PART VI

**SYSTEMS, CULTURE,
AND CONTEXT**

Chapter 36

Caregiving

Brooke C. Feeney
Susan S. Woodhouse

Attachment theory provides an ideal framework for understanding caregiving because it stipulates that the need for security is one of the most fundamental of all basic needs (for individuals of all ages), and it provides a basis for understanding the complex interpersonal dynamics involved in three important and interrelated components of human nature: attachment, exploration, and caregiving (Bowlby, 1969/1982, 1973, 1980, 1988). All three systems are presumed to have survival value; thus, the urge to engage in each form of behavior is likely to be preprogrammed to some degree. The three systems are briefly described below as a backdrop for our discussion of caregiving processes.

First, drawing on ethological principles, *attachment theory* regards the propensity to form strong emotional bonds with particular individuals (attachment) as an innate human characteristic, present in infancy and continuing through adulthood and old age. According to the theory (Bowlby, 1973, 1969/1982), individuals come into the world equipped with an attachment system that functions to maintain their safety and security through contact with nurturing caregivers (also referred to as *attachment figures*). The attachment system becomes activated most strongly in adversity, so that when distressed (e.g., alarmed, anxious, frightened, tired, or ill), the individual feels an urge to seek protection, comfort, and support from

a primary caregiver (Bowlby, 1973, 1969/1982; Bretherton, 1987; Gillath et al., 2006). Attachment theory emphasizes that the desire for comfort and support in adversity should not be regarded as childish or immature dependence; instead, it should be respected as an intrinsic part of human nature that contributes to health and well-being.

Second, attachment theory states that another basic component of human nature is the urge to *explore the environment*—to work, play, discover, pursue goals, and take part in activities with peers (Bowlby, 1988). However, true or unencumbered exploration is expected to occur only when attachment needs have been satisfied (when the attachment system is deactivated). In this sense, exploration can be antithetical to attachment behavior, and vice versa (Bowlby, 1988); that is, when an individual of any age is feeling safe and secure, he or she is able to explore away from the attachment figure (or caregiver) and pursue autonomous activities. However, when feeling distressed in any way, he or she feels an urge to increase proximity. According to the theory, when individuals are confident that an attachment figure (e.g., a parent in childhood, a spouse in adulthood) is available when needed and will be responsive when called upon, they typically feel secure enough to explore the environment, take on challenges, engage in independent activities, and make discoveries. Ex-

ploration is also presumed to contribute to optimal health and well-being.

A third major component of human nature, according to attachment theory, is *caregiving* (Bowlby, 1969/1982, 1988). Caregiving includes a broad array of behaviors that complement (and support) a relationship partner's attachment and exploration behavior (Bowlby, 1969/1982, 1988; Kunce & Shaver, 1994). Thus, caregiving is viewed as serving two major functions: (1) providing a *safe haven* for the attached person by supporting his or her attachment behaviors, and (2) providing a *secure base* for the attached person by supporting his or her exploration of the environment. A major postulate of attachment theory is that individuals who thrive emotionally and socially, and who make the most of their opportunities, are those who have at least one caregiver (e.g., a parent in childhood or a spouse in adulthood) who is encouraging of the individual's autonomy yet responsive to needs when called upon.

We begin this chapter by elaborating on each caregiving function. We then review research on attachment and caregiving in parent-child relationships, followed by a review of research on attachment and caregiving in adult relationships. Following each of these reviews, we discuss directions for future research.

Safe Haven

To remain within easy access of a familiar individual known to be ready and willing to come to our aid in an emergency is clearly a good insurance policy—whatever our age.

—JOHN BOWLBY (1988, p. 27)

A safe haven functions to support behavior that involves "coming in" to the relationship for comfort, reassurance, and assistance in times of stress (Bowlby, 1988; Collins & Feeney, 2000). From an attachment perspective, good caregivers are those who are able to effectively restore their partner's felt security when needed—by providing emotional comfort and facilitating problem resolution. Being *sensitive* and *responsive* to an attached partner's needs and distress cues as they arise is crucial to the maintenance of felt security (Ainsworth, Blehar, Waters, & Wall, 1978; Feeney & Collins, 2014). This involves the provision of the type and amount of support that is dictated by the situation and by the partner's needs—flexibly responding to attachment needs by taking into ac-

count the other's point of view, feelings, and intentions; by encouraging expression of feelings; and by adjusting one's own behavior in response to the contingencies of the situation. A sensitive and responsive caregiver is one who regulates his or her behavior so that it meshes with that of the person who is being cared for, takes his or her cues from and allows his or her interventions to be paced by the recipient, is attuned to the recipient's nonverbal signals, attends to the details of the recipient's behavior, interprets the recipient's signals and behaviors correctly, discovers what response is most appropriate for the individual recipient, responds promptly and appropriately, and monitors the effects of his or her behavior on the recipient and modifies it accordingly (Bowlby, 1988). In response, the care-receiver behaves in ways that take account of the caregiver's interventions. Thus, in a well-functioning partnership, each person is adapting to the other.

In contrast, an insensitive and unresponsive caregiver may not notice the recipient's attachment behaviors or signals, may misinterpret or ignore them when they are noticed, may interfere in an arbitrary way or behave in a rejecting manner, and/or respond late, inappropriately, or not at all to a need for support (Bowlby, 1969/1982, 1988). Thus, these caregivers may be neglectful, overinvolved, or out of sync with their partner's needs (Collins, Ford, Guichard, Kane, & Feeney, 2010; Kunce & Shaver, 1994). Thus, there are many ways that caregivers may be insensitive and unresponsive in times of need because being sensitive and responsive is not always easy, and even well-intended caregiving efforts may have unintended negative consequences. For example, caregivers may offer support in a way that makes the recipient feel weak, needy, or inadequate; that induces guilt or indebtedness; that makes the recipient feel like a burden; that minimizes or discounts the recipient's problem; or that blames or criticizes the recipient for his or her misfortune.

