (1985) have from the start emphasized the importance of assessing narrative *coherence* in determining an individual’s attachment organization. Moments of incoherence are critical indicators of both the activation of the attachment system and as typical defenses against such activations. In line with this, a secure narrative must meet all four of Grice’s

(1989) maxims for narrative coherence: quantity, quality, relevance, and manner. But because it is a linear scale, the coherence scale does not capture these variations, nor does it capture the *kinds of incoherence* that distinguish subtypes of insecurity. Main has always emphasized how differently avoidant, preoccupied, and unresolved/disorganized individuals are incoherent. Daniel's work on discourse patterns takes two important steps toward developing ways of detecting these differences: She directly evaluated quantity by measuring rate of verbal production (which, as anyone who has coded AAIs knows, usually does in fact distinguish avoidant and preoccupied adults), and she evaluates manner by tracking narrative initiative. Finally, Daniel also evaluated the *content* of psychotherapy sessions. To my knowledge, no one working in this area has considered the question of content or theme. Given that *what* patients talk about can often be quite significant, this seems like a crucial oversight. Although Daniel's sample was small and her findings with respect to thematic content ambiguous, her inclusion of these variables signals another important shift in the work. In particular, it would seem crucial going forward to examine shifts in attachment dynamics within a session (through analyzing shifts in coherence and/or discursive behavior) in light of session content.

Recently, Talia and colleagues (2014) reported another set of groundbreaking developments in the study of attachment and psychotherapy. In their study, the in-session speech of patients classified as secure, dismissing, or preoccupied on the AAI was analyzed in light of the ways that their discourse *elicited and maintained emotional proximity* with the therapist. Transcripts of therapist–patient discourse were analyzed using the Patient Attachment Coding System (PACS), developed by Talia and Miller-Bottomo (2014). The PACS is made up of three main scales, which derive directly from the core principles of attachment theory: the Contact Seeking scale, which rates discursive behaviors that “tend to increase emotional proximity and the likelihood of receiving support from the therapist” (p. 7); the Avoidance scale, which rates discursive behaviors that decrease emotional closeness between patient and therapist; and the Resistance scale, which rates discursive behaviors that “tend to thwart the therapist's attempts to support patients and to make sense of their experience” (p. 7).

In a combined sample of 56 patients in different types of psychotherapy, the AAI was administered prior to treatment, and AAI classifica-

tions were shown to predict distinctive in-session discursive patterns, as rated with the PACS by external observers. Patients judged secure on the AAI had significantly higher scores on the Contact Seeking scale than either preoccupied and dismissing patients (although preoccupied patients were significantly more likely to seek contact than dismissing patients), and tended to express distress openly, ask for help, and show gratitude. Avoidant patients were characterized by higher scores on the Avoidance scale than the other two groups, and tended to minimize any disclosure, convey self-sufficiency, and downplay their distress. Preoccupied patients were characterized by higher scores than the others on the Resistance scale, and tended to obstruct the therapist's attempts to intervene, failed to enlist the therapists' own points of view, and conveyed their experience in a vague or confusing way. Particularly fascinating is the discovery that preoccupied patients not only seek contact but also *resist* it. This is, of course, completely in line with Ainsworth's observation of ambivalence in resistant infants' behavior (Ainsworth et al., 1978), and it very much clarifies what it is that can be both so challenging and irritating about working with preoccupied patients.

As Talia and his colleagues (2014) noted, by providing a more precise understanding of the interpersonal functions of particular narrative patterns, this research takes the study of attachment narratives from “the level of representation” and moves it to “the level of the relation” (p. 205). As a result of this study, and a second validation study (Talia, Miller-Bottomo, & Daniel, 2015), we not only know that insecurity makes it difficult to engage in treatment at a variety of levels but also how these difficulties are manifest in form and interpersonal function across categories of attachment. These findings are entirely in line with the dynamic and *relational* aspects of Bowlby's theory, aspects that, as I mentioned earlier, are so often lost in research. And, by detecting the interpersonal aims of discourse and meaningfully linking these to attachment classification, Talia and colleagues were able to track explicitly what were simply trends or hints in previous studies. This demonstrates how crucial it is for research and its methods to be meaningfully grounded in theory.

It is important to underscore the fact that this study grew out of a collaboration across a number of sites. This collaboration allowed the researchers to combine samples in which both AAI data and session transcripts were available. Thus, rather

than rely on a series of paper-and-pencil measures, this study was able to examine in-session processes in a meaningful way across a large number of subjects. Obviously, this is time-intensive, expensive work. But the yields are potentially very significant.

From a clinical perspective, I view these methodologies as allowing researchers and clinicians to track minute-by-minute change in both the therapist's and the patient's discursive *relational* behavior. Presumably, these changes can tell us when a patient's attachment system is activated during the course of a session, and when an intervention (a question, an observation, an interpretation, or even a silence) has helped overcome avoidance or resistance in the patient, or heightened it. Likewise, they can help identify points of activation and defense in the therapist as well, and help track opportunities for repair and therapeutic progress. These are the moments of true change in psychotherapy.

Future Directions

The Integration of Theory, Research, and Practice

If Bowlby were alive today, he would surely be happy to discover that the once vilified term *attachment* has now become a part of the lexicon of psychotherapy researchers and psychotherapists alike. But I believe that he would also encourage us to keep pushing further, to deepen our understanding of attachment processes, and to build bridges across disciplines still in so many respects far apart. In the spirit of such forward momentum, and in light of the work reviewed in this chapter, I close with a list of potential ways to use attachment theory and research to deepen our understanding of our patients and their relational dynamics, to identify what is helpful to whom, and to address aspects of how therapists bring their own difficulties and challenges into the work.

1. *Deepen the way attachment is written about and taught.*

There is today a vast and complex literature on attachment processes (see, e.g., Mikulincer & Shaver, 2007; Slade & Holmes, 2013). Yet, as I hope I have made clear in this chapter, researchers and clinicians alike have often lost sight of the dynamic and relational elements of this theory,

elements that have great implications for clinical research and practice. These were at the heart of Bowlby's writings and shaped the evolution of the theory and its methods. Only recently have these returned to the forefront in research and practice. When we write about attachment, or teach it to our students (whether they are research or clinical students), it is important not to limit our discussions to classifications or styles, but to fully explore and set in context what these classifications *mean* on a number of critical levels.

2. *Expose clinicians to the methods of attachment theory, so that they become better observers of these processes.*

The best way to learn about attachment processes is to *observe* them *in situ*. Yet, except for those lucky clinicians who have really studied the Strange Situation procedure, the AAI, or any other attachment measure, there are few opportunities really to learn about attachment from the inside out. One of the most compelling and attachment-informed interventions in the field today, the Circle of Security intervention (Powell, Cooper, Hoffman, & Marvin, 2013) grew out of the years Glen Cooper, Kent Hoffman, and Bert Powell spent studying attachment with Jude Cassidy, watching Strange Situation procedures together, reading AAI transcripts, and deeply immersing themselves in the theory and research. Likewise, my training on the AAI with Mary Main and Mary Ainsworth was one of the most valuable forms of clinical supervision I ever had. Currently there are few hands-on ways for clinicians to learn really deeply about attachment processes in all their complexity (see Steele & Steele, 2008). For this reason, those of us in the field with this knowledge must become more involved in the training of clinicians if our goal is to ensure that their work is truly attachment-informed.

3. *Explore new methodologies in attachment psychotherapy research.*

As I detailed earlier, I believe that much of the research on psychotherapy and attachment has relied on outcome measures unlikely to distinguish the differential impact of avoidant and preoccupied modes of defense on the process and outcome of psychotherapy. The methods introduced by Daniel and Talia, as well as the rupture and repair methodologies described by Safran and Muran (2003) and the "critical incident" methodologies (e.g., Janzen et al., 2008), are most likely not only to pick up meaningful differences in the course

and outcome of therapy but also to help identify what works best for whom at moments when the attachment system is activated in psychotherapy.

4. *Pay more attention to clinicians' own psychological health.*

It is fascinating to me to realize how little attention has been given in any of the literatures I have reviewed to the importance of a clinician's "security." Obviously, it would be Draconian and in fact absurd to suggest that only secure individuals be allowed to work as clinicians. For one (and I say this with my tongue only slightly in my cheek), such a requirement would significantly decrease the number of practitioners in the field. And the familiarity and comfort with emotional pain, with the loss, separation, trauma, and other hardships that often come out of painful attachment experiences, give many clinicians a special ear and heart for the work. But it is evident from the research (and this has certainly been my experience as a supervisor) that while painful attachment experiences can enrich a therapist's perspective, unmetabolized and unintegrated affect in a therapist has a profound and negative impact on the work. Thus, an individual's relative attachment security should be a relevant to the determination of whether he or she will make a good therapist. In the clinical psychology doctoral program in which I taught for over 30 years (at the City College of New York), in-depth clinical interviews aimed at evaluating some of these characteristics were a key step in the admission process and allowed at least some assessment of important personal characteristics. Even more important, professional development should from the very beginning include individual supervision, with an emphasis on understanding clinical process, transference and countertransference, as well as separate personal psychotherapy. Both are key to clinicians' separating their own struggles from those of their patients, and to having a secure base from which they can think about and regulate their experiences in this activating, challenging work.

In conclusion, I reiterate that the study of the clinical implications of attachment is fascinating, challenging, and complicated. I tip my hat to the generations of researchers and clinicians who struggled with these complexities over the last quarter century, and look forward to joining with future generations as they expand upon these rich foundations.

Acknowledgments

I would like to thank Jeremy Holmes—colleague, friend, and keen reader—for his hugely helpful edits on an early draft. As always, his comments helped me polish the chapter stylistically and conceptually. Thanks, too, to Sarah Daniel, who graciously shared her work (including prepublication drafts) during the writing process, and—together with Alessandro Talia—reviewed and sharpened my descriptions of their research.

Notes

1. In an effort to use terms that are the most descriptive and least confusing, I refer to secure adults as *secure*; avoidant or dismissing adults as *avoidant*; and preoccupied or anxious adults as *preoccupied*. Although not an ideal solution, it seems the clearest, simplest, and least controversial one. Likewise, I refer to adults who are unresolved in relation to loss or trauma as *unresolved/disorganized*, as many clinicians use the term *disorganized* to refer to both children and adults.
2. I regret that space limitations preclude my discussing the literature on mentalization and mentalization-based interventions (e.g., Allen, 2013; Bateman & Fonagy, 2009), both of which are deeply attachment informed. Some of this work is discussed by Fonagy, Luyten, Allison, and Campbell, Chapter 34, this volume.
3. In 1996, Erik Hesse described a fourth insecure adult attachment classification, "cannot classify." This classification has rarely been included either in either research or clinical studies of psychotherapy.
4. Interestingly, Bateman and Fonagy (2009) caution against activating the attachment system of patients with borderline personality disorder by talking about the past, until they have developed the reflective capacities necessary to tolerate such threats.

Chapter 34

Reconciling Psychoanalytic Ideas with Attachment Theory

Peter Fonagy
Patrick Luyten
Elizabeth Allison
Chloe Campbell

The relationship between attachment theory and psychoanalysis, historically, has not been an easy one (Eagle, 2013; Fonagy, 2001; Fonagy, Gergely, & Target, 2008). But in recent years, developments in both fields have led to a growing rapprochement (Eagle, 2013; Holmes, 2009). Changes in psychoanalytic thinking have made it more accommodating of attachment thinking; conversely, aspects of the development of attachment findings, applications, and theory have made it more pertinent to psychoanalysis.

In this chapter we examine the disagreements between psychoanalysis and attachment theory, and point to some of the two disciplines' common foundations. We then describe an approach to the role of attachment in human development that considers it in relation to the capacity to *mentalize*, that is, to understand ourselves and others in terms of intentional mental states, and places both attachment and mentalizing in the context of the development of *epistemic trust*—the capacity to trust others as a source of knowledge about the world. This approach builds on some of Bowlby's assumptions drawn from evolutionary biology, placing some of the better founded psychoanalytic criticisms of attachment theory in a different perspective. We suggest that this context allows the

ongoing significance of Bowlby and Ainsworth's thinking for the psychoanalytic project to be appreciated.

1. Traditional Psychoanalytic Developmental Theory and Attachment Theory: More Different Than Alike?

In his biography of Bowlby, Holmes (1993) identified four points of disagreement with psychoanalysis: (1) the psychoanalytic emphasis on the patient's *internal phantasies* (unconscious imaginative activity) at the expense of environmental influences and the patient's real, lived experiences; (2) what Bowlby perceived as the spirit of *rigid dogmatism* within the psychoanalytic world, which was at odds with intellectual creativity and scientific inquiry; (3) psychoanalytic metapsychology, which Bowlby considered to be a speculative approach to understanding the human mind, which is not open to empirical verification; and (4) the lack of empirical observation to underpin psychoanalytic theories.

Through his focus on the measurable and on the child's environment, Bowlby demanded

causal clarity and an epistemological refinement of psychoanalytic thinking. The adoption of an empirical approach to clarifying and examining the validity of psychoanalytic ideas is still controversial within the clinical psychoanalytic tradition (Aron, 2012; Hoffman, 2009; Stern, 2013), although certain strands within psychoanalysis have taken a more positive approach to empirical research (Luyten, Blatt, & Corveleyn, 2006; Luyten, Blatt, Van Houdenhove, & Corveleyn, 2006).

Bowlby's ethological approach raised considerable challenges for the psychoanalytic position. Attachment was depicted by Bowlby as a form of behavior that the infant adapts according to environmental stimuli. The reflexive, flatly uniform quality that derived from an evolutionary and ethological perspective on attachment seemed starkly opposed to the humanism of the psychoanalytic impulse to recognize and engage with the complexity of individual subjectivity (Chused, 2012; Quinodoz, 1996).

Attachment was also at odds with traditional drive-oriented psychoanalytic theory, which posited that the first few weeks and months of an infant's life are almost solely characterized by drive discharge. Hence, drives were seen as primary; *objects* (i.e., attachment figures) were seen as secondary (Greenberg & Mitchell, 1983). Objects entered the scene only because of the failure of pure primary process functioning, when hallucinatory wish-fulfillments (e.g., imagining the mother's breast) failed to yield real gratification, which secondarily generated social awareness and engagement (Freud, 1915/1957). This view could not be reconciled with Bowlby's insistence on the primacy of attachment relationships, their evolutionary functions and, by implication, the fact that infants were fundamentally and from the beginning of life positively oriented toward others.

Finally, attachment theory was accused of neglecting the developmental role of sexuality and aggression, which are seen as the central human urges in traditional psychoanalysis, responsible for continuous internal conflict and justifying defensive operations (Meissner, 2009). In contrast to the psychoanalytic understanding of human nature and relationships in terms of conflict and compromise (Geyskens, 2003), attachment theory appeared to reduce human relationships to a smooth, evolutionary, prewired unfolding process. Thus, particularly in Neo-Freudian and Lacanian circles, adopting attachment theory would mean a betrayal of fundamental hard-fought insights

into the nature of human development (Symons, 2008; Widlocher & Fairfield, 2004; Zamanian, 2011).

2. The Response of Major Psychoanalytic Thinkers

Predictably, given the major differences in assumptions about the fundamentals of development, attachment theory met with fierce resistance from the psychoanalytic community.

Bowlby's focus on the impact of the lived reality of the child's early emotional experiences, normally in relation to the mother, has distinct parallels with Winnicott's (1965) recognition of the significance of the early caring environment. However, Winnicott, one of the best-known psychoanalytic developmentalists, was unhappy with Bowlby's use of ethology and the statistical approach at the expense of the clinical case study, and was concerned about the loss of the complexity of individual subjectivity (Abram, 2008). Thus, although in retrospect we might locate Bowlby's work within the object relations school of psychoanalytic thinking, with both Bowlby and Winnicott emphasizing the significance of the relationship between infant and caregiver, this was not straightforwardly perceived as a shared intellectual project (Keller, 2011).

Anna Freud, one of the great psychoanalysts of Bowlby's era, was also one of the first psychoanalysts to adopt a coherent developmental perspective on psychopathology. She argued that psychological disorder is most effectively studied in its developmental evolution, asserting that it is the profile or pattern among different *developmental lines* that best captures the nature of the risk faced by the individual child. This view foreshadowed and laid part of the foundation of contemporary developmental psychopathology (Cicchetti, 2013). Anna Freud's developmental lines included, for instance, the line from dependency to self-reliance to adult object relations, so central in attachment theory. But her theory was broader and also included the line from irresponsibility to responsibility in body management, the line from egocentrism to social partnership, and so forth. Unevenness of development was considered a risk factor, and treatment in certain cases adopted the modified aim of restoring the child to the path of normal development (developmental help) (Midgley, 2012).

Despite their shared emphasis on development, Anna Freud was deeply unsympathetic to attachment theory. And, despite her own observations to the contrary, in her theoretical writings Anna Freud based the child's early relationship with the mother on sexual instinctual needs, in line with traditional drive theory. Although she was well aware of unevenness in ego development, she rarely saw this as caused by relationship disturbance. While her clinical focus and interventions were to a marked extent focused on optimizing the social context of the child, her theoretical writings appeared to be constrained by an adherence to classical psychoanalytical ideas (Young-Bruehl, 2011).

Melanie Klein (1936/1964) was the third great thinker who shaped the psychoanalytic milieu within and against which Bowlby worked. Klein's disagreements with Anna Freud have been well documented (Gabbard & Scarfone, 2002); their shared suspicion of attachment theory was perhaps one of the few things that united them. Klein was one of the founders of the object relations school, which, with its conception that subjective experience shapes one's behavior and relationships, considerably narrowed the gap between attachment theory and psychoanalysis (Mikulincer & Shaver, 2007). The relationship between Klein's and Bowlby's thinking was both intimate and highly adversarial, and the points of contact are worth examining because of the great influence of Kleinian thinking on contemporary psychoanalysis (e.g., Brown, 2011).

Klein saw mental structures as arising out of a variety of internal objects (phantasies about people in the infant's life), which change in character as the child develops from infancy. The infant's phantasies are modified by actual experiences of interaction with the environment. Bowlby was deeply influenced by Kleinian thought, and traces of his training and experience in the British Psychoanalytic Society, which was predominantly Kleinian, can be readily identified in his writings. For example, his focus on the first year of life as a crucial determinant of later developmental outcomes is highly compatible with the Kleinian approach. Perhaps most important is the intimate connection that both bodies of work envision between emotional experiences and the cognitive apparatus underpinning thought. This is expressed most clearly in the last volume of Bowlby's trilogy (1980) and in Bion's (1997) elaboration of Klein's ideas. Even in opposition, many of Bowlby's ideas were reactions against the Kleinian influence on him.

One of Bowlby's central objections to Kleinian psychoanalytic theory was its neglect of actual experience and the assumption that a child's anxieties arise predominantly from constitutional tendencies, such as innate (i.e., drive-related) aggression (Klein, 1936/1964). However, recent post-Kleinian psychoanalysts have been quite successful at integrating environmental accounts with Klein's ideas (e.g., Ferro, 2006). The child's capacity to cope with the pain and anxiety of the depressive position, seeing him- or herself as destructive and envious, is now generally attributed in more contemporary Kleinian views to external as well as constitutional factors (Vermote, 2011).

3. Areas of Integration between Psychoanalysis and Attachment Theory

Several trends within psychoanalysis have paved the way for a rapprochement with attachment theory. For a start, psychoanalysis has become more pluralistic and accepting of differences (Holmes, 2009). The emergence of a relational and relationship-focused emphasis in modern psychoanalysis has also led to increasing interest in the formative nature of the child's social environment, and object relations theory has played a pivotal role in this context (Aron & Leichich, 2011; Brown, 2010; Epstein, 2010). In this section we consider more closely some of the most important areas of integration between psychoanalysis and attachment theory.

a. The Internal Working Model

Bowlby's attachment theory, like classical psychoanalysis, has a biological focus (see especially Bowlby, 1969). Bowlby's critical contribution was his unwavering focus on the infant's need for an unbroken (secure) early attachment to the mother. He emphasized the survival value of attachment in enhancing safety through proximity to the caregiver in addition to feeding, learning about the environment and social interaction, and protection from predators.

Perhaps not surprisingly, psychoanalysts were horrified by this apparently simplistic approach, which bore the hallmarks of the worst excesses of behaviorist reductionism. However, in the second volume of *Attachment and Loss*, Bowlby established the set-goal of the attachment system as maintain-

ing the caregiver's accessibility and responsiveness, which he covered with a single term: *availability* (Bowlby, 1973, p. 202). This availability translates into the confident expectation, gained from "tolerably accurately" (p. 202) represented experience, over a significant time period, that the attachment figure will be available. The attachment behavioral system thus came to be underpinned by a set of representational models or, following the pioneering psychologist Craik (1943), internal working models (IWMs; see Bretherton & Munholland, Chapter 4, this volume).

The positing of a representational system underpinning attachment permitted a far more sophisticated consideration of individual differences (Bowlby, 1973, 1980). Given the power of the biological forces driving the human attachment system, Bowlby assumed that almost all human beings will become attached. The concept of the disorganization of the attachment system was not yet available (Main & Solomon, 1986); for Bowlby, attachment could be only secure or insecure. Secure attachment implied a representational system in which the attachment figure was seen as accessible and responsive when needed. Anxious attachment implied a somewhat dysfunctional system in which the caregiver's responsiveness was not assumed and the child adopted strategies for circumventing his or her perceived unresponsiveness (Ainsworth, Blehar, Waters, & Wall, 1978).

Thus, the central feature of the IWM concerned the infant's encoding of interactions in terms of what they implied about the expected availability of the attachment figure. Bowlby also envisioned a complementary working model of the self. The key feature of this was how acceptable or unacceptable the child felt in the eyes of the attachment figure. A child whose IWM of the caregiver focused on rejection was expected to evolve a complementary working model of the self as unlovable, unworthy, and flawed. Although not explicitly stated by Bowlby, these models of the attachment figure and the self were somewhat transactional, interactive models representing self–other relationships. The explanatory power of Bowlby's model rested in his proposal that these encoded expectations were capable of providing prototypes for all later close relationships.

Bowlby's original concept has been elaborated by some of the greatest minds in the attachment field (see Bretherton & Munholland, 2008). Through the working model, Bowlby created a wider theory about the construction of the psyche, which is sometimes underrepresented in the more

schematic portrayals of attachment theory. In *Loss*, for instance, Bowlby (1980) described how an individual defensively excludes stimuli that are incompatible with the IWM, leading to an inability to accommodate external reality, often in relation to other people's emotional states or attachment needs. This led to a new take by Bowlby on repression and dissociative phenomena (the kind of territory more normally associated with psychoanalytic thinking), which are often the result of deactivation of the attachment system (Dykas & Cassidy, 2011)—most notably in a disorganized individual dealing with grief or bereavement (Bretherton & Munholland, 1999).

The concept of the IWM was key to the rapprochement with psychoanalytic object relations theory and psychoanalysis more generally (e.g., Blatt, Auerbach, & Levy, 1997; Wachtel, 2009, 2010). This so-called "move to the level of representation" elaborated by Main, Kaplan, and Cassidy (1985) has had enormous influence, particularly via the Adult Attachment Interview (AAI). Main and colleagues' work (Main, Hesse, & Hesse, 2011; Main et al., 1985) reconceptualized individual differences in attachment organization as individual differences in the mental representation of the self in relation to attachment; it enabled the examination of attachment in older children and adults.

b. Object Relations

The notion of IWMs is consistent with psychoanalytic object relations theory's emphasis on the central role of self and object representations in development (Blatt et al., 1997; Greenberg & Mitchell, 1983; Kernberg & Caligor, 2005). In both perspectives, representations of self and others are seen as the fundamental building blocks of normal and disrupted development, with representations of self and others becoming increasingly integrated, differentiated, and positive in normal development. Fairbairn's (1952, 1963) simple insight that people are fundamentally driven by relationships and their need for them, and that the pursuit of relationships is not a secondary by-product of the primary drives for gratification described by Freud, is in essence highly congruent with Bowlby's insight in relation to the biological priority of the "secure base." For both attachment theory and object relations theory, it is axiomatic that the infant's psyche, his or her relationship representational structure, is shaped by early

relationship experiences. As the object relations model replaced ego psychology as a dominant international psychoanalytic paradigm, attachment theory's emphasis on the innate need for a relationship came to be embraced by a majority within the field.

Psychopathology, from these perspectives, is seen as reflecting impairments in the structure and content of mental representations of self and others (e.g., Blatt, 1974; Westen, 1991). This led to a burgeoning research literature (Huprich & Greenberg, 2003; Mikulincer & Shaver, 2007) that uses concepts denoting very similar constructs, but often with somewhat different names, ranging from object representations (Brinich, 1980) to cognitive-affective schemas of self and others (self-object-affect triads) (Kernberg, 2014), role responsiveness (Sandler & Sandler, 1998), representations of interactions that have been generalized (Stern, 1985), and IWMs (Blatt et al., 1997). The strong psychometric contributions of attachment research were recognized and further developed by psychoanalytic researchers. In particular, the links between the adult attachment construct and object relations patterns of self-other representation have been carefully studied (Blatt et al., 1997; Loeffler-Stastka & Blueml, 2010; Luyten & Blatt, 2013; Priel & Besser, 2001).

Attachment theory's emphasis on an autonomous need for a relationship has not gone completely unchallenged within psychoanalysis (e.g., Geyskens, 2003; Green, 2005; Widlocher & Fairfield, 2004). However, the embarrassment caused by the apparently endemic neglect of childhood maltreatment (Masson, 1984; Simon, 1992) has been followed by an embrace of the trauma concept and the role of early relationships more broadly (e.g., Levine, 2014; Person & Klar, 1994). More generally, the emergence and dominance of object relations theory in the 1980s and 1990s contributed to increasing psychoanalytic recognition of the formative nature of the child's external, social environment. Engaging with the psychological consequences of childrearing patterns characteristic of families with serious social disadvantages has forced psychoanalysts to rethink the concept of trauma (e.g., Bohleber, 2007), bringing their conceptualization closer to attachment formulations (Allen, Fonagy, & Bateman, 2008).

Yet, as noted, not everyone agrees, and it is striking that with the growing popularity of attachment and object relations theory, interest in sexuality in psychoanalysis has declined significantly (Fonagy, 2008). This has happened despite

the fact that sexuality, along with aggression, remains one of the most problematic human experiences, as evidenced by the role of sexuality and aggression in a variety of psychological problems and disorders (Fonagy & Luyten, 2016; Zamaniyan, 2011). With some exceptions (e.g., Kernberg, 2012), the integration of attachment theory with a comprehensive theory of human sexuality and aggression remains to be developed (see Birnbaum, Chapter 22, this volume).

c. Relational and Relationship-Focused Psychoanalysis

The 1980s saw the beginning of an integration of relational approaches augmented and modified by the intersubjectivist vision of philosophically oriented psychoanalysts such as Stolorow (1997) and infant researchers such as Emde (Emde, Kubicek, & Oppenheim, 1997). This interpersonal relationship-focused perspective is perhaps best exemplified by the so-called "relational school," partly rooted in the work of Sullivan (1953; Benjamin, 1998; Bromberg, 1998; Mitchell & Aron, 1999). The theory is more of an orientation than a coherent body of ideas, and many theoreticians and clinicians who emphasize relational issues do not necessarily identify themselves as "relational psychoanalysts." Yet relational psychoanalysis combines the concerns of modern psychoanalysis with the traditional concerns of attachment theory. It emerged as psychoanalysis moved toward the developmental framework established within attachment theory and other dynamic psychological approaches rooted in observing early development. Psychodynamic therapists who wish to embrace the relational approach often move toward an attachment model, albeit unwittingly (Cortina, 2001).

The relational model assumes that subjectivity is interpersonal: that is, the intersubjective replaces the intrapsychic (Mitchell, 1988). This renders the individual human mind a contradiction in terms, since subjectivity is invariably rooted in an intersubjective matrix of relational bonds within which personal meanings are embedded (Mitchell, 2000) rather than in biological drives. Unlike most other psychoanalytic theories, the relational model lacks a specific explanation of how relationality and intersubjectivity develop. For this reason, attachment theory and conclusions drawn from the observation of attachment relationships may be helpful.

Bowlby's focus on child–caregiver interaction as the primary driver of social development makes him a quintessential relational theorist. Among others he influenced, Bowlby clearly influenced Trevarthen (e.g., Trevarthen & Aitken, 2001), who argues that infants are innately predisposed to social relationships and that primary intersubjectivity characterizes the mental experience of infants during infant–caregiver interactions (Trevarthen, 1993; Trevarthen, Aitken, Vandekerckhove, Delafield-Butt, & Nagy, 2006). In addition to a predisposition to relate, attachment theory posits and describes other adaptations—including defensive processes—that develop in the context of specifically elaborated relational processes, which themselves occur at the interface between infant distress and caregiver response. That is, attachment theory, like relational theory, is a two-person theory of conflict and defense, which sees defenses as arising from the conflict between the infant's needs and the caregiver's responses (Lyons-Ruth, 1999, 2003).

The hypothesis of procedural representations of implicit relational knowing raises the theory of internal object relations to a more general “systems” conception. The implicit relational knowing of two partners or of a patient and an analyst will be altered by moments of meeting—by the enactment of a new potential that will come to be represented as a future possibility. The best-documented forms of procedural implicit relational knowing are displayed during the first 2 years of life, when interactions are registered in representations of interpersonal events in a non-symbolic form. The unique configuration of adaptive strategies that emerges from the attachment relationship constitutes the initial organization of the child's domain of implicit relational knowing (IWMs, protonarrative envelopes, themes of organization, relational scripts).

In general, both attachment theorists and interpersonalists are reluctant to privilege fantasy over actuality. Interpersonal and intrapsychic factors are seen as equally important. Sullivan's break from traditional psychoanalysis mirrors Bowlby's conflict with the British psychoanalytic community: Bowlby shared an emphasis on dyadic relationships with interpersonalists, but he also shared with Sullivan (1964) an interest in observable behavior. Neither Bowlby nor Sullivan could specifically be labeled “behaviorist,” but they shared a systematic interest in what happens between people. For Sullivan, this entailed a detailed inquiry into who said what to whom, whereas Bowlby's

focus was on what happened in the past to explain the present.

Current relational thinking often uses psychopathological accounts of trauma to highlight the relational aspects of actual experience (e.g., Davies, 1996). “What really happened” is combined with attention to the patient's subjective experience, not in order to separate veridical events from distortions associated with unconscious fantasy, but rather to elaborate the overwhelming nature of the experience itself—especially because the context of trauma is assumed to preclude awareness of its meanings (Pizer, 2003). It is the inherent paradox of attachment trauma that a stance of “not knowing what one knows” (Bowlby, 1988, p. 99) may be adopted to keep the crucial relationship intact. Relational psychoanalytic (Stern, 1997) and attachment-inspired (Hesse & Main, 2006) clinical descriptions provide similar formulations of dissociation linked with traumatic experience.

d. The Self Psychology Tradition

The emergence of self psychology from the work of Heinz Kohut (1971) has, like attachment theory, contributed to focusing psychoanalytic interest on the earliest phases of development. Self psychology grew out of the increasing dominance of object relations theory, but because its origins were in North America, it was less affected by the Kleinian focus on aggression and destructiveness. The work of Kohut revolutionized North American psychoanalysis in the last decades of the 20th century. Kohut broke the iron grip of ego psychology by forcing psychoanalysts to think in less mechanistic terms—in terms of selfhood rather than psychological function and *selfobjects* rather than the drive gratification provided by the object.

Self psychology holds empathy to be central in both development and therapy (Ornstein, 2008); without it we would not have access to the world of the other. *Empathy* is a process that emerges between two or more people when their interaction creates the possibility of a world of meanings based on mutual understanding, and empathy generates a sense of connection through dialogue (Orange, 2009). The seminal contribution of Kohut (1971, 1977; Kohut & Wolf, 1978), at least in the context of this chapter, lies in his innovative suggestion that the development of *narcissism* (originally self-love or self-esteem) has its own developmental path, and that caregiving individuals (objects) serve special functions along

this line of development, as selfobjects that evoke the experience of selfhood. Empathic responses from the selfobject facilitate the unfolding of infantile grandiosity and encourage feelings of omnipotence, which enable the building of an idealized image of the parent, with whom the child wishes to merge. This “transmuting internalization of the mirroring function” gradually leads to a consolidation of a nuclear self (Kohut & Wolf, 1978, pp. 414–416). The idealization of the selfobject leads to the development of ideals. At the opposite pole of this “bipolar self” is a representation of natural talents gained through the mirroring function. Selfobjects continue to be needed throughout life, to some degree, to sustain self-cohesion (Kohut, 1984). Kohut’s self psychology relies on the notion of attachment as a central motivation for the establishment and maintenance of self-cohesiveness (Shane, Shane, & Gales, 1997). Like Bowlby, Kohut replaced the dual drives of classical analysis with a relational construct. Like Winnicott, he linked self-development with mirroring or maternal sensitivity. And like attachment theorists, he reversed the relationship of drives and self-structure, regarding the self as superordinate and drive conflicts as indications of “an enfeebled self” (Kohut, 1977).