In his writings regarding responses to attachment system activation, Bowlby (1988) emphasized that adequate time and a relaxed atmosphere are necessary conditions for caregivers to behave in a sensitive manner. He also suggested that there is a strong tendency to treat others the same way that we ourselves have been treated; that is, although caregiving behavior is thought to be preprogrammed to some degree (meaning that it is ready to develop along certain lines when certain conditions elicit it), all the detail is learned. Thus, individuals are likely to learn either healthy or

unhealthy caregiving patterns from the significant people who have previously been responsible for their care.

Secure Base

All of us, from the cradle to the grave, are happiest when life is organized as a series of excursions, long or short, from the secure base provided by our attachment figure(s).

—JOHN BOWLBY (1988, p. 62)

A secure base functions to support behavior that involves “going out” from the relationship for autonomous exploration in the environment (Bowlby, 1988; Feeney, 2004; see also Crowell et al., 2002; Waters & Cummings, 2000). Good caregivers must know how to not only respond appropriately to attachment behavior and signals of distress but also support their partner’s autonomous exploration (e.g., goal strivings, personal growth; Bowlby, 1988). This involves providing a base from which an attached person can make excursions into the outside world (to play, work, learn, discover, create, make new friends), knowing that he or she can return for comfort, reassurance, and/or assistance should he or she encounter difficulties along the way. Bowlby (1988) describes the concept of a secure base as one in which caregivers create the conditions that enable their relationship partners to explore the world in a confident way:

In essence this role is one of being available, ready to respond when called upon to encourage and perhaps assist, but to intervene actively only when clearly necessary. In these respects it is a role similar to that of the officer commanding a military base from which an expeditionary force sets out and to which it can retreat, should it meet with a setback. Much of the time the role of the base is a waiting one but it is none the less vital for that. For it is only when the officer commanding the expeditionary force is confident his base is secure that he dare press forward and take risks. (p. 11)

Based on this description, three important characteristics of a secure base have been extrapolated (Feeney & Thrush, 2010). First, a secure base supports exploration by being *available* in the event that the base is needed (e.g., to assist in removing obstacles). Second, a secure base supports exploration by *not unnecessarily interfering* with it. According to attachment theory, intrusive/interfering behavior is antithetical to sensitive/responsive caregiving, and it is a major inhibi-

tor of exploration. This behavior likely inhibits exploration because it communicates a variety of negative messages to the recipient (e.g., that he or she is not capable of engaging in independent exploration, that autonomous exploration is threatening to close others). Third, a secure base supports exploration by being *encouraging and accepting* of it (Feeney & Thrush, 2010). Encouragement is expected to facilitate exploration because it conveys an excitement/enthusiasm regarding exploration, as well as confidence in the explorer’s abilities.

Insensitive caregivers who do not provide an adequate, secure base are likely to take little notice of the partner’s goals and goal-related feelings, to intrude in the partner’s explorations, to fail to respect the person’s desire for autonomy by discouraging or impeding exploration, to discourage bids for support and encouragement, or to respond in an ill-timed and unhelpful manner. Nonetheless, the importance of a secure base is evident for individuals of all ages. Just as children can be seen using their parents as a secure base for exploration by keeping track of the parents’ whereabouts, exchanging glances, and from time to time returning to the parents to share in mutually enjoyable contact, adults can be seen engaging in similar types of behaviors. For example, an adult is likely to maintain phone contact when exploring away from a spouse for an extended period of time and share details of his or her explorations with the spouse. Bowlby (1988) suggested that individuals who are confident that their base is secure and ready to respond if called upon are likely to take it for granted. Yet should the base suddenly become unavailable or inaccessible, the importance of the base to the emotional equilibrium of the individual is immediately apparent.

Research on Attachment and Caregiving in Parent–Child Relationships

Over 40 years ago, Mary Ainsworth and her colleagues (see Ainsworth, Bell, & Stayton, 1971; Ainsworth et al., 1978) were the first to report evidence that sensitive maternal caregiving (in response to both attachment and exploration needs, in both safe haven and secure base contexts) is linked to later infant attachment. Ainsworth and colleagues (1978) defined *sensitivity* as a caregiver’s ability to perceive and accurately

interpret infant cues, then respond promptly and appropriately to those infant cues. Their view of sensitivity included prompt and appropriate caregiver responses to both attachment and exploration needs. This seminal work inspired many other researchers to examine the role of parental caregiving (primarily mothers', but also fathers' caregiving, as discussed below) in attachment. A meta-analysis by De Wolff and Van IJzendoorn (1997) established that there is a significant link between maternal sensitivity and later child attachment security, with a moderately strong effect size of $r = .24$. In fact, according to a meta-analysis of intervention studies, interventions that improved parental sensitivity were more effective than other interventions in terms of attachment outcomes (Bakermans-Kranenburg, Van IJzendoorn, & Juffer, 2003). This meta-analysis was influential because it provided empirical support for a causal link between caregiving quality and child attachment.

Moreover, the data suggest that sensitivity is important in predicting not only infant–mother attachment but also infant–father attachment. A meta-analysis of 16 studies conducted over a 30-year period showed a significant link between fathers' sensitivity and infant attachment, with a small effect size of $r = .12$ (Lucassen et al., 2011). It is not clear why the effect size was small. It has been theorized that there may be other factors uniquely important in paternal caregiving, such as stimulating play (Grossmann, Grossmann, Kindler, & Zimmermann, 2008), that should be considered in assessing fathers' sensitivity. The meta-analysis, however, showed that sensitivity in combination with stimulating play did not predict attachment outcomes better than paternal sensitivity alone (Lucassen et al., 2011). Thus, despite evidence that some but not all cultures have differing expectations of mothers and fathers (Lewis & Lamb, 2003), it appears that the sensitivity construct is relevant for understanding both maternal and paternal caregiving.

We now know that sensitivity is linked not only to later child attachment but also to a number of other important child outcomes. For example, low sensitivity early in life has been empirically linked to both later internalizing problems (e.g., Mount, Crockenberg, J6, & Wagar, 2010) and externalizing problems (e.g., Shaw, Lacourse, & Nagin, 2005). Cassidy (1994) proposed that emotion regulation is a mechanism through which the link between attachment and later psychopathology occurs, and that children adapt their own

behavioral and regulatory strategies to the caregiving environment in which they find themselves.

Sensitive responding to infant distress is linked to decreases in infant distress (e.g., Jahromi, Putnam, & Stifter, 2004), suggesting that sensitive caregiving plays a role in regulating the infant at a time when it is developing the capacity to self-regulate. In fact, research shows that maternal sensitivity in infancy is associated with child emotion regulation both in infancy (Gl6ggler & Pauli-Pott, 2008) and later in childhood (Lecuyer & Houck, 2006). There is also empirical evidence that parental caregiving is linked to physiological regulation, as indexed by vagal tone, an indicator of parasympathetic nervous system activation (e.g., Moore & Calkins, 2004), and that patterns of vagal regulation vary depending on maternal sensitivity (Moore et al., 2009). Likewise, maternal sensitivity is linked to infant adrenocortical function (i.e., infant cortisol reactivity and recovery; Atkinson et al., 2013).

Parental Caregiving and the Intergenerational Transmission of Attachment: The Transmission Gap

Much of the research on parental caregiving has focused on the intergenerational transmission of attachment from parent to child. Parental caregiving is theorized to be rooted in parents' representations of their own attachment experiences. Secure representations of attachment allow the caregivers to remain nondefensively open to a child's needs and to respond in a way that provides the child with a secure base from which he or she can explore, and a safe haven to which the child can return in times of distress (Ainsworth et al., 1978; Bowlby, 1988). In short, we would expect caregivers' attachment representations to be linked directly to infant attachment, with caregiver sensitivity as the mediating mechanism for this intergenerational transmission. A series of meta-analyses have addressed each of these links and have shown that (1) there is a robust link ($d = 1.09$, a large effect size) between adult attachment representations and infant attachment, with a 75% concordance between the two at the level of secure–insecure (Van IJzendoorn, 1995); (2) there is a significant link between adult attachment representations and sensitivity, with a moderate effect size of 0.72 ($r = .34$); and (3) the link between sensitivity and infant attachment is significant with a moderate effect size ($r = .24$). Yet this final link is, statistically speaking, the weakest link

in the meditational model, and it is significantly weaker in low-income families (De Wolff & Van IJzendoorn, 1997). A meta-analytic test of the full model showed that parenting behavior accounted for a smaller-than-expected proportion of the association between parental attachment representations and child attachment, which Van IJzendoorn (1995) termed the *transmission gap*. This transmission gap remains one of the most vexing puzzles in attachment research. We are left with a question: How are we to understand the role of caregiving in the development of attachment? Clearly, sensitivity matters, but what else is important?

One possibility is that researchers may rely too heavily on brief observations of sensitivity in standardized laboratory interactions. A meta-analysis, however, showed that the results were no different for studies with longer observation periods (De Wolff & Van IJzendoorn, 1997) or for those that assessed sensitivity via more ecologically valid home observations (e.g., Tarabulsky et al., 2005). The effect size (corrected $r = .85$) found by Ainsworth and colleagues (1978) was far larger than subsequent ones, yet De Wolff and Van IJzendoorn (1997) noted that had their meta-analysis been limited to those studies that used the Ainsworth (1969) scale, there would have been no increase in the effect size. Van IJzendoorn (1995) raised the question of whether genetics (instead of caregiving) may explain the intergenerational transmission of attachment. However, a number of studies examining this question indicated that the link between parent attachment representations and child attachment cannot be explained genetically (e.g., Fearon et al., 2006; Mesquita et al., 2013; Roisman, Booth-LaForce, Belsky, Burt, & Groh, 2013; Roisman & Fraley, 2008).

Belsky and Fearon (2008) argued that the transmission gap may be due to unidentified moderators, such as child characteristics. Indeed, a large body of research on temperament \times environment interactions supports the idea that not all children are equally affected by their caregiving environments (Rothbart & Bates, 2006). Two new hypotheses suggest that children may vary in their neurobiological sensitivity to environmental influence, whether for the worse or for the better: (1) the differential susceptibility hypothesis (Belsky & Pluess, 2009) and (2) the hypothesis of biological sensitivity to context (Boyce & Ellis, 2005). Both approaches suggest that infant negativity should not be considered a risk factor, but rather an endophenotypic marker of susceptibility to the environment. In fact, studies provide some support

for the idea that more negatively reactive/irritable infants may benefit more than other infants from caregiving interventions (e.g., Cassidy, Woodhouse, Sherman, Stupica, & Lejuez, 2011).

Another possibility in trying to understand the relatively weak link between parental sensitivity and child attachment is that researchers have been conceptualizing and/or measuring sensitivity incorrectly—or perhaps not measuring all important facets of what it means to provide a sensitive and responsive safe haven and secure base. Bowlby (1969/1982) theorized that attachment is based on real experiences with important caregivers. The question then becomes, *which* experiences are important? The answer has important implications for not only the science of attachment but also clinical intervention. Effective intervention relies on knowing which parenting behaviors to target. Different researchers have focused on different aspects of parental caregiving in assessing sensitivity.

Mesman and Emmen (2013) reviewed the eight most commonly used observational measures of parental sensitivity, out of the 50 or so existing observational systems. They pointed out that the scales were quite different from one another in terms of how they defined and operationalized sensitivity. Some of the scales differed from Ainsworth's definition of sensitivity by including positive affect and/or warmth as one of the indicators of sensitivity. Only one scale, the National Institute of Child Health and Human Development Studies of Early Child Care and Youth Development (NICHD SECCYD; Owen, 1992), like Ainsworth's, did not include warmth or positive maternal affect at all in its definition of sensitivity. Ainsworth (1967) believed that warmth was not necessary for attachment security because in her work with mothers and infants in Uganda, she had seen that the mothers tended to be sensitive and responsive, yet were not typically affectionate; nevertheless, the majority of the infants were securely attached. MacDonald (1992) suggested that warmth and sensitivity might belong to different motivational systems and presented data indicating that they were independent. MacDonald argued that warmth may serve as a reward but is not related to protection in the context of fear or distress. More recently, Davidov and Grusec (2006) found that sensitivity was associated with child regulation of negative affect and empathy toward others who were in distress, but that warmth was linked to child regulation of positive affect.