Unlike attachment theorists, however, self psychologists view the cohesion of the self as the primary motivation guiding human behavior rather than as a biologically predefined relationship pattern. Kohut separated anxiety about object loss from anxiety about disintegration of the self. For self psychology, the root of anxiety is the self’s experience of a defect, a lack of cohesiveness and continuity (Cohler & Weiner, 2011). This subtle but important shift of emphasis relegates the attachment figure to second place.

It is also difficult to identify within attachment theory a concept analogous to grandiosity or omnipotence as naturally occurring in infant development. The notion of infantile omnipotence is certainly challenged by findings indicating that on the majority of occasions the infant is not able to elicit synchronous (mirroring) behavior from the mother (Tronick, 2007). Although infants undoubtedly enjoy experiences of mastery (Rochat, 2009), there is no evidence that this leads to a sense of omnipotence. It seems far more likely that we are once more encountering the problematic tendency of psychoanalytic thinkers to describe infant behavior in terms of adultomorphic constructs. This is the very problem Bowlby’s entire theoretical effort aimed to address.

e. Developmental Research and Attachment

The work of Daniel Stern (1985) bridged the gulf between infant researchers and psychoanalysts in a highly successful and productive way. His primary concern was with the development of self-structure. He distinguished four stages of early formation of the self: (1) the sense of emergent self (0–2 months) involves the process of the self’s coming into being and forming initial connections; (2) the sense of core self and the domain of core relatedness (2–6 months) are based on the single organizing subjective perspective and a coherent physical self; (3) the sense of subjective self and the domain of intersubjective relatedness (7–15 months) emerge with the discovery of subjective mental states beyond physical events; and (4) the sense of verbal self forms after 15 months.

Stern (1985, 1994) described three types of relationships of self-with-other: (1) self–other complementing, (2) state sharing, and (3) state transforming. Although these relationships can be characterized by the degree of attachment or separateness they imply, Stern was interested in their contribution to structuring the self through the schematization of experience. Stern’s most important point of contact with attachment theory is probably in the elaboration of the IWM. His starting point is the “emerging moment,” which is the subjective integration of all aspects of lived experience. The “moment” takes its input from emotions, behaviors, sensations, and all other aspects of the internal and external world from schematic representations of various types (e.g., event representations, semantic representations or conceptual schemas, perceptual schemas, and sensorimotor representations). He adds two further modes of representations: “feeling shapes” and “pronarrative envelopes.” These schemas form a network, which he terms “the schema of a-way-of-being-with.” The schema of a-way-of-being-with is conceptualized by Stern (1998) from the assumed subjective perspective of the infant in interaction with the caregiver.

The infant organizes his or her experience around a motive and a goal. The goals are not only biological, but include object relatedness (Fairbairn), affect states (Kernberg), states of self-esteem (Kohut), and safety (Sandler), as well as the gratification of physical needs, whether hunger, thirst, sexuality, or aggression. Stern’s theory elaborates that of Winnicott (1971): attunement satisfies the infant’s need for omnipotence, while

the caregiver's capacity to accept protest without retaliation or anxiety allows the child to have confidence in the caregiver as resilient to the infant's attacks.

Stern's framework has much to offer attachment theory, particularly in terms of the careful integration of infant observation studies with concepts concerning interpersonal development. Nevertheless, it lacks two critical dimensions essential to attachment theory. First, it lacks a genuine longitudinal observational perspective. A great strength of attachment theory is its almost unique empirical handle on longitudinal and cross-generational predictions. Although Stern's observations are well operationalized in terms of mother–infant interaction and infant development, they lack operationalization in the context of adult behavior; therefore, longitudinal studies based on Stern's framework have rarely been attempted. Second, while Stern (1998) probably appropriately claims that schemas of ways-of-being-with are the building blocks of IWMs, close links between the two systems have not yet been demonstrated. However, important pioneering work by Beatrice Beebe and her group (Beebe, Lachmann, & Jaffe, 1997) has drawn on this ambition. In the tradition of pioneers such as Stern and Emde (e.g., Emde & Spicer, 2000), this work has sought to demonstrate the significance of the growth of scientific understanding of early development for clinical and theoretical psychoanalysis. It has led to the gradual modification of the image of the “psychoanalytic infant” from a hypothetical creature based on speculative reconstruction from adult narratives, to a picture that is constrained and moderated by actual systematic observations of children.

The Beebe and Lachmann (2014) microanalytic studies of mother–infant interactions, from as young as 4 months of age, provide a robust way to apply attachment thinking to psychodynamic psychotherapy. Video microanalysis allows for the capture of rapid and often very subtle communicative events that can help us to tease out the origins of communication disturbances in infancy. The detailed empiricism of Beebe's observations is reminiscent of the complex and meticulous observational work originally undertaken by Mary Ainsworth (Beebe & Lachmann, 2014).

Tronick (2003) has also deepened our understanding of the uniqueness of attachment relationships and proposed an important model for how these relationships increasingly differentiate themselves. This work has taken us beyond attachment theory's early, reductive views on proximity, and

has helped us to conceptualize the nuances of the mother–infant relationship and the mechanisms through which attachment is achieved and maintained. In particular, by pointing to the uniqueness of each attachment bond, Tronick's (2008) contribution has challenged the view that the child's relationship with the mother is paradigmatic for later relationships. At the same time, however, the model radically revised our understanding of how relationships do influence one another (Tronick, 2005, 2007).

Tronick's (1989, 2007) mutual regulation model (MRM) of infant–adult interaction focuses on the subtle, nonverbal, microregulatory and socioemotional processes that unfold in mother–infant interactions. The MRM postulates that infants have “self-organizing neurobehavioral capacities” and “biopsychological processes” that allow them to “organize behavioral states” and make “sense of themselves and their place in the world” (Tronick, 2007, pp. 8–9). At the same time, Tronick pointed to the limits of these capacities and stated that they need to be supplemented by a “larger dyadic regulatory system” in which the infant participates with the caregiver (Tronick, 2007, p. 9). In this way Tronick brings together the notion of sensitivity with the overriding construct of meaning making.

Successful mutual regulation is achieved when an infant and caregiver together generate, communicate, and integrate meaningful elements of consciousness. This creates a synchrony in implicit relational knowing, allowing each to anticipate and “know” the moves of the other. This “knowing” is initially of a pattern of physiological responses or activations rather than of intentional states, although clearly it can be the platform for knowing of intention given developmental time. The parent–infant collaboration results in a singular, organized dyadic state that is believed to be more than the sum of its parts. This leads to what Tronick terms a state of “co-creativity” in which infant and caregiver shape their relationship through a process of mutual regulation (Tronick, 2003, p. 476).

The focus of both Beebe and colleagues' (1997) interactive regulation model and Tronick's (1989, 2007) MRM includes the “messiness” of interpersonal communications, as well as the greater cohesion allowed through reparation and co-creativity. These models allow us to operationalize such psychoanalytic concepts as the *holding environment* (Winnicott, 1965) and *background of safety* (Sandler, 1960), and take us toward a genu-

inely relational model of change in psychoanalytic treatment. Furthermore, studies of the contingency between the mother's and infant's vocalizations can help us to predict secure attachment relationships (Jaffe, Beebe, Feldstein, Crown, & Jasnow, 2001).

Work by Mayes (e.g., Mayes & Leckman, 2007) has taken some of the ideas first plotted in psychoanalytic terms and powerfully worked them through an empirical, child-development perspective. Mayes has been particularly notable in her use of Winnicott's (1958) clinical and theoretical insights. His idea of maternal primary preoccupation and his thoughts on maternal care and its role in child development have, for example, been explored by Mayes in her study of the course of and fluctuations in early primary preoccupation (Leckman & Mayes, 1999). The study found that parents' perceptions of the maternal care they received during childhood predicted postpartum fluctuations in mood. Mayes and colleagues suggest that parents whose representations of early parenting are colored by perceptions and experiences of unavailable or inadequate care are less able to sustain the intense, adaptive preoccupied focus on their new infant without also experiencing dysphoria. In this model, early parenting experiences may determine the extent to which new parents might be vulnerable in the peripartum period (Mayes & Leckman, 2007; for clinical applications, see Berlin, Zeanah, & Lieberman, Chapter 32, this volume).

4. Mentalizing Theory and Attachment

The mentalizing model is a recent psychoanalytic extension of attachment theory and research that claims a synergistic relationship between attachment processes and the growth of a child's capacity to understand interpersonal behavior in terms of mental states (Fonagy, Gergely, Jurist, & Target, 2002). This capacity is referred to as *mentalizing* or *reflective functioning*. Recent elaborations of this theory have pointed to the key role of attachment relationships in the development of the capacity for epistemic trust (which we discuss later). Both evolutionary considerations and experimental developmental research suggest that epistemic trust plays a key role in the intergenerational transmission of knowledge and in learning that is specific to human beings (Fonagy, Luyten, & Allison,

2015). These new theoretical and empirical developments, which have emerged out of a new dialogue among attachment theory, the mentalizing approach, and evolutionary theory, also shed new light on the nature and emergence of personality disorders (PDs), as outlined below, and attest to the ongoing productivity of the interface between psychoanalytic ideas and attachment theory.

Mentalizing is often simplistically understood, but research findings clearly demonstrate that it involves a spectrum of capacities. It is underpinned by four dimensions involving relatively distinct neural circuits: (1) automatic versus controlled, (2) based on external features (e.g., facial expression, posture) versus internal indicators, (3) regarding the self and others, and (4) cognitive versus affective (Bateman & Fonagy, 2012). Effective mentalizing requires the individual to maintain a balance across these four dimensions.

Over the past 25 years, a systematic program of research has demonstrated that the capacity to mentalize emerges in the context of early attachment relationships and is a key determinant of self-organization and affect regulation. Specifically, studies examining different ways in which caregiver mentalizing is operationalized—including prenatal reflective function (Fonagy, Steele, Steele, Moran, & Higgitt, 1991), child-specific reflective function (Slade, Grienberger, Bernbach, Levy, & Locker, 2005), mind-related comments (Meins, Fernyhough, Fradley, & Tuckey, 2001; Meins et al., 2002), and a diverse range of other measures (Aber, Slade, Berger, Bresgi, & Kaplan, 1985; Koren-Karie, Oppenheim, Dolev, Sher, & Etzion-Carasso, 2002; Oppenheim, Koren-Karie, & Sagi, 2001; Solomon & George, 1999)—indicate that each of these aspects of mentalizing capacity predicts attachment security in the child. Furthermore, the caregiver's capacity to mentalize can offer protection from risk factors in the caregiver that are associated with generating attachment insecurity, such as maternal trauma and disruptive maternal behaviors. We also now know that the benefits of caregiver mentalizing extend beyond attachment outcomes: it is associated with children's better performance in social cognition tasks (Laranjo, Bernier, Meins, & Carlson, 2010; Meins et al., 2002), as well as general social-cognitive development (Meins et al., 2003). By contrast, social environments characterized by adversity in child development (e.g., neglect, abuse) impair the development of cognition (Ayoub et al., 2009; Fernald, Weber, Galasso, & Ratsifandrihamanana, 2011; Goodman, Quas,

& Ogle, 2010; Rieder & Cicchetti, 1989). The mentalizing approach proposes that problems in affect regulation, attentional control, and self-control stemming from dysfunctional attachment relationships (Agrawal, Gunderson, Holmes, & Lyons-Ruth, 2004; Lyons-Ruth, Yellin, Melnick, & Atwood, 2005; Sroufe, Egeland, Carlson, & Collins, 2005), as manifested perhaps most clearly in severe personality problems such as borderline personality disorder (BPD), are mediated through a failure to develop a robust mentalizing capacity (Bateman & Fonagy, 2010).

While the mentalization-focused model of development places strong emphasis on the relationship between attachment and mentalizing, this relationship is situated within a broader developmental approach that also emphasizes the role of gene-environment interplay (for a fuller discussion of this point, see Fonagy & Luyten, 2016). Although the capacity to mentalize is not a constitutional given, it does seem to be a capacity that is partly prewired (Kovacs, Teglas, & Endress, 2010). Thus, this is not a naive environmentalist model: the interaction between genetic predisposition and early and later influences on the development of the capacity to mentalize is thought to be crucially important.

In this section we outline the mentalizing model and show how certain observed associations between attachment and psychopathology can be understood in terms of the vicissitudes of the development of the capacity to mentalize, taking BPD as a paradigmatic example.

a. Disordered Attachment in BPD

Studies using both self-report and interview-based measures of attachment have shown that BPD is associated with increased levels of attachment insecurity (Agrawal et al., 2004). Cross-sectional investigations show that individuals with borderline features have preoccupied, disorganized, and unresolved patterns of attachment (Levy, Beeney, & Temes, 2011). A cross-sectional study examining the attachment styles of patients with mood disorder and those with BPD found that although both groups showed greater preoccupation and fearfulness than controls, only patients with BPD simultaneously showed preoccupation *and* fearfulness. This study therefore confirms the suggestion from a number of attachment theorists that the key marker of BPD may be a lack of any functional regulation strategy to reduce attachment distress (Fonagy & Bateman, 2008; Main, 2000).

To understand these associations, we must consider the nature of early attachments. Our model hypothesizes that suboptimal early attachment experiences are robust predictors of BPD in later life, not so much because of the attachment experiences themselves, but because it is in the context of attachment relationships that the infant learns to understand his or her own emotional states, acquires the capacity for affect regulation, and discovers him- or herself as a psychological entity through marked mirroring interactions (Fonagy et al., 2002; Fonagy, Gergely, & Target, 2007). In line with this hypothesis, Carlson, Egeland, and Sroufe (2009) reported significant, although weak, correlations between borderline symptoms at 28 years of age and indicators of a suboptimal early environment (maltreatment, maternal hostility, attachment disorganization, and family stress in the first 3–4 years of life). These culminated in a range of social-cognitive anomalies—attentional disturbance, emotional instability, and relational disturbance—that were evident by 12 years of age. A path-analytic approach offered strong evidence that disturbances in self-representation in early adolescence mediated the link between disorganization of early attachment relationships and PD.

b. BPD and Childhood Adversity

The role of developmental trauma in BPD in general has been a significant focus of research. Among individuals with PDs, rates of childhood trauma are very high (Ball & Links, 2009). Compared with nonclinical adults, patients with PDs are four times as likely to have suffered early trauma (Johnson, Cohen, Brown, Smailes, & Bernstein, 1999), and BPD is more consistently associated with childhood maltreatment than any other PD diagnosis (e.g., Baird, Veague, & Rabbitt, 2005; Battle et al., 2004; Buchheim et al., 2008).

A particularly impressive study following up several hundred abused and neglected children and matched controls into adulthood reported a 2.5-fold increase in the prevalence of BPD associated with abuse and neglect (Widom, Czaja, & Paris, 2009). In this prospective investigation of children who were identified as maltreated by child protection services, early neglect appeared to be the most potent risk factor for both genders, whereas physical abuse represented a risk only for males. A systematic review of the literature on BPD and trauma by Crombie (2013) found that generally high-quality studies across a range of de-

signs and measurement methodologies converge in showing, both prospectively and retrospectively, that emotional neglect and abuse predict BPD symptoms and diagnosis in line with or in excess of the impact that can be observed to be associated with physical and sexual abuse. This observation supports our expectation that even in the absence of dramatic maltreatment, the individual's competence to represent mental states may be undermined by the absence of contingent responses to their subjective experience, resulting in increased vulnerability for BPD. Subsequent brutality in an attachment context may then further disrupt mentalizing as part of an adaptive adjustment to adversity (Fonagy, Steele, Steele, Higgitt, & Target, 1994; Stein, Fonagy, Ferguson, & Wisman, 2000). Hence, early emotional neglect in particular, rather than physical or sexual abuse as such, may predispose individuals to the development of BPD by limiting their opportunity to acquire the capacity to mentalize and leaving them vulnerable to disruptions in mentalizing under the influence of later stress.

c. Disruptions of the Caregiving Environment and the Development of Mentalizing

Consistent with these claims, studies show that insecurely attached children do not perform as well as secure children in mentalizing tasks (e.g., de Rosnay & Harris, 2002). The London Parent-Child Project (Fonagy, Steele, Steele, & Holder, 1997), for instance, found that 82% of children who were secure with their mother in the Strange Situation passed Harris's Belief-Desire-Reasoning Task at 5.5 years, compared with 50% of those who were avoidant and 33% of the small number who were preoccupied. The mentalizing approach has emphasized the importance of secure attachment in providing a context in which the child is allowed to develop the ability to mentalize and regulate his or her own emotions. But even more importantly, in an environment that is invalidating and emotionally abusive, an insecure and disorganized attachment pattern is likely to develop, and this is likely to seriously hinder development of the capacity for mentalizing (Fonagy, 2000; Fonagy & Luyten, 2009).