Some researchers (e.g., Raval et al., 2001) have emphasized the importance of examining

context in trying to better understand the link between parental caregiving and child attachment, arguing that unmeasured aspects of the larger context may influence child attachment security above and beyond the effects of parental caregiving. Tarabulsy and colleagues (2005) found that the meditational role of maternal sensitivity in the link between maternal and child attachment emerged more clearly if contextual variables (i.e., maternal education, maternal depression, paternal support, infant maternal grandmother support) were accounted for in the model. More research is needed to confirm such ecological effects and understand the mechanisms through which they function.

Much of the research on parental sensitivity toward children has not distinguished between sensitivity to distress (safe haven) and sensitivity during exploration (secure base). Rather, parental sensitivity has been conceptualized in terms of parental capacity to respond flexibly to child cues *across contexts* in ways that match those cues (i.e., responding appropriately to cues for either safe haven or secure base). Thus, sensitivity has been conceptualized as flexible and appropriate responding to children's cues in what Ainsworth and colleagues (1971) termed the *attachment-exploration balance*. Given that infants and children move rapidly between exploration and attachment needs, an ability to move flexibly between different types of caregiving (i.e., both secure base and safe haven) may be important. In theory and research on attachment in childhood, the term *secure base* has often appeared as a shorthand for secure base and safe haven together (Dykas, Woodhouse, Cassidy, & Waters, 2006; Sroufe & Waters, 1977; Steele et al., 2014; Waters & Cummings, 2000; Woodhouse, Dykas, & Cassidy, 2009). Such usage is likely rooted in early writings on attachment. Ainsworth and colleagues (1978) and Bowlby (1988) theorized that a secure base is impossible without availability of the caregiver to provide a safe haven when needed. Nevertheless, research has begun to differentiate between sensitivity to infant distress (safe haven) and sensitivity to non-distress (secure base).

A number of studies have found that caregiver sensitivity in the context of infant distress predicts infant attachment and other key child outcomes (e.g., social competence, adjustment, affect regulation) better than concurrently assessed caregiver sensitivity in response to infant non-distress (e.g., Davidov & Grusec, 2006; Leerkes, 2011; Leerkes, Blankson, & O'Brien, 2009). Leer-

kes, Weaver, and O'Brien (2012) argued that these findings are consistent with Bowlby's (1969/1982) focus on the evolutionary importance of infant crying as a compelling social cue signaling to the caregiver that the infant needs safety, protection, and comfort. This suggests that differentiating between caregiving for attachment needs in times of stress (safe-haven caregiving) and caregiving for exploration (secure-base caregiving) could be important in understanding the links between caregiving and later child outcomes.

It is important to note, however, that classifying infant or child distress as always signaling a need for a safe haven may be too simplistic (Cassidy, Jones, & Shaver, 2013). Upon reunion, an infant who has been left alone in the Strange Situation may cry with arms lifted up toward the mother as a signal of wanting to be picked up. This would be an example of infant distress in a situation that is clearly related to the child's need for a safe haven. Alternatively, an infant may cry when a toy it was actively exploring is taken away (e.g., when limits need to be set for safety or other reasons). In this case, the distress is not related to a need for a safe haven. In fact, the distress may be terminated immediately if the toy is returned and the child is able to return to exploration. If the parent attempts to soothe a child who is crying due to frustration of exploration, the child's distress may increase because the exploration needs are not being met. Thus, it is possible for distress to occur in secure-base contexts. Such distress may best be dealt with through the provision of secure-base caregiving, with parental attention to helping the child explore. Likewise, there may be times when a child is expressing a need for safe haven without exhibiting any distress. Cassidy and colleagues (2013) give an example of an infant who has been playing contentedly for 20 minutes while her mother sits with a toddler in her lap and braids the toddler's hair. After the toddler leaves the mother's lap, the infant goes to the mother's lap and snuggles with her. This proximity seeking signals attachment needs because the infant's exploration ceased until she was able to experience the comforting assurance of the mother's presence and closeness. The movement toward the mother is linked to the mother as a safe haven of reassurance, safety, and emotional refueling.

Thus, the distinction between distress and nondistress contexts may not precisely indicate a need for a safe haven or a secure base. Instead, it may be better to examine the caregiving context (exploratory/secure-base context vs. safe-haven

context) *in conjunction with* distress (distress vs. nondistress) to best understand parental caregiving and its links to later child attachment. Cassidy and colleagues (2013) proposed that such a two-dimensional approach may allow for stronger links to emerge between specific types of parental caregiving and later child attachment, as well as other important child outcomes.

Another conceptualization of caregiving has been proposed as a potential solution to the transmission gap (Cassidy et al., 2005). In an effort to understand whether there may be a way to conceptualize and measure caregiving that could help to bridge the transmission gap and address the fact that the sensitivity–attachment link is significantly weaker in low-income mother–infant dyads (De Wolff & Van IJzendoorn, 1997), Cassidy and colleagues (2005) conducted a qualitative study that focused on a sample of racially and ethnically diverse, low-income mothers. The researchers observed mother–infant interactions including structured tasks in the laboratory when the infant was 4.5 months old and three 30-minute, naturalistic, videotaped home visits that occurred on three separate days when the infant was between 4.5 and 9 months old. Surprisingly, the majority of the mothers were not even minimally sensitive to infant cues when the infant was 4.5 to 9 months old. Nevertheless, approximately half of the infants were securely attached at 12 months. It appeared that infants could tolerate an unexpectedly high level of maternal insensitivity, as long as two conditions were met. First, certain negative behaviors could not be present (e.g., frightening behavior, extremely cold or hostile behavior, or consistent intrusive efforts to keep the infant’s attention on the mother). Any mother who exhibited these negative behaviors had an insecure infant. Second, the mother needed to communicate that both sides of the attachment–exploration balance were acceptable to her by ultimately meeting exploration and attachment needs, even if she was insensitive along the way. Cassidy and colleagues observed that most of the insensitive behavior observed during exploration at 4.5 to 9 months had little association with attachment at 12 months. For example, mothers could be quite intrusive during infant play by introducing too many toys at too rapid a pace, pulling away toys in which the baby was interested, and following the mothers’ rather than the infants’ interests. Despite high levels of intrusion, infants were secure at 12 months as long as mothers were not intrusive in ways that activated the child’s attachment system. As long as