Again, the broader context seems to be key here. Significantly, Widom and colleagues (2009) found that the impact of child abuse and neglect became nonsignificant in a regression model pre-

dicting BPD features when other family and lifestyle characteristics were included (e.g., parental substance use, employment, education level, and Axis I disorders). These authors concluded that maltreatment may represent a marker for family dysfunction, and that family dysfunction may actually be more significant in leading to a greater risk of BPD. This is congruent with the notion that abuse and neglect are typically part of a broader context characteristic of "risky families and environments" (Repetti, Taylor, & Seeman, 2002) or "pathogenic relational environments" (Cicchetti & Toth, 2005). A number of family-related factors—all likely to undermine the acquisition of mentalizing—have been reported to be significant predictors of BPD, including parental psychopathology, witnessing domestic violence in childhood, and parental imprisonment and suicide attempts (Afifi et al., 2011; Helgeland & Torgersen, 2004; Widom et al., 2009; Zanarini, Frankenburg, Hennen, Reich, & Silk, 2006). More detailed prospective studies of caregiver-child interactions are needed to investigate these assumptions further, but we may expect growing up in an environment of insecure and unpredictable attachment relationships to disrupt the acquisition of robust mentalizing. In this context, a recent comprehensive systematic review (Macintosh, 2013) identified five studies (Bouchard et al., 2008; Fonagy & Bateman, 2006; Fossati et al., 2009; Fossati, Feeney, Maffei, & Borroni, 2011; Stein & Allen, 2007) supporting the assumption that impairments in mentalizing mediated the relationship between insecure attachment and/or adversity and adult functioning. However, more research is clearly needed in this area.

Considered in relation to attachment, mentalizing deficits associated with childhood maltreatment may be a form of decoupling, inhibition, or even a phobic reaction to mentalizing. Various studies indeed suggest that (1) adversity may undermine cognitive development in general (Cicchetti, Rogosch, & Toth, 2000; Crandell & Hobson, 1999; Stacks, Beeghly, Partridge, & Dexter, 2011), (2) mentalizing problems as a result of maltreatment may reflect arousal problems associated with exposure to chronic stress (see Cicchetti & Walker, 2001), and (3) the child may avoid mentalizing to avoid perceiving the abuser's hostile and malevolent thoughts and feelings about him or her (e.g., Fonagy, 1991; Goodman et al., 2010).

Regardless of the precise nature of the impact of early adversity on mentalizing, these findings imply that the foundations of subjective selfhood

will be less robustly established in those who have experienced early neglect. However, whereas some readers might interpret this approach as a deficit theory, our emphasis is on adaptation. The specific configuration of mentalizing capacities characterizing individuals with BPD (and other types of psychopathology associated with impairments in mentalizing) may be conceived of as optimizing the child's adaptation to the challenges of his or her social context (Blair & Raver, 2012; Frankenhuis & Panchanathan, 2011; Frankenhuis, Panchanathan, & Clark Barrett, 2013). Our speculation that in circumstances of neglect and/or abuse, it may be preferable to forgo reflective considerations—particularly of the cognitions of others (Fonagy, 1991)—is consistent with an evolutionary-developmental view that suggests we have to study the likely impact for survival and the costs and benefits (to children) of developing particular mental capacities in particular social contexts (Belsky, 2012; Ellis et al., 2012). While the impairments in mentalizing that we have noted may bring benefit to the child under some social conditions, in normal adult contexts, they render the individual more vulnerable—even in the face of social adversity in adulthood. The precise nature of these impairments, research suggests, largely depends on individuals' dominant secondary attachment strategies for dealing with experiences, which become increasingly generalized. In the next section, we review these strategies and their influence on mentalizing in more detail.

d. Neurobiology of Stress, Attachment, and Mentalizing

Beyond the general impact of attachment disruptions on mentalizing, secondary attachment strategies (deactivation or hyperactivation of the attachment system in an effort to cope with threats; Cassidy & Kobak, 1987) have a more specific influence on mentalizing and may explain individual differences in mentalizing profiles.

Following the model outlined by Arnsten and colleagues (1998, 1999) and Mayes (2000, 2006), we suggest that with increased arousal a switch occurs from cortical to subcortical systems, from controlled to automatic mentalizing, and, subsequently, to nonmentalizing modes. Two points are critical for understanding impairments in mentalizing in this context. First, owing to the neurochemical switch associated with escalating emotional stress, patterns of brain functioning can shift from flexibility to automatic functioning: that is,

from relatively slow executive functions mediated by the prefrontal cortex (PFC) to faster habitual behaviors mediated by posterior cortical (e.g., parietal) and subcortical (e.g., amygdala, hippocampus, and striatum) structures. At the same time, mentalizing seems to disappear as self-protective physical reactions (i.e., fight–flight–freeze) begin to dominate behavior. This has the presumed evolutionary value of promoting immediate adaptive responses to danger. However, in situations of interpersonal stress, where complex cognitive–emotional functioning (i.e., mentalizing) may be helpful, the switch from executive (mentalizing) to automatic (fight–flight–freeze) responses may be counterproductive, to say the least. We also assume, following Arnsten and colleagues and Mayes (2000), that exposure to early stress and trauma can lower the threshold for switching, an assumption that has received considerable empirical support in the meantime. Second, both situational and more stable within-person variations play a role in the switch from more controlled to automatic mentalizing (for detailed discussion, see Fonagy & Luyten, 2009; Luyten, Fonagy, Lowyck, & Vermote, 2012).

In individuals with *secure attachment*, activation of the attachment system predictably involves a relaxation of normal strategies of interpersonal caution. There is good evidence that intense activation of the neurobehavioral system underpinning attachment is associated with deactivation of the arousal and affect-regulation systems (Fonagy & Luyten, 2009; Luyten et al., 2012), as well as the deactivation of neurocognitive systems likely to generate interpersonal suspicion, that is, those systems and brain regions involved in social cognition or mentalizing, including the lateral PFC, medial PFC (mPFC), lateral parietal cortex, medial parietal cortex, medial temporal lobe, and rostral anterior cingulate cortex (Bartels & Zeki, 2000, 2004; Lieberman, 2007; Satpute & Lieberman, 2006; Van Overwalle, 2009). For example, with increased intimacy, regions of the brain associated with reflective mentalizing will be deactivated—which perhaps explains the many linguistic and cultural variations of the popular sentiment that love is blind.

Moreover, as noted, the neuropeptides oxytocin and vasopressin play key roles in two aspects of creating attachment relationships: (1) by activating the reward/attachment system, and (2) by deactivating neurobehavioral systems that are involved in mediating social avoidance (Bartels & Zeki, 2004). For instance, oxytocin and vasopres-

sin have been shown to inhibit aversion of both female and male rodents to infant pups, and to promote a number of affiliative behaviors, including caregiving behavior (Heinrichs, von Dawans, & Domes, 2009; Insel & Young, 2001). Oxytocin also reduces behavioral and neuroendocrine responses to social stress and seems to enable animals to overcome their natural avoidance of proximity and to inhibit defensive behavior, thereby facilitating approach behavior (Simeon et al., 2011). Vasopressin has primarily been implicated in male-typical social behaviors, including aggression and pair-bond formation, and mediates anxiogenic effects (Heinrichs & Domes, 2008). Thus, in the context of secure attachment, activation of the attachment system will generate not only increased experience of reward, increased sensitivity to social cues, and decreased social avoidance, but also the potential for the reward to override lack of trust. This complex set of associations with social behavior may help to account for the puzzling combination of facilitative and inhibitory associations between attachment history and social cognition. For instance, in two separate imaging studies, Bartels and Zeki (2000, 2004) reported that the activation of areas mediating maternal and/or romantic attachments appeared simultaneously to suppress brain activity in several regions mediating different aspects of cognitive control, including those associated with making social judgments and mentalizing. The second set of brain areas observed to be deactivated by the activation of attachment concerns included the temporal poles, temporoparietal junction, amygdala, and mPFC—areas consistently linked to explicit and internally focused mentalizing, including judgments of social trustworthiness, moral judgments, theory of mind tasks, and attention to one's own emotions.

In contrast, studies suggest that *anxious-preoccupied attachment strategies* are associated with simultaneously lowered thresholds for attachment system activation and deactivation of controlled mentalizing. In these individuals, more automatic, subcortical systems, including the amygdala, have a lower threshold for responding to stress.

Attachment deactivating strategies have in turn been shown to be associated with the capacity to keep systems involved in controlled mentalizing online for longer, including systems involved in judging the trustworthiness of other individuals (i.e., the “pull” mechanism associated with attachment; Vrticka, Andersson, Grandjean, Sander, & Vuilleumier, 2008). Yet whereas securely attached individuals are able to keep the controlled men-

talizing system online even when stress increases, which means that the attachment system is less likely to be triggered, the deactivating strategy of dismissive individuals is likely to fail in these circumstances. If securely attached individuals are those who are able to retain a relatively high activation of prefrontal areas in the presence of activation of the dopaminergic mesolimbic pathways (the attachment and reward system), then differences in mentalizing between securely attached individuals and those individuals who primarily rely on attachment deactivating strategies may become apparent only under increasing stress; this seems consistent with the findings of experimental studies (Mikulincer & Shaver, 2007).

This model allows us to explain why, for instance, mentalizing deficits in BPD are more likely to be observed in experimental settings that trigger the attachment system, such as in studies collecting AAI narratives (e.g., Fonagy et al., 1996; Levinson & Fonagy, 2004), and also why patients with BPD who mix deactivating and hyperactivating strategies, as is characteristic of *disorganized attachment*, show tendencies for both hypermentalizing and mentalizing failure. On the one hand, because attachment deactivating strategies are typically associated with minimizing and avoiding affective content, patients with BPD often have a tendency for hypermentalizing; that is, continuing attempts to mentalize, but without integrating cognition and affect. On the other hand, because the use of hyperactivating strategies is associated with a decoupling of controlled mentalizing, this leads to failure of mentalizing as a result of overreliance on modes of social cognition that antedate full mentalizing (Bateman & Fonagy, 2006).

We see BPD as being in some ways at the opposite end of the spectrum from *interpersonal resilience* (Gunderson & Lyons-Ruth, 2008; Higgitt & Fonagy, 1992). Studies suggest that the ability to continue to mentalize even under considerable stress leads to so-called “broaden and build” (Fredrickson, 2001) cycles of attachment security, which reinforce feelings of secure attachment, personal agency, and affect regulation (“build”) and lead one to be pulled into different and more adaptive environments (“broaden”) (Mikulincer & Shaver, 2007). Congruent with these assumptions, studies on resilience have shown that positive attachment experiences are related to resilience in part through relationship recruiting, that is, the capacity of resilient individuals to become attached to caring others (Hauser, Allen, & Golden, 2006). Hence, high levels of mentalizing and the associated use of se-

curity-based attachment strategies when faced with stress are good candidates to explain the effect of relationship recruiting and resilience in the face of stress. In contrast, attachment hyperactivation and deactivation have been shown to limit the ability to broaden and build in the face of stress. Moreover, they have also been shown to inhibit other behavioral systems that are involved in resilience, such as exploration, affiliation, and caregiving (Insel & Young, 2001; Mikulincer & Shaver, 2007; Neumann, 2008). This may also partially explain these individuals' difficulties in entering lasting relationships (including relationships with mental health care professionals) and the intergenerational transmission of borderline pathology.

To summarize, we may envision three types of association between aspects of mentalizing and attachment. These are created by (1) attachment relationships based on intense romantic or maternal love, (2) attachment relationships based on threat/fear, and (3) secure and predictable attachment relationships. Although any given attachment relationship may have features of each of these three types, they are important to distinguish because the relationship between attachment activation and mentalizing may differ considerably depending on which feature is activated within an attachment relationship: (1) mediated by dopaminergic structures of the reward system in the presence of oxytocin and vasopressin, the love-related activation of the attachment system can inhibit the neural systems that underpin the generation of negative affect; (2) threat-related activation of the attachment system (e.g., triggered by perceived threat, loss, or harm) may also evoke intense arousal and overwhelming negative affect, bringing about an activation of posterior cortical and subcortical areas and switching off frontal cortical activity, including mentalizing (Arnsten, 1998; Arnsten et al., 1999; Mayes, 2000); (3) meanwhile, a secure and predictable attachment relationship may be most effective in *preempting* threat, which possibly reduces the need for frequent activation of the attachment system.

e. Attachment, Mentalizing, and Epistemic Trust

Recent elaborations of thinking about mentalizing have pointed to a further important function of attachment relationships: the development of epistemic trust, enabling social learning in a constantly changing environment (Fonagy & Luyten, 2016; Fonagy et al., 2015).

As we have seen, there is now considerable evidence that the caregiver's capacity to mentalize predicts secure attachment in the child. This raises the related question: how does the child learn from their caregiver's behavior? This question has powerful ramifications for our understanding of human social development. We have argued elsewhere (Fonagy et al., 2015), based on both evolutionary findings and theory (Sperber et al., 2010; Wilson & Sperber, 2012), as well as experimental developmental research (e.g., Corriveau et al., 2009), that secure attachment experiences pave the way for not only the acquisition of mentalizing but also, potentially more generally, the formation of epistemic trust, that is, an individual's willingness to consider another person's communication of new knowledge as trustworthy, generalizable, and relevant to the self. As noted, these theoretical developments promise to lead to major changes in our views concerning the importance of attachment relationships in human development.

The theory of natural pedagogy (ToNP; Csibra & Gergely, 2009) has offered a compelling empirically based model to explain how attachment history can create distinct types of epistemic states. ToNP is based on research suggesting a human-specific, cue-driven social-cognitive adaptation of mutual design dedicated to ensuring the most effective and efficient transfer of culturally relevant knowledge. This fast route for transmission of knowledge is needed in humans because most of our knowledge about the world is cognitively opaque. Csibra and Gergely (2009) used an idea first discussed by Bertrand Russell (1940), but extensively used by Sperber and Wilson (1995), suggesting that certain signals (*ostensive cues*) are employed by an agent to indicate his or her intent to communicate to the addressee. These cues may also serve to counteract natural *epistemic vigilance* (an adaptive self-protection against potentially damaging, deceptive, or inaccurate information). The ToNP model claims that ostensive cues generate a particular attentional state in which natural disbelief is temporarily suspended and the addressee feels that the communication contains information specifically relevant to him or her, which should be remembered and encoded as knowledge that is generally relevant to social situations. The information can be laid down and used as part of procedural and semantic memory, not uniquely or primarily episodic memory.

Research in this context suggests that a securely attached child is more likely to feel that the caregiver is a reliable source of knowledge because

the predictors of secure attachment relationships are in essence also ostensive communication cues. A sensitive caregiver's consistent emotional responses to the child are communicated via the caregiver's ostensive cues, which include eye contact, turn taking, contingent reactivity, and the use of a special tone of voice, all of which appear to trigger a special mode of learning in the infant. The caregiver's marked mirroring of the infant's emotional expression that underpins the development of emotion understanding can be seen as ostensive in nature, signaling the relevance of the caregiver's display to the infant's accumulating knowledge base about his or her own subjective experience (Fonagy et al., 2007).

In brief, ostensive cues trigger epistemic trust and simultaneously engender secure parent-child attachment (Fonagy et al., 2007). They set aside the biological protection provided by epistemic vigilance. They open a channel of information exchange about the social and personally relevant world (an "epistemic superhighway") that allows us to acquire new knowledge rapidly. The knowledge transmitted is generalized beyond the specific experience in which it is acquired, remembered, and encoded with the authority but not the person of the communicator. Epistemic trust is necessary to allow us to change our position safely in the light of new experiences.

Several fascinating developmental experiments summarized by Csibra and Gergely (2009) offer compelling evidence from infancy for the power of this dialogic learning process. In one simple demonstration, 6-month-old infants were shown to follow an agent's gaze-shift selectively to an object only if it had been preceded either by eye contact with the infant or by infant-directed speech (Senju & Csibra, 2008). Shared attention with an agent is triggered by the infant experiencing the agent's interest. The interest triggers the infant's expectation (epistemic trust) that there may be something relevant for the infant to learn.

A second study employing an automated eye-tracker used an infant-induced contingent reactivity paradigm (Deligianni, Senju, Gergely, & Csibra, 2011). During the familiarization phase, 8-month-old infants observed a display of five unfamiliar animated objects (looking more like jugs or kettles than anything else). Four of these, in the four corners of the display, moved unpredictably. The object at the center acted differently in two conditions. In the interactive condition, whenever the infant's gaze wandered toward the object, it would apparently respond to the infant's

gaze with movements and sound. In the control condition, the central object would move a comparable amount, but this would be independent of the infant's gaze. In the test phase, only three objects were present. The central object in this phase turned toward either the left or the right object. It should be noted that although none of the five jug-like objects had eyes, they had a clear, unequivocal front signaled by a pointed "hat" and an elongated "nose" (somewhat reminiscent of a kettle with an upturned beak). The 8-month-olds in the interactive condition detected the contingent activity of the central object and looked at the object it turned toward (i.e., followed its "gaze") far more. In the noncontingent control condition, the infants did not look longer, more frequently, or more promptly at the object toward which the central object turned. It seems that the contingent reactivity of this nonhuman and somewhat bizarre object was sufficient to influence the infant's orientation. The study is important in showing that it is the experience of response-induced contingencies that creates epistemic trust and elicits a "joint attention response."

As noted, studies in this context emphasize the key importance of attachment history. For example, in a longitudinal study of attachment, 147 children assessed for attachment in infancy were tested twice for epistemic trust at the ages of 50 and 61 months (Corriveau et al., 2009). In this study, the child's mother and a stranger made conflicting claims to a child concerning (1) the name of a novel object, (2) the name of a hybrid animal made up of 50% of each of two animals (e.g., an image made up of 50% rabbit and 50% squirrel; the mother might call it a squirrel, while the stranger says it is a rabbit), and (3) the name of a hybrid animal made up of 75% of one animal and 25% of another. In the third case it was always the mother who made the improbable claim (e.g., that a picture made up of 75% bird and 25% fish was a fish), while the stranger gave the more likely answer (in this example, "bird"). The nature of a child's attachment relationship powerfully conditioned the child's trust in the information imparted by the attachment figure (mother) and others (strangers) as informants. Children who were securely attached in infancy displayed a flexible strategy, showing a preference toward accepting claims made by their mother when appropriate. Insecure-avoidant children withheld trust in their mother, preferring to attend to information from the stranger, while insecure-resistant children withheld trust in the stranger even when their

mother made improbable claims. Children with insecure-disorganized histories evidenced what we may call *epistemic hypervigilance*; they appeared to regard both sources of information with suspicion.

Hence, security of attachment, rooted in a history of feeling recognized, appears to increase the likelihood of trust in the source of communication when it is reasonably credible. Yet a secure attachment history also generates confidence in one's own experience and belief, and empowers one's (i.e., the child's) judgment. A history of attachment avoidance may generate epistemic mistrust, while anxious attachment creates epistemic uncertainty through overreliance on the views of the attachment figure. Disorganized attachment, rooted in a history of chronic misattunement, unsurprisingly can create mistrust of both the attachment figure and strangers as a source of information. It is the unresolvable question of "Whom can I trust?" that might contribute to epistemic hypervigilance in a child with a history of disorganized attachment.

Here, attachment researchers are faced with a conundrum. While these studies suggest that attachment may be a key mechanism for the mediation of epistemic trust, the theoretical formulations reviewed suggest that it may be secondary to an underlying biological process preserved by evolution. We have seen that stimuli such as the bizarre kettle-shaped object in the study described earlier are capable of at least momentarily triggering the same category of response as human beings. In other words, secure attachment is not likely to be a necessary condition for generating epistemic trust, but it may be sufficient, and perhaps the most pervasive in early childhood because it is a highly evolutionarily effective indicator of trustworthiness.

Looked at from a distance, microanalytic (e.g., Beebe et al., 2010) and more global (e.g., DeWolf & Van IJzendoorn, 1997; Isabella, Belsky, & von Eye, 1989; Kiser, Bates, Maslin, & Bayles, 1986; Mills-Koonce et al., 2007) ratings of sensitive caregiving can be seen as in essence recognizing the child's agentive self. It is this recognition that we believe offers the cognitive advantage to secure attachment, which has been fairly consistently noted, although not, to our knowledge, commonly studied (e.g., Crandell & Hobson, 1999; Jacobsen & Hofmann, 1997; Moss, Rousseau, Parent, St-Laurent, & Saintong, 1998) and contributes to the cognitive disadvantage of developmental adversity (Ayoub et al., 2009; Fernald et al., 2011; Goodman et al., 2010; Rieder

& Cicchetti, 1989). We believe that through the down-regulation of affect triggered by proximity seeking in the distressed infant, attachment not only establishes a lasting bond but also opens a channel for information to be used for the transfer of knowledge between the generations.

Attachment insecurity is likely to be associated with a greater likelihood of cognitive closure, a lower tolerance for ambiguity, and a more pronounced tendency for dogmatic thinking (Mikulincer, 1997). Saving intellectual effort and adopting stereotypes is also more likely in individuals whose attachment is insecure (Mikulincer, 1997). The same predisposition to knowledge inflexibility is revealed by the tendency of insecure individuals to make judgments on the basis of early information and to pay insufficient heed to subsequent data even if it is incompatible with the configuration first created (Green-Hennessy & Reis, 1998; Mikulincer, 1997). Insecure individuals, who fear the loss of attachment figures, also anxiously hold on to their initial constructions. Kruglanski (1989; Kruglanski & Webster, 1996; Pierro & Kruglanski, 2008) proposed the concept of *epistemic freezing*, characterized by a tendency to defend existing knowledge structures, even when they are incorrect or misleading (see also Fiske & Taylor, 1991).

Returning to the earlier theme of seeing adversity as leading not to deficit but rather to a superior adaptation to challenging environments (Frankenhuis et al., 2013), we may see such a defensive strategy as adaptive if an individual's self-esteem is vulnerable. Cognitive closure, dogmatism, and conservatism may simply be strategies to create a bulwark to safeguard an inadequately individuated self (Bowlby, 1980). By contrast, the greater confidence of secure individuals that they will be able to recover from dysregulation also enables them to be less defensive and more able to open their minds to information that may challenge their assumptions.

Mikulincer (1997) suggested that insecure individuals are more readily threatened by information that challenges their knowledge structures because of the vulnerability of their sense of self, and their vulnerability in particular to being emotionally overwhelmed. If emotional dysregulation is experienced as a real and imminent threat, they may opt for knowledge stability, as it temporarily serves to down-regulate arousal. Such individuals are less likely to revise their knowledge in the face of information that challenges their assumptions (Green & Campbell, 2000; Green-Hennessy & Reis, 1998; Mikulincer, 1997; Mikulincer & Arad,

1999) as if they not only have less confidence in the robustness of their bond to their attachment figure but also fear the loss of epistemic trust. In summary, we assume that the epistemic superhighway provided to us by evolution in order to learn from experience is partially closed to those whose attachment to their caregiver is insecure.

Anomalies of early parent–infant communication that predict attachment disorganization and later personality pathology (e.g., Lyons-Ruth, Bureau, Holmes, Easterbrooks, & Brooks, 2013) may be, from this perspective, understood as cases of *misuse of ostensive cueing*, by which we mean using cues to lead the infant to anticipate personally relevant, generalizable knowledge through a kind of pseudosensitivity followed by the transmission of disruptive and even destructive knowledge. From the perspective of epistemic trust as the mediator of culture, and its key underlying engine for progression, we see the destruction of trust in social knowledge as a key mechanism in pathological personality development. Developmental adversity, perhaps most deeply attachment trauma (Allen, 2012, 2013), may trigger a profound destruction of trust. The absence of epistemic trust generates an apparent rigidity in the eyes of the communicator, who, in accordance with the principles of theoretical rationality, expects the recipient to modify his or her behavior on the basis of the information received and apparently understood. But in the absence of trust, the capacity for change is absent. The information presented is not used to update the individual's social understanding. In terms of the ToNP (Csibra & Gergely, 2009) the person has (temporarily) lost the capacity for learning. From a therapist's standpoint, he or she has become "hard to reach" and interpersonally inaccessible.

According to the evolutionary perspective we are advancing, a particular attachment style should be seen less as a measure of the extent to which the caregiver succeeded in generating infant attachment security and, more broadly, as the child learning of the most appropriate method for his or her social survival in a complex interpersonal world (Belsky, 2006; Ein-Dor, Mikulincer, & Shaver, 2011; Mikulincer & Shaver, 2007; Simpson & Belsky, 2008). An avoidant-dismissive model of attachment might be more protective in certain environments than a secure one. Similarly, the anxious-preoccupied style may be an effective means of ensuring a child learns to effectively harness interpersonal attention and resources in a context of resource uncertainty. Even serious PDs

such as BPD, while conspicuously dysfunctional in our normative social setting, may have adaptive benefits for individuals living in an emergency milieu characterized by high levels of interpersonal violence, where there is a need for extreme vigilance on issues of self-protection and significant benefit in being able to form intense emotional relationships, which might elicit critical protection or resource supply, very quickly. The mentalizing strengths that have been noted in many individuals with BPD—a tendency to be able to make quick inferences of other people's mental states on the basis of their visual and emotional cues, hypersensitivity to facial expressions, hyper-reactivity to positive and emotional stimuli—are all suggestive of a mentalizing profile that may be an adaptation to functioning in a threatening or high-risk environment.

5. The Future of Attachment Theory and Psychoanalysis

Despite the limitations of attachment theory, it is clear that the attachment relationship provides the context in which we learn to make sense of ourselves and others, or, to use the language of psychoanalysis, in which we create our internal world. Yet we contend that the future of attachment theory lies in developing our understanding of the relationship of attachment and mentalizing.

The mentalizing construct bridges the gap between psychodynamic and attachment models by focusing on the relationship of attachment processes and the growth of the child's sense of self and his or her capacity to comprehend the mental states of others. The future clinical importance of attachment lies in understanding how mentalizing difficulties, impairments, and imbalances are generated and how they can be alleviated. Mentalizing also provides a broader developmental model within which we can reconsider and accommodate the developmental challenges and themes traditionally emphasized within psychoanalytic thinking: the ways in which individuals differently respond to the developmental, environmental, and instinctual challenges posed by sexuality and aggression, and cope with these challenges in a complex social world. Any genuinely convincing developmental understanding of the ways in which the emotional environment may affect the mind in infancy and childhood must accommodate the reality of evolutionarily driven adap-

tiveness. We postulate that mentalizing provides the missing link in understanding the evolutionary mechanism at work in the transmission of attachment. This broader evolutionary perspective, rather than creating a reflexive, flatly Pavlovian model for human development, allows us to appreciate the richness of human subjectivity through a theory that accommodates the complex mix of factors that makes us who we are: that is, the early emotional environment, genes, and the barrage of wider social pressures that each individual learns to interpret and respond to in particular ways depending on his or her epistemic history and mentalizing capacities.

At one level, our views on the relationship among attachment, mentalizing, and epistemic trust may appear to downplay the clinical significance of attachment. However, we would argue that attachment thinking remains fundamental to understanding the mechanism through which mentalizing and epistemic trust are made possible. From the outset, the most effective way an infant is first mentalized and first able to develop epistemic trust is in the context of a secure attachment relationship. Similarly, it is only in the context of stable attachment relationships, and then within the wider social environment, that mentalizing can be developed and epistemic hypervigilance can safely be relaxed. According to this thinking, as humans evolved greater social complexity, the attachment relationship became coaxial with the transmission of other, more species-specific social-cognitive processes, such as mentalizing and the promotion of natural pedagogy.

This latest elaboration of thinking in relation to attachment takes us back to one of Bowlby's original intentions in the formulation of attachment theory: making sense of emotional development and psychopathology in an evolutionary context. Psychoanalytic thinking, and psychology more broadly, has been criticized for failing to take into account the impact of the socioeconomic environment on the individual psyche (Fonagy, Target, & Gergely, 2006). We can no longer neglect this influence. For instance, there is accumulating evidence that increasing levels of social inequality are connected with an increased prevalence of BPD (Grant et al., 2008; Wilkinson & Pickett, 2009). If we consider that the evolutionary drive behind mentalizing was to enable our survival in increasingly complex social situations involving matters of hierarchy, cooperation, exclusion, and inclusion, it makes eminent sense that representations of ourselves and those

around us should calibrate the extent to which we are experiencing social isolation, alienation, or inferiority. Psychological resilience enables the individual to resist these pressures to some degree; individuals with BPD are often conspicuously reactive to such pressures—to be wholly impervious to their effects suggests mentalizing impairments of a different nature altogether. Both extremes, however, derive from an inability to absorb information from the social environment in a way that is compatible with the construction of a normatively coherent sense of self.

Chapter 35

Couple and Family Therapy

An Attachment Perspective

Audrey Brassard
Susan M. Johnson

Attachment theory, as a well-researched perspective on close relationships, can guide a therapist to the heart of a couple's difficulties, elucidating the task of restructuring key interactions, cognitions, and emotional responses. Attachment theory highlights the need for secure emotional connections with specific loved ones, and the regulation of emotions such as fear of loss and disconnection, as the implicit organizing elements in the interactions observed during couple and family therapy (C&FT). Bowlby (1973, p. 180) spoke of the relation between an individual and his or her environment (most essentially, loved ones) as the "outer ring" of a system, proposing that this outer ring is complementary to the "inner ring" that maintains an emotional "homeostasis" within each person's body and mind. Attachment is systemically oriented, in the traditional sense used in family therapy, and it also adds this "inner ring" to our understanding of relationships. Key concepts of child and adult attachment have been progressively integrated into existing models, such as behavioral couple therapy (Davila, 2003; Mondor et al., 2013) and multidimensional family therapy (Liddle, 1999). Attachment-centered C&FT interventions have also been adapted to specific difficulties and tested in a variety of settings. These

include attachment-based family therapy (ABFT; Diamond, Siqueland, & Diamond, 2003), emotionally focused therapy (EFT) for couples, and emotionally focused family therapy (EFFT) (Johnson, 2004).

Attachment theory and research are crucial parts of an emerging relationship science (Johnson, 2013) that has begun to address the core mysteries of human relationships. In this emerging field of science, many different kinds of research, relationship concepts, and clinical findings are coming together to form a coherent whole, for example, data on the dyadic interplay of attachment, conflict, and support in determining satisfaction in couple partnerships (Brassard, Lussier, & Shaver, 2009; Kane et al., 2007), research on the nature of love as outlined by attachment theory and research (Johnson, 2003), and understandings of emotion and the "panic" triggered by disconnection (Panksepp, 1998). This research suggests that emotional responsiveness between adult partners predicts stability and satisfaction in relationships, and that positive cycles of interactions in which each partner responds to the other's attachment vulnerabilities are key to relationship repair and to the regulation of the primal panic that arises in negative interactions. Attachment theory and

relationship science offer a perspective that integrates physiology, emotion, and interactional patterns, allowing a therapist to home in on, bring into focus, and restructure the organizing elements of close relationships.

In this chapter, we outline the unique contributions of attachment theory to C&FT and explain how these contributions are significant departures from the traditions of the field of C&FT. We then present prominent clinical models of C&FT based on attachment theory, along with recent outcome research. Finally, we outline future promising directions for attachment-oriented interventions in C&FT.