mothers were *comfortable enough* with exploration that they did not terminate it, the child developed a secure attachment. Likewise, mothers of both insecure and secure infants might ignore infant crying or too quickly turn a crying baby away from her. Mothers of infants who would later be secure finally relented and “got the job done” of soothing the baby to calm in a chest-to-chest position. Cassidy and colleagues referred to this conceptualization of caregiving as *secure-base provision* and defined it in terms of doing a “good-enough” job of supporting both attachment (safe haven) and exploration (secure base) needs.

Based on this work, Woodhouse, Beeney, Doub, and Cassidy (2015) developed a quantitative measure of secure-base provision and found that it predicted 12-month infant attachment in a racially and ethnically diverse, low-socioeconomic status (SES) sample, whereas sensitivity did not. The findings of Brody and Flor (1998) are relevant to the way in which Woodhouse and her colleagues interpreted their findings. Brody and Flor suggested that parents living in dangerous or stressful conditions may adopt parenting strategies such as more stringent child management techniques, more authoritarian parenting, and more parent-centered (rather than child-centered) parenting in an effort to support child adaptation to those stressful conditions. What they termed *no-nonsense parenting* is meant to promote children’s self-regulation and independence, to protect children from danger, and to help children avoid involvement with antisocial activities and its potential consequences. Brody and Flor’s data provided no evidence that such no-nonsense parenting practices were linked to later insecure attachment. Woodhouse and her colleagues argued that use of the secure-base provision approach in assessing caregiving avoids emphasizing certain culturally bound parenting practices found in white, middle-class samples (e.g., sweet tone of voice, affectionate verbal comments).

Other researchers have found evidence that sensitivity during nondistress may also be important in predicting attachment in older infants. Bernier, Matte-Gagné, Belanger, and Whipple (2014) found that both sensitivity (at 12 months) and autonomy support (at 15 months) fully accounted for the relation between maternal attachment representations (assessed at 7 months) and child attachment at 24 months. They argued that researchers have not attended enough to parental support for exploration in the relation between maternal and child attachment. These results raise

the question of whether particular aspects of caregiving matter at different stages of child development. It could be that the balance of attachment and exploration looks different depending on the child's stage of development. It may be that in the first year of life, the regulation of distress is the predominant role of caregivers, whereas by 15 months, support for exploration becomes equally important.

Interestingly, there is not a strong empirical link between parental sensitivity and child disorganization (e.g., NICHD Early Child Care Research Network, 1997). Empirical evidence suggests that it is atypical or anomalous parenting that is linked to disorganized attachment (e.g., Lyons-Ruth, Bronfman, & Parsons, 1999), such as parents' frightened or frightening behavior (Main & Hesse, 1990). Lyons-Ruth and colleagues (1999) proposed that infants may become disorganized when caregiving is disrupted in other ways, such as parents presenting irresolvable caregiving strategies to the child (e.g., heightening arousal of the infant's attachment system while simultaneously rejecting attachment cues). Longitudinal work has highlighted maternal withdrawal in infancy (e.g., distanced interactions and a lack of initiative in greeting or comforting) as a key predictor of a variety of types of psychopathology in the transition to young adulthood (e.g., Lyons-Ruth, Bureau, Holmes, Easterbrooks, & Brooks, 2013; Shi, Bureau, Easterbrooks, Zhao, & Lyons-Ruth, 2012). See Lyons-Ruth and Jacobvitz (Chapter 29, this volume) for further discussion of caregiving and disorganized attachment.

Research on Factors that Predict Caregiving Quality

Adult attachment representations as assessed by the Adult Attachment Interview (AAI; George, Kaplan, & Main, 1984, 1985, 1996), as discussed earlier, are a robust predictor of parenting quality based on meta-analytic findings (Van IJzendoorn, 1995). Yet, as Jones, Cassidy, and Shaver (2015) noted in a review of the 64 relevant studies that appeared between 1994 and 2013, parents' adult attachment styles, as assessed by self-report measures of attachment emerging from social psychology, such as the Experiences in Close Relationships Scale (ECR; Brennan, Clark, & Shaver, 1998), are also empirically linked to parental caregiving. The fact that both adult attachment representations and attachment styles are linked to parenting is intriguing given that the two approaches

to assessing adult attachment are only modestly linked with one another (Roisman et al., 2007). Taxonomic work on measures of adult attachment style has shown that adult style can best be conceptualized in terms of two dimensions: attachment anxiety and avoidance (Fraley & Waller, 1998). Avoidance reflects the degree to which an individual tends to deactivate the attachment system, and to avoid interpersonal closeness or disclosure of emotions within relationships. Attachment anxiety, in contrast, reflects a tendency toward hyperactivating the attachment system, preoccupation with abandonment or rejection in relationships, and a desire to be unusually close in interpersonal relationships that can be unsettling to relational partners. Jones and colleagues (2015) found that across multiple studies, avoidance was linked to less sensitive and responsive caregiving. In contrast, results for attachment anxiety were more mixed. Nevertheless, the review showed that attachment styles were linked in theoretically expected ways with parenting behaviors, emotions related to parenting, and parent cognitions.

Researchers have considered parental mental states (e.g., the capacity “. . . to see things from the [child's] point of view”; Ainsworth, 1969, “Scale 1: Sensitivity vs. Insensitivity to the Baby's Signals,” para. 3) as predictors of caregiving quality. First, a body of research has linked maternal reflective functioning to parental caregiving (e.g., Rosenblum, McDonough, Sameroff, & Muzik, 2008; Stacks et al., 2014), and improvements in reflective functioning have been linked to improvements in parenting (Suchman, DeCoste, Leigh, & Borelli, 2010). *Reflective functioning* is defined as parents' ability to keep their children's (and their own) mental states (e.g., feelings, thoughts, intentions, and desires) in mind and to link this understanding to their own and their children's behavior (Fonagy, Gergely, Jurist, & Target, 2002). Second, research has shown consistent links between mind-mindedness and sensitivity (e.g., Demers, Bernier, Tarabulsy, & Provost, 2010; Laranjo, Bernier, & Meins, 2008; Meins et al., 2012). *Mind-mindedness* is defined as “the mother's proclivity to treat her infant as an individual with a mind, rather than merely as a creature with needs that must be satisfied” (Meins, Fernyhough, Fradley, & Tuckey, 2001, p. 638). Third, Dix (1991, 1992) theorized that parents with child-oriented parenting goals (that focus on the child's perspective) would be more sensitive. Consistent with this idea, Leerkes (2010) showed that mothers with more infant-oriented goals re-

sponded to infant distress more sensitively than did mothers with self-oriented goals.

Attachment theory suggests that parental emotions that are self-focused (e.g., anger, anxiety) rather than infant-focused (i.e., empathic) interfere with sensitive caregiving because they may lead mothers to avoid the distress, withdraw from the child, or respond intrusively (Cassidy, 1994; Dix, 1991). This idea has been empirically supported (Dix, Gershoff, Meunier, & Miller, 2004; Leerkes, 2010; Leerkes, Parade, & Gudmundson, 2011).

There has been little research on links between maternal physiological regulation and maternal caregiving, despite evidence from research on animals that maternal physiological regulation is important in organizing parenting behavior (e.g., Insel, 2000). A notable exception is a study showing that sensitivity to distress was linked to vagal withdrawal (a physiological sign of attending to a challenge) for mothers of 6-month-old infants who would later be insecure-avoidant, suggesting that these mothers experience sensitivity to distress as challenging (Mills-Koonce et al., 2007). Another study showed that mothers of secure 12-month-old infants showed greater vagal withdrawal during the final reunion of the Strange Situation than did mothers of avoidant infants, suggesting that mothers of secure infants were attending more to their children than were mothers of insecure-avoidant infants (Hill-Soderlund et al., 2008). Similarly, Leerkes and colleagues (2015) found that less adaptive physiological regulation prenatally was associated with lower maternal sensitivity to infant distress at 6 months. This link was mediated by mothers' self-focused and negative processing of infant cues.

Parental Caregiving and Attachment across Cultures

Ainsworth (1967) began her research on maternal caregiving in Uganda. Thus, from the beginning, her thinking about caregiving was rooted in repeated naturalistic observations in a cross-cultural context. Bowlby's (1969/1982) theory of attachment was based in an ethological perspective in which caregiving and attachment are thought to be how the human species evolved to promote survival. Thus, theory would suggest that although there may be cultural differences in parenting beliefs, goals, and behaviors, there should be underlying similarities as well. Much of the research on caregiving and attachment, however, has tended

to neglect cultural/contextual differences and has instead focused on middle-class families in Western industrialized societies. Van IJzendoorn and Sagi-Schwartz (2008; see also Mesman, Van IJzendoorn, & Sagi-Schwartz, Chapter 37, this volume) made a case that more research is needed to better understand attachment across cultures. There is some evidence suggesting that sensitivity is important across cultures. For example, Posada (2013) summarized a series of studies assessing the link between parental sensitivity and child attachment in different cultural and SES groups in Colombia and the United States, and found the expected associations between sensitivity and attachment in all groups.

Similarly, True, Pisani, and Oumar (2001) examined the link between maternal sensitivity and infant attachment in a sample of mothers and their infants from the Dogon ethnic group of Mali, West Africa. Despite culturally based parenting practices that differed from typical Western parenting practices and differences in infant behaviors, the associations between parent sensitivity and infant attachment approached significance in this small sample ($n = 27$), and frightened/frightening behaviors significantly predicted insecurity (typically disorganized attachment). Maternal sensitivity and frightened/frightening behaviors explained 19% of the variance in infant attachment. Nevertheless, there are likely cultural/contextual issues that should be considered in connection with caregiving (see Yovsi, Kärtner, Keller, & Lohaus, 2009, for a discussion of this issue).

A systematic review of the literature on observational studies of parental sensitivity in racial/ethnic minority groups showed that parental sensitivity tends to be lower in these parents than in racial/ethnic majority groups (Mesman, Van IJzendoorn, & Bakermans-Kranenburg, 2012). This difference, however, appeared to be associated with the confounding effects of low SES, which was linked to minority status. SES is typically more strongly related to sensitivity than is ethnicity or race (e.g., Chaudhuri, Easterbrooks, & Davis, 2009). Moreover, SES is linked to within-group differences in sensitivity in the United States (e.g., Barnett, Shanahan, Deng, Haskett, & Cox, 2010) and the Netherlands (e.g., Bocknek, Brophy-Herb, & Banerjee, 2009). These results are consistent with a family stress model (e.g., Yaman, Mesman, Van IJzendoorn, Bakermans-Kranenburg, & Linting, 2010) in which economic difficulties diminish parents' ability to parent sensitively (Conger & Donnellan, 2007).

Directions for Future Research on Parent–Child Caregiving

Despite the fact that research on caregiving has been vigorously pursued since the seminal work by Ainsworth and her colleagues (1978) on the link between parental caregiving and child attachment, there is still much to learn. Research demonstrates that caregiving matters for later attachment and other important outcomes. However, we need to know more about the dimensions of caregiving that matter and empirically map how important aspects of caregiving may change during a child's development. For example, it may be that emotion regulation (support for attachment needs) is the key function of caregiving in infancy, but that as the child grows, support for active, autonomous exploration and limit setting (to create a sense of safety as children engage in more autonomous exploration) may become important aspects of caregiving.