Attachment: A Unique Perspective on Couple and Family Systems

What Attachment Theory Offers to C&FT

On a general level, attachment theory offers couple and family therapists a broad, integrated theory of close relationships and normal growth within such relationships, including a clear outline of basic human needs and emotional processes from the cradle to the grave. For a therapist, this is invaluable. The theory is specific enough to guide the formulation of individual couples' or families' problems, then to shape interventions enacted in therapy sessions. The process of change includes helping partners to recognize and "own" their attachment needs and to guide partners to ask for these needs to be met in a clear, cogent way that fosters partner responsiveness.

Attachment theory also provides a compass in the intrapsychic and interpersonal maelstrom of couple and family distress. The goal of therapy is the creation of new, positive interaction cycles of emotional responsiveness that redefine the relationship as a whole. By providing a picture of relationship health, attachment theory offers an answer to the long-standing clinical question: What constitutes necessary and sufficient change? Attachment theory is arguably the only relational theory that offers a large body of research detailing the key interactions in healthy relationships and documenting the specific results of these interactions. Attachment theory and research inform a therapist about the nature of the pivotal processes and watershed events that define close relationships, and they offer guidance about how

to restructure these events in therapy. In all of the attachment-oriented models of C&FT described in this chapter, key change events and specific interventions are explained.

Finally, primary relationships have great healing power. Attachments to key people provide our "primary protection against feelings of helplessness and meaninglessness" (McFarlane & van der Kolk, 1996, p. 24). Attachment theory empowers a therapist to link self and system, and to create interactions that not only change a relationship but also address individual problems within that relationship. Attachment-oriented interventions have been used successfully to address a variety of clinical issues, including depression in adults and adolescents (Denton, Wittenborn, & Golden, 2012; Diamond et al., 2010), traumatic stress in adults (Dalton, Greenman, Classen, & Johnson, 2013), and negative, defiant behaviors in adolescents (Moretti & Holland, 2003).

The remainder of this section provides a closer examination of how the main tenets of attachment theory are relevant for couple and family therapists. These may be summarized in terms of how attachment theory addresses the following key issues: Attachment theory depathologizes dependency, emphasizes the power of emotion in organizing interactions, has clear implications for the therapeutic alliance and the role of the therapist in C&FT, offers a therapist a map to individual differences in relationship style, adds a cognitive component of working models to the focus on emotional response and interaction patterns, helps to explain how behaviors are passed on and perpetuated in families, and fosters engagement in therapy in that it is highly relevant to the lived realities clients bring to therapy (Johnson & Talitman, 1996).

Depathologizing Dependency

The dominant discourse in the field of C&FT has long been one that promotes autonomy and is critical of dependency (Fishbane, 2005). In contrast, the central tenet of attachment theory is that seeking and maintaining contact with significant others is an innate, primary motivating force in human beings at all phases of the lifespan. Dependency is an innate part of being human, not a sign of enmeshed relationships or of lack of differentiation from others (Bowlby, 1988). Rejection and emotional isolation are inherently traumatizing. A sense of connection with loved ones can be maintained more readily on the cognitive, representa-

tional (working model) level as we mature, but contact is still a primary need. This need is universal across cultures (Mesman, Van IJzendoorn, & Sagi-Schwartz, Chapter 37, this volume), although it may be expressed somewhat differently in different contexts. The attachment perspective focuses the therapy on issues of connection and disconnection, and allows for the active validation of needs and fears concerning attachment. It offers the therapist a language for the “emotional starvation” (Levy, 1937) that characterizes an insecure relationship.

This perspective suggests that members grow and differentiate *with* each other rather than *from* each other. A felt sense of secure connection is seen as the best route to confident autonomy—a state that is often a key goal in family therapy, especially with adolescents. The *secure base* provided by a loving attachment figure encourages a cognitive openness to new information (Mikulincer, 1997). It promotes the confidence necessary to risk, learn, and continually update models of self and others, so that adjustment to new contexts is facilitated. It also strengthens the ability to stand back and reflect on oneself, including one’s behavior and mental states (Fonagy, Luyten, Allison, & Campbell, Chapter 34, this volume). An increase in emotional accessibility and responsiveness is therefore a key goal in attachment-oriented C&FT, rather than focusing only on setting boundaries and developing assertiveness skills.

The Pivotal Role of Emotion

Emotion is central to attachment, and attachment theory provides a guide for understanding and normalizing many of the extreme emotions that accompany distressed relationships. *Separation distress*, indicated by powerful emotions of anger, panic, and abandonment and sadness, results from the perception that an attachment figure is inaccessible or does not care. It is in attachment relationships that our strongest emotions arise and seem to have the most impact. When an individual is threatened—either by traumatic events or by a sense of disconnection in an attachment relationship—powerful affect arises, attachment needs for comfort and connection become particularly compelling, and attachment behaviors are activated.

A positive sense of connection with a loved one is a primary emotion regulation device (Mikulincer & Shaver, Chapter 24, this volume). The attachment view of family members as “hid-

den regulators” of each other’s physiological and emotional worlds is supported by empirical studies (Coan, Schaefer, & Davidson, 2006; Johnson et al., 2013)

Attachment theory focuses the therapist on emotional experience and elucidates the logic and meaning of emotional responses. The valuing and active recognition of emotion has not, until recently, been a primary focus in C&FT. Emotion was considered to be either part of the problem or epiphenomenal to changes in family systems or individual behavior. In contrast, the models mentioned in this chapter are used to explore and reprocess key emotions, use emotion as a key change mechanism, and focus on barriers to emotional responsiveness.

The Nature of the Therapeutic Alliance

The tenet of attachment theory that outlines the need for a safe haven and a secure base suggests that the creation of safe emotional engagement with a therapist is central to the clinical change process (Bowlby, 1988). Although C&FT has long espoused therapeutic alliances of a collaborative nature, the explicit validation and careful creation of a secure base in the therapies presented in this chapter, as well as the level of emotional engagement fostered between therapist and clients, reflects the attachment perspective. An attachment-oriented therapist acts as a surrogate attachment figure by actively helping clients regulate emotion, particularly the attachment-related anxiety or panic (Panksepp, 1998) that triggers negative emotional flooding or requires strongly avoidant suppression in insecure relationships.

Emotion is also more differentiated in the attachment perspective and so can be addressed and regulated in a more specific fashion by an emotionally present and attuned therapist. Therapists who understand the process of separation distress can tune in to a client’s emotional perspective, look beyond disruptive responses such as hostile criticism or stonewalling, and place them in the context of legitimate attachment needs and fears, translating what might appear to be characterological deficits or lack of social skills into context-specific responses to loss of connection—responses that can be validated and restructured.

Bowlby (1988) noted that human beings are “strongly inclined towards self-healing” (p. 152). The therapist’s job is to provide the context—namely, a secure base—that allows this natural

healing process to occur. This is a very different theoretical frame from the one that casts the therapist as a magician or creator of miraculous reversals of negativity, which has been sometimes seen in the C&FT field.

Understanding and Addressing Individual Differences

Attachment theory also offers the couple and family therapist a way to understand and address individual differences in affect regulation and engagement with partners. There has been an increasing emphasis in this field on respecting individual differences and moving away from a one-size-fits-all set of interventions. There are only so many ways of coping with disconnection—that is, with a negative response to the question, “Can I depend on you when I need you?” Attachment strategies in both parent–child and adult relationships can be described in terms of two main dimensions, anxiety and avoidance (Ainsworth, Blehar, Waters, & Wall, 1978; Brennan, Clark, & Shaver, 1998; see also Crowell, Fraley, & Roisman, Chapter 27, this volume).

When the connection with an irreplaceable other is threatened, the attachment system may become hyperactivated. Attachment behaviors become heightened and intense as anxious clinging, pursuit, and even aggressive attempts to obtain a response from the loved one escalate. The second strategy for dealing with the lack of safe emotional engagement, especially when hope for responsiveness has been lost, is to deactivate the attachment system and suppress attachment needs. This is done by focusing on other issues, such as work, and avoiding distressing attempts to engage emotionally with attachment figures (Mikulincer & Shaver, Chapter 24, this volume). These two strategies, anxious clinging and detached avoidance, can develop into habitual styles of engagement with intimate others.

A third insecure pattern has been identified—a combination of yearning for closeness, then fearfully avoiding reliance on a relationship partner because of potential emotional pain. This pattern is referred to *fearfully avoidant* in the adult social-psychological literature (Bartholomew & Horowitz, 1991). In infants, a failure to establish a coherent, organized strategy is associated with chaotic or traumatic attachment experiences with frightening or abusive attachment figures (Main & Hesse, 1990).

All of these insecure patterns, which begin as accommodations to the ways in which key attach-

ment figures fail to provide a secure base/safe haven, can be rigidly and inappropriately applied in subsequent relationships, thereby generating ongoing negative cycles of interaction and lack of connection with loved ones. These adaptations become “self-maintaining patterns of social interaction and emotion regulation” (Shaver & Clark, 1994, p. 119). For example, when a partner anxiously demands contact, then withdraws when it is offered, a therapist sees a pattern of fearful avoidance and understands the dilemma of the client who not only longs for closeness but also turns it down, unable to regulate the associated fear and pain.

Attachment research has shown that these habitual forms of engagement can be modified by new or changed relationships (Simpson, Collins, Tran, & Haydon, 2007), which suggests that new interaction patterns created in therapy can have a significant impact on individuals and their relationships. In distressed relationships, attachment-related styles of perceiving and responding to others often operate outside awareness and are so habitual that they cannot easily be modified by the skills-building and cognitive reframing interventions so often used in C&FT. In the attachment-oriented models, the focus is expanded to include new attachment-related emotional experiences; a clearer way to address attachment needs; and the potential alteration of working models of self, partner, and relationship.

Working Models: The Self in the System

Secure attachment is theoretically characterized by a working model of self as worthy of love and care and as competent. Research has strongly supported this aspect of the theory by showing that measured attachment security is associated with greater self-efficacy and a more coherent, articulated, and positive view of self (e.g., Mikulincer, 1995). Secure individuals, who have experienced their attachment figures as responsive and supportive when needed, also tend to have working models of others as dependable and trustworthy. These models of self and others are based on thousands of social interactions. They are carried forward into new interactions and new relationships not as one-dimensional cognitive schemas, but as emotionally charged procedural scripts for how to create relatedness under particular conditions. A person may have multiple and conflicting models, but most often one is dominant in a given context.

Working models are formed, elaborated, maintained, and—most importantly for the couple and family therapist—*changed* through emotional communication. The therapist can point out the pitfalls of specific perceptions that arise from negative working models, showing how they prohibit openness toward loved ones, block relationship change, and ultimately keep a person stuck with self-damaging perceptions and behaviors. At the end of therapy, for example, a 13-year-old boy might be able to say to his stepfather, “When I was little, with my first dad, I decided I was a bad kid. That was why he was so mad at me. Now I assume you think I’m bad, and when you get upset with me, I just tell you I don’t care. I’ll never please you anyway. I just give up.” His stepfather can now tell him, “I don’t want you to feel like you’re a bad kid. You are my kid now—my special son. I don’t want you to give up with me. And I want to learn to be a kinder dad.”

A Relevant Focus for Intervention

Bowlby began his career as a health care professional by studying the effects of maternal deprivation and separation on children. Attachment theory describes and explains the trauma of deprivation, loss, rejection, and abandonment by those we need most. Couple and family therapists know about the stress of deprivation and separation. They can see, for example, what Bowlby described in his 1944 article, “Forty-Four Juvenile Thieves”—that “behind the mask of indifference [of avoidant children] is bottomless misery and behind apparent callousness, despair” (p. 39). Bowlby saw his young charges as frozen in the attitude “I will never be hurt again” and paralyzed by their isolation and rage. Attachment theory encourages a therapist to reach, with empathic questions, reflections, and conjectures, behind partners and family members’ masks and unpack separation distress, anger about rejections and hurts, and the attachment longings that color emotional reactions. Attachment theory has supreme relevance to the lived experience and dilemmas of couple and family members in distressed relationships.

Attachment-Oriented Models of Intervention in Family Therapy

Although there are some emerging and potentially promising attachment-based family interventions

with adolescents (Mackey, 2003; Moretti & Holland, 2003) and younger children (Hughes, 2011), there are only two family therapy models that have received empirical validation of their effectiveness and that systematically use an attachment framework to assess and address problems in families. These are ABFT (Diamond, 2005; Diamond et al., 2003) and EFFT (Johnson & Lee, 2000; Johnson, Maddeaux, & Blouin, 1998). These approaches assume that adolescents who enter therapy need to reconnect with parents in order to move toward more confident autonomy, and that a new level of emotional communication is necessary for this to occur. They address a wide range of symptoms, both internalizing (e.g., depression) and externalizing (e.g., conduct disorder). Both assume that attachment issues such as rejection, neglect, and abandonment are often obscured by conflicts related to behavioral problems (e.g., neglecting chores or homework), and that therapy must foster empathic, attuned conversations about relationship ruptures and attachment injuries.

Attachment-Based Family Therapy

For adolescents, secure attachment nurtures healthy development, whereas insecure attachment is associated with depression and other problems in adaptation (Allen, Porter, McFarland, McElhaney, & Marsh, 2007; Herring & Kaslow, 2002). Practitioners of ABFT—an approach whose clinical procedures draw from many systems approaches, including EFT (Diamond et al., 2003)—have specialized in working with depressed and/or suicidal adolescents, who benefit from more direct communication with parents. Secure attachment is characterized by this kind of communication, which fosters perspective taking and effective, collaborative problem solving (Allen & Tan, Chapter 19, this volume; Kobak & Duemmler, 1994). ABFT aims to improve the family’s capacity for problem solving, affect regulation, and organization. This strengthens family cohesion, which can buffer against suicidal thinking, depression, and risk behaviors.

Diamond and colleagues (2003) note that depressed adolescents usually talk in the first therapy session about feeling hopeless, alone, and angry at their parents. The parents speak of frustration about their own perceived failure to help their children. The parents’ lack of availability at critical moments has often become a source of injury and alienation for the adolescents. ABFT is an attempt to help parents and adolescents address

these “relational ruptures,” address core attachment concerns (including increasing the adolescents’ sense of entitlement to care), and develop a coherent understanding of attachment events. All of this increases the adolescents’ sense of felt security and helps them to revise negative working models of self and other. A major challenge in this approach, and in all attachment-based family interventions, is to build the parents’ capacity for providing a sense of security in their children. Diamond and colleagues point out that an adolescent’s ability to express vulnerability and attachment needs often rekindles the desire for a parent’s care, and the parent can then be helped by the therapist to connect with the child. This approach targets parental criticism and ineffective parenting, and the adolescent’s withdrawal/hopelessness, inability to regulate emotions, and negative self-concept. The first session involves the family unit; the second is with the adolescent alone; and the third is with the parent(s) alone. The remaining sessions involve combinations of one or both parents and the adolescent, the adolescent alone, or a parent alone.

Treatment focuses on five specific tasks:

1. The *relational reframe task*, which aims at reducing hostility and criticism by reframing the problem in terms of negative interaction cycles (e.g., parental reaching out, adolescent rejection of help, parental criticism, and adolescent withdrawal).
 2. The *alliance-building task with the adolescent*, in which the therapist connects with the adolescent, validating any sense of abandonment, acknowledging the burden of being “parentified” (i.e., having to take care of a parent), and empathizing with the pain of being triangulated in conflicts between the parents, as well as helping the adolescent to identify his or her concerns and goals.
 3. The *alliance-building task with the parents*, in which the therapist prepares the parents to listen to and respond to the adolescent’s concerns, reducing the parents’ distress, which promotes their motivation to provide attachment security to their children and their willingness to learn emotion-focused parenting skills.
 4. The *reattachment task*, in which the therapist sets up a conversation addressing core relationship failures, encouraging parents to respond to the adolescent’s grievances with empathy, so that a new kind of family encounter can occur.
- Parents at least acknowledging, when not apologizing, for past attachment failures promotes forgiveness and renewed mutual trust, thus revising the adolescent’s expectancy and desire for parents protection and support.
5. The *competency promoting task*, in which the therapist promotes the adolescent’s self-esteem and competency by encouraging parents to challenge and support the adolescent, and urging the adolescent to take more responsibility for his or her behavior.