Research on Attachment and Caregiving in Adulthood

While research on parent–child caregiving has typically viewed the safe-haven and secure-base functions jointly (as part of the same sensitivity construct), research in the adult literature has more commonly viewed the provision of a safe haven (support for attachment needs) and secure base (support for exploration) as two different caregiving functions that occur in two different life contexts. Also, in adult relationships, the caregiving and care-seeking roles are bidirectional, with each partner at times providing care and at other times receiving care. In well-functioning adult attachment relationships, “taking care” of a partner involves supporting that person's need for comfort/assistance when the attachment system is activated, and supporting his or her explorations (personal growth, goal strivings) when the attachment system is not activated.

Safe-Haven Processes: Support of Attachment Needs

An assumption of attachment theory is that across the lifespan, when individuals are distressed (attachment system activation), they feel an urge toward proximity to attachment figures (who may include romantic partners, close friends, parents,

or other family members in adulthood), and that attachment behavior will be activated with greater intensity as the degree of perceived threat increases. Consistent with these assumptions, observational and daily diary studies have shown that care-seeking behavior in adulthood increases in response to stressful or threatening events (Collins & Feeney, 2000, 2005; Collins, Kane, Guichard, & Ford, 2008), and that secure individuals have a higher threshold for attachment system activation than do insecure individuals (Bartholomew, Cobb, & Poole, 1997; Mikulincer & Florian, 1995; Ognibene & Collins, 1998; Simpson & Rholes, 1994) and show a greater willingness/ability to seek/mobilize support (e.g., Collins & Feeney, 2000; Feeney, Cassidy, & Ramos-Marcuse, 2008; Florian, Mikulincer, & Bucholtz, 1995; Mikulincer & Florian, 1995; Mikulincer, Florian, & Weller, 1993; Ognibene & Collins, 1998; Rholes, Simpson, & Orina, 1999; Simpson, Rholes, & Nelligan, 1992).

Links between Care-Seeking and Caregiving Behaviors

Normatively, signs of distress in a close other should activate the attachment figure's caregiving system. Because care-seeking and caregiving behaviors are directed toward the same goal (i.e., reducing distress and restoring felt security) in well-functioning partnerships, they should be linked in complementary ways. Research in support of this idea has shown that specific care-seeking behaviors were associated with specific caregiving behaviors enacted during discussions of stressful life events (Collins & Feeney, 2000; Feeney et al., 2008). For example, clear and direct expressions of need were associated with helpful forms of support, whereas indirect expressions of need were associated with unhelpful forms of support, and the type of help offered (e.g., instrumental or emotional support) was matched to the type of help sought (Collins & Feeney, 2000). Similarly, in a daily diary study of couples, participants received more support on days when they expressed greater need (Collins & Feeney, 2005). Also, in an experimental study in which expressions of distress (a form of care seeking) was experimentally manipulated, caregivers wrote more supportive messages to their partner when they believed the partner was more distressed (Feeney & Collins, 2001). Thus, the evidence suggests that safe-haven care-seeking and caregiving behaviors are coordinated in complementary ways.

Individual Differences in Safe-Haven Caregiving

Theoretically, and consistent with evidence for parental caregiving, secure individuals should find it easier to perceive and respond to others' distress than do insecure individuals. This is because sensitive and compassionate reactions to the needs of others are products of a well-functioning caregiving behavioral system, which cannot function effectively when one's own needs for security have not been met (Collins et al., 2010; Mikulincer & Shaver, 2005). Secure individuals are also more likely to possess the skills, resources, and adaptive caregiving motives that are necessary for being responsive to the needs of others (Feeney & Collins, 2001, 2003, 2014).

Corroborating this, a series of self-report studies reveal that secure attachment (low anxiety and avoidance) is associated with more effective caregiving in intimate relationships (Carnelley, Pietromonaco, & Jaffe, 1996; B. C. Feeney & Collins, 2001; J. A. Feeney, 1996; Kane et al., 2007; Kunce & Shaver, 1994). Overall, secure adults are sensitive to their partner's cues and willing to provide physical comfort when needed; they are more cooperative than controlling in their caregiving style, and they are less likely to be overinvolved in their caregiving efforts. In contrast, insecure attachment (high anxiety and/or avoidance) is associated with less effective caregiving behavior, but the particular pattern of ineffective care depends on the particular type of insecurity. Avoidant individuals are relatively neglectful and controlling, whereas anxious individuals are relatively intrusive, overinvolved, and controlling.

Observational studies provide converging evidence for attachment differences in patterns of caregiving. In a series of studies, Simpson, Rholes, and colleagues (Rholes et al., 1999; Simpson, Rholes, Orina, & Grich, 2002; Simpson et al., 1992) showed that avoidant attachment is associated with less effective caregiving behavior. For example, when men were placed in the caregiving role (Simpson et al., 1992), those who were high in avoidance provided less reassurance and support as their partner's level of distress increased; they also expressed more anger toward their partners during the stress period, and interacted more negatively with them during the recovery period (after the stressor was removed), especially when their partners sought more support (Rholes et al., 1999). These findings suggest that avoidant men found their partner's expressions of need to be aversive,

and that they responded by distancing themselves from their partners. In these studies, anxious attachment was unrelated to observed caregiving behavior. However, an observational study that examined individual differences in caregiving behavior while one member of the couple described a personal stressor to his or her partner (Collins & Feeney, 2000) revealed that attachment anxiety is associated with less effective support behavior. Anxious individuals provided less instrumental support, were less responsive, and exhibited more negative support behavior, especially when their partner's needs were less clear—indicating that attachment anxiety (as well as avoidance) limits one's ability to be a good caregiver.