Emotionally Focused Family Therapy

The goals of EFFT are to modify the distressing cycles of interaction that amplify conflict and undermine the potentially secure connection between parents and children, and to shape positive cycles of accessibility and responsiveness that offer the developing adolescent a safe haven and secure base (Johnson, 2004). Therapy takes place in three stages: deescalation of negative cycles, restructuring of attachment interactions, and consolidation, across 10–20 sessions. The first two of these include the entire family. Once the network of alliances has been mapped out, the family members’ views of the problem have been grasped, and the adolescent’s problematic behavior has been placed in the context of family attachment patterns, sessions may be conducted with the adolescent alone or with any combination of family members. The therapist focuses on two tasks: the elucidation and reprocessing of key attachment-related emotions and emotional responses (the “music” of the relational “dance”) and the gradual revision of key patterns of interaction to create a more secure attachment. The therapist focuses on emotion as the organizing element in interactions and acts as less of a coach than the therapist does in ABFT, relying instead on the power of new emotional signals to evoke new behaviors and revise expectations, perceptions, and models of relationships in both parents and children. The recognition, validation, and expression of attachment needs is a key part of EFFT, as is addressing the adolescent’s frustration and despair over disconnection.

In the first stage of EFFT, the therapist focuses on the presenting problem and assesses dynamics with relevant family members, while validating each family member’s perception of the presenting problem, and identifying and reflecting the family’s negative interaction pattern. The therapist explores the impact of the negative family patterns on different family subsystems (e.g., the parental

or sibling subsystem, mother and adolescent). The therapist then reframes the family problem as one arising out of an attachment crisis, thus normalizing family difficulties without blaming anyone (Palmer & Efron, 2007). At the end of the first stage, the therapist reframes dysfunctional or secondary emotional responses as part of a broader negative interactional pattern fueled by underlying primary emotions (e.g., fear, hurt, sadness, feelings of failure or unlovability) and attachment needs. Accessing the primary emotions creates empathy and responsiveness among family members, and helps the family deescalate (Johnson et al., 2005).

In the second stage of EFFT, the goal is to facilitate the restructuring of the family negative interactional pattern identified in the first stage. The therapist focuses on accessing and highlighting the unmet attachment needs of children and adolescents, while promoting parental accessibility and responsiveness to children's underlying emotions and needs. The change event in this stage occurs when the therapist facilitates the enactment of children reaching out to their parents with these underlying needs, followed by the parents' responsiveness to the child's vulnerability and bids for care, connection, and comfort. The therapist needs to support both parents and children in working through the fears associated with the vulnerability experienced in distressed family relationships and reengaging in new patterns of availability and responsiveness (Johnson, 2004).

In the final stage of EFFT, the therapist focuses on consolidating the changes family members have made in the second stage. At the end of this stage, the family is able to integrate the new ways of engaging in discussions, which are characterized by openness, responsiveness, and engagement among family members. The family new sense of connection can then translate into everyday cooperation and problem solving.

There are some similarities between both EFFT and ABFT and the work of John Gottman on emotional communication between parents and children. However, Gottman's model is more focused on teaching parents how to coach their children directly about emotions and emotion regulation (e.g., Gottman, Katz, & Hooven, 1997). Both EFFT and ABFT promote a particular way of being emotionally present with and attuning to family members. Trevarthen and Aitken's (2001) concept of *primary intersubjectivity* within an attachment framework, which explains how children's view of themselves emerges from their

experience of what their parents tune in to and respond to in them, would also appear to be relevant here. In both EFFT and ABFT, there is more recognition of emotion than has been customary in the majority of family therapies; even so, ABFT appears to be somewhat more cognitive than EFFT and to use heightened emotion less when creating new kinds of parent-child interactions. All attachment-oriented models and interventions referred to in this chapter focus on helping parents and children repair attachment rifts and injuries, and elucidate interaction patterns and responses in a way that makes "the attachment needs that underlie problem behaviors visible" (Moretti & Holland, 2003, p. 245).

Dyadic Developmental Psychotherapy

Dyadic developmental psychotherapy (DDP) was originally developed by Dan Hughes to treat children in foster or adoptive homes who have suffered abuse and neglect, and who manifest severe psychological difficulties associated with complex trauma and difficulties with attachment (Hughes, 2004, 2006). DDP has as its core the maintenance of a contingent, collaborative, sensitive, reflective, and affectively attuned relationship between therapist and child, between caregiver and child, and between therapist and caregiver. DDP focuses on and relies on the intersubjective sharing and joint development and organization of emotional experience. Hughes (2011) gradually expanded DDP into a comprehensive model of family therapy, also referred to as attachment-focused family therapy. The therapy model focuses on the attachment bond as a way to navigate complex emotions and behaviors in parent-child relationships, and understands problematic child behaviors in the context of past attachment traumas or injuries, as well as current stresses on the attachment relationship.

DDP is very similar to EFFT in terms of clinical process given their joint focus on emotion and bonding interactions, and removing the blocks to those interactions. In DDP, children are assisted in regulating and expressing their emotions and communicating emotional messages in ways that foster secure connection with a parent who is supported and responds with an attitude characterized by playfulness, acceptance, curiosity, and empathy. DDP is different from EFFT in that it is used not only with adolescents but also with children (as young as age 4 or 5) and their parents.

Empirical Support for Attachment-Based Family Interventions

Two important randomized controlled trials of ABFT (12 sessions) have been conducted in the United States. In the first, Diamond, Reis, Diamond, Siqueland, and Isaacs (2002) randomly assigned 32 adolescents suffering from major depressive disorder (and their parents) to either ABFT or a 6-week waiting list. Results showed the efficacy of ABFT in reducing depressive symptoms post-treatment and at a 6-month follow-up. Treatment also significantly decreased adolescent levels of anxiety symptoms and family conflict. According to Diamond (2005), when parents were shown videotapes of sessions and asked to discuss changes that had occurred, the key factor seemed to be that the parents had come to understand how ruptures in their relationships with their adolescents contributed to the depression, and that their adolescents desired and needed their love. In ABFT, an adolescent first discloses anger about relationship failures. A parent is supported to remain non-defensive, apologize, and explain his or her own inability to make better choices. The parent and adolescent then share more vulnerable feelings and needs, and come to a better appreciation of each other's struggles. In a more recent randomized controlled trial, Diamond and colleagues (2010) showed that ABFT is more efficacious than enhanced usual care (EUC) in reducing suicidal ideation post-treatment and at 6-month follow-up in a sample of 66 adolescents. ABFT was more effective than EUC, regardless of whether adolescents had a sexual trauma history (Diamond, Creed, Gillham, Gallop, & Hamilton, 2012).

Examining the mechanisms of change, Shpiegel, Diamond, and Diamond (2012) found that increases in maternal autonomy led to increases in adolescents' perceived parental care (during treatment) and decreases in attachment-related anxiety and avoidance (at follow-up) but were not related to change in depression or suicidal ideation. In terms of recent developments, Kissil (2011) proposed an application of ABFT to adolescent self-injury and presented a case study supporting the use of ABFT in this population. ABFT may be especially relevant to this problem, considering that self-harm is often conceptualized as an affect regulation strategy, a way to self-soothe that is more likely to be used by insecurely attached adolescents. According to De Silva and colleagues

(2013), ABFT is a "promising" empirically supported practice for the treatment of suicidal ideation and self-harm.

There has been less empirical support for the effectiveness of EFFT. In a preliminary study, the effectiveness of EFFT was supported in a study of 13 young women diagnosed with bulimia nervosa at an outpatient hospital clinic (Johnson et al., 1998). Most also met criteria for clinical depression, and several had attempted suicide. All subjects except one rated themselves as having either an anxious or a fearfully avoidant attachment, as assessed with the Relationship Questionnaire (Bartholomew & Horowitz, 1991). A cognitive-behavioral educational group ($n = 4$) was compared with an EFFT group ($n = 9$). Both treatments (10 sessions) were supervised by experts in these interventions, and implementation checks were conducted. Both were found to result in decreased severity of bulimic symptoms, lower scores on the Beck Depression Inventory, and reduced general psychiatric symptomatology. Remission rates for bingeing and vomiting were better than those reported for individual therapy. More recently, Robinson, Dolhanty, and Greenberg (2015) revisited EFFT as a promising model of therapy for families dealing with eating disorders (EDs) in children and adolescents, and case studies have provided some support to the efficacy of EFFT as a therapeutic intervention with families in which adolescents are struggling with symptomatic behaviors (Bloch & Guillory, 2011; Palmer & Efron, 2007), including nonsuicidal self-injury (Schade, 2013), or interventions with stepfamilies facing adjustment issues (Furrow & Palmer, 2007).

Although DDP does not meet criteria as an evidence-based treatment, the theoretical validity for DDP and what might be considered an initial pilot study are summarized by Becker-Weidman and Hughes (2008). Further study of DDP and its efficacy using larger samples, randomization, and restricted age range of the participants is warranted.

Attachment-Oriented Couple Therapy

The couple therapy field appears to be moving toward greater recognition of adult attachment needs and the desirability of promoting emotional connection and nurturance in couples. A few commentators (e.g., Davila, 2003) have suggested

ways in which the attachment perspective could be used to enhance behavioral couple therapy. In a recent study, Mondor and colleagues (2013) showed that attachment anxiety predicts early termination in cognitive-behavioral couple therapy. They suggested that because attachment insecurities might interfere with treatment continuation, therapists should assess and address attachment orientations in couple therapy, regardless of their therapeutic model.

Attachment theory suggests that many relationship problems are essentially due to the insecurity of the bond between partners and to the struggle to define the relationship as a potential safe haven and a secure base (Bowlby, 1969/1982, 1988). The key issue in distressed relationships is the negative cycles that maintain disconnection and limited responsiveness to emotional signals and attachment cues. As a distressed woman remarked to her husband, "It's not the fights that really matter. I could handle disagreements if I felt like you were there for me. But I can never find you when I need you. I feel alone in this relationship."

There is now an impressive body of research on the relevance of attachment theory to adult relationships (reviewed, e.g., by Mikulincer & Shaver, 2007, Chapter 24, this volume; J. A. Feeney, Chapter 21, this volume) both in clinical and nonclinical samples. Secure attachment, whether measured by questionnaires or interviews (see Crowell, Fraley, & Roisman, Chapter 27, this volume, for a review of measures), has been found to predict such positive aspects of relationship functioning as greater interdependence, commitment, trust, and satisfaction in couples (e.g., Mondor, McDuff, Lussier, & Wright, 2011); higher levels of seeking and providing support (e.g., Davila & Kashy, 2009; Kane et al., 2007); greater empathy and less withdrawal and verbal aggression (e.g., Fournier, Brassard, & Shaver, 2011; Péloquin, Lafontaine, & Brassard, 2011); more sensitive and appropriate caregiving behavior (B. C. Feeney, 2004, 2007; Millings & Walsh, 2009); and more satisfying sexual interactions (e.g., Brassard, Péloquin, Dupuy, Wright, & Shaver, 2012; Dewitte, 2012). Recent studies have also documented the interplay among the attachment, caregiving, and sexual systems (Péloquin, Brassard, Delisle, & Bédard, 2013; Péloquin, Brassard, Lafontaine, & Shaver, 2014). This research parallels other findings that indicate the pivotal importance of soothing and supportive responses in high-functioning relationships and the absolute requirement for safe emotional engagement (e.g., Gottman, 1994; Pasch & Bradbury, 1998).

EFT uses systemic and experiential interventions to promote change in couple relationships but places these in the context of an attachment-theoretical understanding of adult love relationships. As a couple therapy based on attachment theory, EFT is characterized by the following:

1. A focus on and validation of attachment needs and fears, and the promotion of safe emotional engagement, comfort, and support.
2. A privileging of emotional responses and communication, and directly addressing attachment vulnerabilities and fears to foster emotional attunement and responsiveness.
3. The creation of a respectful collaborative alliance, so that the therapy setting itself is a safe haven and a secure base.
4. An explicit shaping of responsiveness and accessibility (withdrawn partners are to be reengaged, and blaming partners are guided to ask that their attachment needs be met in a positive manner, so that bonding events can occur and serve as an antidote to negative cycles and insecurity).
5. A focus on self-definitions that can be redefined through emotional communication with partners (attachment figures).
6. An explicit shaping of pivotal attachment responses that redefine a relationship (as each person asks that attachment needs be met, and the other partner responds to ensure that positive bonding interactions occur).
7. Addressing and healing specific attachment injuries, including betrayals (e.g., infidelity) and abandonment at key moments of need (e.g., at the time of a miscarriage).

This approach has received extensive empirical validation in terms of both relationship outcomes and defined change processes. A meta-analysis of the most rigorous studies of EFT found that 70–73% of couples recovered from relationship distress after 10–12 sessions (with therapists who were receiving clinical supervision), and that 86% rated their relationship as significantly improved (Johnson, Hunsley, Greenberg, & Schindler, 1999). This meta-analysis also revealed a mean effect size of 1.3 across studies reviewed, which is considerable in psychotherapy research. The effectiveness of EFT does not appear to be as heavily influenced as other approaches by initial relationship distress levels. Specifically, initial distress was found to account for only 4% of the variance in satisfaction at follow-up, compared to

an estimated 46% in the behavioral approaches tested (Whisman & Jacobson, 1990).

The attachment framework offers both clinicians and scientists a way of understanding how to create lasting changes and avoid relapse, even in brief therapy. There is evidence that results are stable, even in very stressed, high-risk relationships in which relapse might be expected (Clothier, Manion, Gordon-Walker, & Johnson, 2002; Halchuk, Makinen, & Johnson, 2010). If interventions reach to the heart of the matter (attachment injuries), they are more likely to create lasting change.

The nine steps in EFT are well documented in the couple therapy literature (Johnson, 2004; Johnson et al., 2005). The process of change moves from outlining negative interaction patterns and their attachment consequences to deepening the awareness of the core attachment-related emotions underlying these interaction patterns. A silent, withdrawn partner (typically a man) is able to attune to and express his helplessness and hopelessness when he sees the anger in his partner, and he can link this anger to his tendency to remain silent. He also begins to understand that his silence creates panic in his partner, which then fuels her critical complaining. In Stage 1 of EFT, *deescalation*, both partners begin to express newly accessed and formulated emotions, and to frame the negative cycle and disconnection as a mutual enemy. Once this cycle is deescalated, partners are guided in Stage 2 of EFT, *restructuring the bond*, to engage authentically with their emotions and to express the fear, sadness, or shame that keeps them blaming or distancing. Longings for connection and comfort can then emerge and be used to create more explicit and coherent bids for responsiveness from each other. This process is crystallized into key change events in Stage 2, in which the focus is on restructuring attachment responses and building positive cycles of connection. Here, more withdrawn, avoidant partners can assert their needs for validation and safety, and more anxiously attached, blaming partners can ask that their needs for comfort and connection be met. Stage 2 of EFT ends with a new kind of safe emotional engagement for both partners. These changes are then consolidated in Stage 3, *consolidation*: A new narrative or story about how the relationship was threatened and repaired is created; new attachment behaviors are highlighted; and it becomes easier to solve pragmatic problems from a position of safety.

In the key change events of Stage 2, change occurs on multiple levels. As a blaming partner (typically a woman) finds herself asking that her attachment needs be met, she moves to a new level of affect regulation in which vulnerable emotions can be encountered, ordered, and expressed congruently, so that her attachment needs are made clear. She also moves away from her attributions of weakness and accepts her “softer side” as legitimate, integrating attachment fears and needs into her sense of self. As her partner responds favorably, her image of others as untrustworthy is challenged. As new, more secure interactions occur, a new pattern of attuned responsiveness is created that expands the couple’s behavioral repertoire and model of relatedness.

In a typical session, attachment not only provides an overall perspective on a couple’s problems but also elicits specific interventions. Empathic reflection of emotional responses and interaction processes, validation, and empathic questioning are used to create a sense of safety and focus the process on attachment needs. Here is an example:

“Peter, you said you try not to react so as to stop the fights. You also said, ‘I put up a wall, and that is kind of sad.’ The word *sad* really struck me. It is sad. It’s a loss to you when you wall out someone you love. Yes? I wonder what it feels like behind that wall—the wall that Mary then rails against and ‘hurls’ herself toward with more and more fury. Do you ever talk to *her* about that sadness?”

The therapist then distills inner emotions and outer moves with the client, and clarifies attachment-oriented messages to the other while promoting new, more attachment-friendly interactions through enactments (i.e., directing one partner to talk to the other as the therapist intervenes in the evolving, moment-to-moment processes; see Tilley & Palmer, 2013):

“So you say that Mary sees this ‘cool’ guy, but inside you feel small and sad and lonely. You just don’t know what to do when she tells you she isn’t happy. You’re scared of making a mistake, so you freeze up. You freeze not because she is unimportant, as she believes, but because she has such an impact on you. Can you tell her, please, ‘When I feel small and scared, I do shut you out, and I see now how that upsets and frus-

trates you. I am so unsure of how to please you, I shut down before I can even think.”

The therapist then turns to Mary and helps her respond to this new kind of interaction. Attachment theory has great breadth, but it is also specific enough to focus on the agreed-upon priority for most clinicians (Beutler, Williams, & Wakefield, 1993)—that is, to specify the therapist and client behaviors that create important moments of change.

A major development in EFT—the focus on the forgiveness of attachment injuries that block the creation of new levels of trust—speaks to the fact that a powerful theoretical map elucidates the nature of impasses in the therapeutic process and suggests how to deal with these impasses. Attachment theorists have pointed out that incidents in which one partner responds or fails to respond at times of urgent need seem to influence the quality of an attachment relationship disproportionately (Simpson & Rholes, 1994). Attachment injuries have been described as a perceived abandonment, betrayal, or breach of trust in a critical moment of need for support expected of attachment figures (Johnson, Makinen, & Millikin, 2001). Such incidents either shatter or confirm one partner’s assumptions about attachment relationships and the dependability of the other partner, causing seemingly irreparable damage to close relationships. Many partners enter therapy not only in general distress, but also with the goal of bringing closure to such events and thereby restoring lost intimacy and trust. During therapy, these events often re-emerge in an alive and intensely emotional manner and overwhelm the injured partner, creating an impasse and hindering the process of change. These incidents usually occur in the context of life transitions, loss, physical danger, or uncertainty (e.g., after a medical diagnosis or miscarriage), when attachment needs are most salient and compelling; as such, they can be considered relationship traumas. Attachment theory offers an explanation of why certain painful events, such as specific abandonments, become pivotal in a relationship, as well as an understanding of what the key features of such events will be, how they will affect a particular couple’s relationship, and how such events can be optimally resolved. Such events are taken into account throughout therapy but are focused on and worked through in Stage 2 of EFT.

Makinen and Johnson (2006) conducted a study to test the effectiveness of the formulation

of the EFT attachment injury resolution model (AIRM). The injured party is encouraged to clarify his or her pain associated with the event and to frame it in attachment terms. The other partner is then guided to respond with empathy and regret in a congruent and engaged manner. The injured party is supported to face his or her fears of becoming vulnerable again, and is able to ask that the attachment needs aroused by the incident be addressed. The other partner can now respond empathically, creating a positive reenactment of the original injuring event. This process is then integrated into the couple’s story of the injury and their new ability to repair it. In Makinen and Johnson’s study, all distressed couples with a single attachment injury recovered from relationship distress, reduced the pain caused by the injury, and reached positive levels of forgiveness. These results were maintained over a 3-year period (Halchuk et al., 2010). Couples with more than one attachment injury and very low initial levels of trust did experience reduced pain but had less positive results in the domains of forgiveness and relationship satisfaction. Dealing with these more seriously damaged kinds of relationships may be difficult or require more sessions than the limited number offered in this study. The steps of the AIRM were further validated in a recent psychotherapy process study (Zuccarini, Johnson, Dalgleish, & Makinen, 2013). Greenberg, Warwar, and Malcolm (2010) examined the impact of a similar EFT approach in 20 couples who experienced what they called “emotional interpersonal injury” and found that most individuals rated themselves at the end of treatment as forgiving their partners. They showed a significant improvement in dyadic satisfaction, trust, and forgiveness, as well as improvement on symptom and target complaint measures. These couples were able to maintain their gains at 3-month follow-up. Meneses and Greenberg (2014) identified three processes that predicted change in couple satisfaction and forgiveness among 33 couples: the “injuror’s expression of shame,” the “injured partner’s accepting response to the shame,” and “the injured partner’s in-session expression of forgiveness.”

Recent Empirical Support for EFT for Couples

Based on an extensive review of research, EFT is considered to be an evidence-based treatment

for couple distress (Snyder, Castellani, & Whisman, 2006), and it has been successfully adapted to clinical populations in which relational distress was either comorbid with or exacerbated by other stressful couple or family concerns, including parenting chronically ill children (Walker, Johnson, Manion, & Cloutier, 1996), facing postpartum depression (Whiffen & Johnson, 1998), or dealing with posttraumatic stress disorder (PTSD) (Johnson, 2002). Here we review recent evidence relevant to empirical validation of EFT for couples as a treatment for comorbid depression, chronic illness, and trauma/PTSD.

Depression

Dessaulles, Johnson, and Denton (2003) initially randomly assigned 12 couples in which the female partner was clinically depressed to either EFT alone or antidepressant pharmacotherapy. They found no significant differences between the two conditions, but their results showed that levels of depression decreased from pre- to post-treatment in both groups. Moreover, only women from the EFT group continued to decrease their depressive symptoms from posttreatment to the 6-month follow-up. More recently, Denton and colleagues (2012) conducted the first study to compare antidepressant medication alone to antidepressant medication augmented with EFT for women with comorbid major depressive disorder and relationship discord. Although both treatments contributed to a diminution in depressive symptoms, women who received medication plus EFT reported more improvement in relationship satisfaction than did women who received medication alone. Replication of these results with larger samples is needed.

Chronic Illness

EFT has also been viewed as a promising treatment option for couples experiencing psychological and relational distress following the diagnosis and treatment of chronic illness (see Tie & Poulsen, 2013, for a review). In early studies, McLean and Nissim (2007) provided two case studies of couples facing advanced cancer (colon, ovaries) and treated with EFT; in both cases, couples were able to switch from unresponsive or compulsive caregiving to reciprocal caregiving. Couture-Lalande, Greenman, Naaman, and Johnson (2007) studied two patients diagnosed

with breast cancer and their spouses; these couples received 16 sessions of EFT. Qualitative results suggest that the therapeutic process experienced by couples facing breast cancer is similar to that experienced by couples with partners in normal physical health. Significant improvement in symptoms of depression and couple satisfaction among patients diagnosed with advanced cancer and partners were also found in a study of 16 couples receiving EFT (McLean et al., 2008). More recently, a randomized controlled trial (McLean, Walton, Rodin, Esplen, & Jones, 2013) supported the efficacy of EFT in the treatment of relationship distress in end-stage cancer patients and their partners (but not their depressive symptoms) as compared to a standard care approach. Chawla and Kafescioglu (2012) presented case examples of the application of EFT to couples coping with traumatic brain injury and couples coping with cardiovascular disease. Their case studies suggest that EFT can produce deep couple/family attachment experiences in therapy and contribute to positive relationship outcomes.

Trauma/PTSD

A preliminary qualitative study by MacIntosh and Johnson (2008) revealed that affect regulation is the most significant area of challenge for sexual abuse survivors in EFT. Shame, anger, hypervigilance, and an inability to trust and take risks were significant challenges for the studied couples. This type of extreme relational trauma and the relationship problems that it causes normally require a minimum of 30 couple therapy sessions (Johnson & Courtois, 2009). In a pilot study of seven couples in which one partner was a war veteran suffering from PTSD, there were statistically significant decreases in veterans' PTSD symptoms after participation in an average of 30 sessions of EFT (Weissman et al., 2011). Greenman and Johnson (2012) presented a case example to support the relevance of EFT in the treatment of couples in which one partner was diagnosed with PTSD. They suggested that EFT is suited to numerous aspects of the clinical presentation of PTSD, including difficulties with affect regulation, isolation, flashbacks, and dissociation. More recently, Dalton and colleagues (2013) published the first randomized controlled trial on the efficacy of EFT for relationship distress in which the female partner was a victim of severe childhood abuse. It showed significant increases in relationship satisfaction among the EFT treatment

group at posttest, providing evidence of the effectiveness of a couple-based treatment for women with comorbid relationship distress and a history of childhood abuse.

Process-of-Change Studies

Couple therapists need a detailed guide for their interventions to make significant differences in the lives of the couples with whom they work because they are managing two individuals whose thoughts, behaviors, and emotions are in constant interaction. This is problematic in light of repeated findings over the past 30 years suggesting that between 25 and 30% of couples who receive therapy do not demonstrate significant improvement, and that there are substantial rates of relapse (close to 40%) among those who do show improvement (Halford & Snyder, 2012; Halford et al., 2012). Despite claims of the relevance of process research for the day-to-day practice of couple therapy (e.g., Gurman, 2011) and calls for more practice-focused research with an emphasis on “specific mechanisms of change” (Sexton et al., 2011, p. 379), there has been scant research linking the process of therapy (i.e., what therapists actually do in session and how their clients respond to their interventions) to successful outcomes.

In a recent review of EFT process studies, Greenman and Johnson (2013) concluded that research conducted to date has allowed the validation of certain key assumptions of EFT. A growing number of studies has indicated that deep emotional experiencing in both partners is related to positive outcomes such as greater relationship satisfaction and a preponderance of empathic interactions (e.g., Couture-Lalande et al., 2007; Zuccarini et al., 2013). McRae, Dalglish, Johnson, Burgess Moser, and Killian (2014) recently showed that EFT is successful in helping to increase partners’ levels of emotional experiencing throughout therapy. Studies have also supported the assumption that critical change events, such as “blamer softening” when a previously hostile/critical partner asks, from a position of vulnerability and within a high level of experiencing, for reassurance, comfort, or for an attachment need to be met, are essential components of relationship improvement (Bradley & Furrow, 2004; Furrow, Edwards, Choi, & Bradley, 2012). Most such studies have relied on a task analysis of proximal outcomes to assess the process of change (Heatherington, Friedlander, & Greenberg, 2005).

Attachment and C&FT: Where Do We Go from Here?

The attachment perspective is changing the field of C&FT. It is giving rise to systematic, empirically validated interventions and as part of the new science of relationships (Johnson 2013), it is also offering the field an explanatory framework for relationship problems, a detailed, research-based model of health, and a map for intervention. There have been important developments during the last decade, yet there are many additional questions to answer.

There is now preliminary functional magnetic resonance imaging (fMRI) research showing that a couple’s participation in EFT is related to modification of neural responses to threat (Johnson et al., 2013). In a recent study of 24 couples, insecure female partners in distressed relationships at pretest did not benefit from holding hands with their partner to counter their fearful response to anticipated electric shocks or to dampen their perception of pain. At posttest, upon completion of EFT for couples, they were less sensitive to threat cues when they held their husbands’ hands, compared to handholding with a stranger or being alone. This study supports the theoretical claim that, in addition to improving relationship satisfaction, EFT can affect couple members’ ability to soothe each other’s difficult emotions by strengthening their attachment bond and modifying the way in which the brain responds to threats in the presence of a romantic partner.

Another important development is the recent finding that EFT can change couples’ levels of attachment insecurity, as assessed with both observational coding of attachment behaviors and a self-report measure of attachment anxiety and avoidance (Burgess Moser et al., 2015). More specifically, 32 moderately distressed and insecurely attached couples attended an average of 21 sessions of EFT. Couples significantly increased their secure base use and secure base provision from pre- to posttherapy, as assessed with the Secure Base Scoring System (SBSS; Crowell et al., 2002). Attachment-related avoidance significantly decreased over the course of EFT, whereas results were less consistent for attachment anxiety. Significant decreases in attachment anxiety occurred only for the subset of partners (16 of 32) who were able to engage in a key change event in EFT, the blamer-softening event, wherein a partner is able to ask for his or her needs to be met from a position

of soft vulnerability (Burgess Moser, Dalglish, Johnson, Wiebe, & Tasca, 2015).

A third development worth mentioning is that couple therapists using EFT, as well as behavioral clinical approaches, are now recognizing the importance of attachment insecurity as a predictor of change in marital satisfaction (Dalglish et al., 2015), as a risk factor for early therapy termination (Mondor et al., 2013), or as an outcome of couple therapy (Benson, Sevier, & Christensen, 2013).

In the coming decade, attachment theory and research could contribute to our understanding of and ability to address pivotal transitions in close relationships. The transition to parenthood—a time when many relationships begin to unravel, and many women succumb to depression—is being examined through the lens of attachment (Rholes et al., 2011). The emotional support offered by the new father appears to affect the number of women who become more anxiously attached at this time (Simpson, Rholes, Campbell, Tran, & Wilson, 2003). If we understand these transitions in attachment terms rather than simply in terms of factors such as role change or general stress, we can more effectively help struggling couples and reduce the likelihood of clinical problems such as postpartum depression (Whiffen, 2003). Other transitions such as remarriage also warrant clinical and empirical research, as it may involve several attachment challenges such as attachment loss, loyalty struggles, unrealistic expectations, or competing attachment needs (Furrow & Palmer, 2011; see B. C. Feeney & Woodhouse, Chapter 36, this volume).

Another potential development is that attachment theory and research, paired with recent clinical evidence, can refine our understanding of sexual difficulties within a relationship (Johnson & Zuccarini, 2010, 2011). In a clinical sample of 242 couples seeking therapy, 60% of women and 64% of men were dissatisfied with their sex lives even though they were not necessarily seeking therapy for sexual difficulties (Brassard et al., 2012). This study also showed that attachment insecurity (anxiety, avoidance) was related not only to individuals' own sexual well-being but also their partners' sexual satisfaction (see Birnbaum, Chapter 22, for discussion of attachment and sex). Johnson and Zuccarini (2010, 2011) have proposed that EFT be adapted to deal with a number of sexual issues experienced by couples seeking EFT treatment (e.g., low sexual desire, erectile dysfunction). By reframing the sexual issues and

patterns as part of the dysfunctional interactional dynamic, it is possible to restructure them into a more functional and secure dynamic in which "emotional responsiveness, tender touch, and erotic playfulness can all come together" (Johnson & Zuccarini, 2010, p. 436). Empirical studies are needed to support the efficacy of EFT with couples facing sexual difficulties.

As research continues, it should contribute to the refinement and validation of C&FT interventions in couples where relationship distress is complicated by comorbid symptomatology, such as depression, PTSD, and other anxiety disorders. In addition to the recent evidence presented in this chapter, Priest (2013) has suggested the adaptation of EFT to the treatment of generalized anxiety disorder (GAD), a syndrome often associated with marital distress (e.g., Whisman, 2007) and insecure attachment orientations (Eng & Heimberg, 2006). Soltani, Shairi, Roshan, and Rahimi (2014) have also provided early support for EFT in reducing stress, depression, and anxiety symptoms in couples facing infertility. Attachment theory gives us a way of seeing the coherence in the web of symptoms and interpersonal difficulties that our clients present; it therefore helps us identify the most effective targets for change.

Recent work by EFT therapists has also provided descriptions of the application of EFT for same-sex couples (Hardtke, Armstrong, & Johnson, 2010; Zuccarini & Karos, 2011) and culturally diverse couples (Liu & Wittenborn, 2011). To our knowledge, only one study (Diamond et al., 2013) has obtained preliminary data on the feasibility and efficacy of the adapted ABFT treatment with suicidal lesbian, gay, and bisexual (LGB) adolescents.

Many studies have supported the associations between attachment insecurity and intimate partner violence (IPV) in couples from the community (e.g., Lafontaine & Lussier, 2005; Péloquin et al., 2011) and among clinical samples of men seeking treatment (e.g., Brassard et al., 2014; Fournier et al., 2011). They have identified mechanisms by which more insecure individuals behave aggressively toward their partners: poor anger regulation and empathy, low relationship satisfaction, and the presence of a demand-withdraw pattern of communication. Because EFT requires a secure environment in which deeper and more vulnerable emotions can be addressed, IPV has been used as an exclusion criterion for couples seeking therapy. Research could examine the possibility of carefully using EFT when minor aggressive behav-

iors are perpetrated by partners in the context of a dysfunctional interactional dynamic.

The promise of attachment research is that with the conceptual map provided by this perspective, interventions can both systematize relationship repair and thereby stabilize families and also open the door to all the benefits associated with more secure attachment, such as resilience and increased empathy for others. Einstein asked how the sciences could ever hope to explain so important a biological phenomenon as love. The science of attachment is in fact continuing to expand our understanding of the bonds of love between family members and adult partners, and this understanding allows us to provide better therapeutic interventions. We believe that relationship-oriented, attachment-informed interventions are among the most exciting developments in the field of psychotherapy and psychology more generally.