A study designed to examine attachment differences in responsiveness to attachment needs experimentally manipulated the caregiver's belief that his or her partner was either extremely distressed about an upcoming speech task (high need for support) or not at all distressed (low need for support; Feeney & Collins, 2001). From an attachment perspective, responsive caregiving should be appropriately contingent on the partner's needs; thus, support providers should show increased support effort in response to greater need. However, results revealed that avoidant individuals showed no evidence of responsiveness; they provided relatively low levels of emotional support regardless of their partner's level of need, and they provided more instrumental support in the low-need condition (when their partner had little need for it) than in the high-need condition (when their partner needed it most). Anxious individuals showed some evidence of responsiveness, but they were not always in sync with their partner's needs; they provided more instrumental support in the high-need condition than the low-need condition (a pattern of responsiveness), but they provided the same relatively high level of emotional support regardless of their partner's level of need (a pattern of overinvolvement).

Westmaas and Silver (2001) also showed that insecure attachment impeded effective caregiving when women interacted with a peer whom they were led to believe had just been diagnosed with cancer. Avoidant women were rated by observers as less supportive and as making less eye contact during the interaction. Attachment anxiety was unrelated to behavioral support but was associated with reports of feeling uneasy during the interaction and self-critical thoughts (occupied with thoughts about their own interpersonal performance).

Taken together, observational studies provide clear evidence that secure individuals are more sensitive to the needs of others and better able to modulate their cognitive, emotional, and behavioral resources in ways that are contingent on their partner's expression of distress. In contrast, insecure adults have substantial deficits in their ability to support and care for others, but the specific nature of the deficit differs for avoidant and anxious individuals. One limitation of these studies is our inability to draw causal inferences concerning the effect of secure attachment on caregiving behavior. However, recent experimental studies (in which attachment security was manipulated using priming techniques) have shown that experimentally induced attachment security increases empathy, the endorsement of prosocial values, and prosocial behavior (Mikulincer et al., 2001, 2003; Mikulincer & Shaver, 2001; Mikulincer, Shaver, Gillath, & Nitzberg, 2005). These investigations provide evidence for a causal link between feeling secure and compassionate responses to others in need.

Mechanisms That Explain Individual Differences in Caregiving

In taking an attachment-theoretical approach to understanding caregiving, it is important to go beyond the mere documentation of attachment differences to identify the mechanisms that explain these patterns. Research and theorizing in this area have suggested that effective caregiving (sensitively responding to needs as they arise) requires a constellation of skills, resources, and motivations that individuals possess to varying degrees (Feeney & Collins, 2003, 2014). One study using observational, survey, and experimental methods (Feeney & Collins, 2001) showed that unique patterns of motives (e.g., egoistic vs. altruistic motives for helping one's partner), skills (e.g., knowledge about how to support others), and resources (e.g., self-focus) can explain why people with different attachment characteristics differ in their caregiving. Avoidant adults are unresponsive because they lack knowledge about how to support others, lack a prosocial orientation toward others, and fail to develop the deep sense of relationship closeness, commitment, and trust that appear to be critical for motivating effective caregiving behavior. Anxious adults are overinvolved caregivers because although they feel close and committed to their partners, they simultaneously distrust their

partners and are selfishly motivated in their caregiving attempts.

Other research examining specific motives that underlie the provision of responsive or unresponsive caregiving (Feeney & Collins, 2003) has revealed that avoidant individuals help their partners for relatively egoistic reasons (e.g., they feel obligated to help, want to avoid sanctions for not helping, or expect to get something in return), whereas anxious individuals help for both egoistic and altruistic reasons (e.g., they not only feel concern for their partner's welfare but they also want to gain their partner's love or make their partner dependent upon them). These motives, in turn, predicted the quality of support provided in the relationship. Altruistic motives were linked with a responsive caregiving style, whereas egoistic motives were linked with an unresponsive or overinvolved caregiving style (see also Feeney, Collins, Van Vleet, & Tomlinson, 2013).

With regard to emotional mechanisms, researchers have examined caregivers' emotional reactions to their partners' expressions of anxiety in times of stress (Monin, Feeney, & Schultz, 2012). Caregivers who are unable to regulate their own emotions or who are uncomfortable with others' emotion expression may have negative emotional reactions to witnessing a significant other's distress, which should impede effective caregiving. This was supported in an observational study in which one member of married/dating couples was exposed to a stressor, and in an experimental study in which participants watched standardized videos of clear versus ambiguous emotion expression. Results indicated that insecure-avoidant individuals felt angry in response to their partners' expression of distress, whereas insecure-anxious individuals felt anxious/nervous. These results are consistent with research showing that avoidant (and sometimes anxious) individuals display anger when their partners are distressed or seek support from them (Rholes et al., 1999).

Safe-Haven Caregiving as a Predictor of Important Outcomes for Recipients

An individual who receives safe-haven caregiving should experience immediate outcomes, including problem resolution, reduced stress/physiological arousal, better coping capacity, enhanced feelings of security, and enhanced relationship satisfaction. Consistent with these ideas, research has shown that small acts of caring from a partner can have

immediate effects on well-being and relationship quality. For example, in a daily diary study, both men and women felt more loved/valued and happier in their relationship on days when their partner provided more caring support, and these positive effects lingered the following day (Collins & Feeney, 2005). Likewise, an observational study of couples in which one partner disclosed a personal worry to the other showed that care-recipients experienced immediate improvements in emotional well-being when their partner provided more responsive support (Collins & Feeney, 2000). Similarly, Simpson and colleagues (1992) found that participants who were waiting to begin a stressful procedure were more calmed when their romantic partners made more supportive remarks, and they were less calmed when their partners avoided or downplayed their concerns (see also Cutrona, 1986; Winstead & Derlega, 1985). There is also evidence that the receipt of safe-haven support facilitates problem resolution; studies have shown that supportive behavior provided by companions (e.g., talking about a problem-solving task) is a strong predictor of subsequent problem-solving performance (e.g., Lakey & Heller, 1988; Winstead, Derlega, Lewis, Sanchez-Hucles, & Clarke, 1992).

Experimental research also shows that caring support from a partner can have immediate effects on emotional well-being and relationship functioning. In one study, immersive virtual environment technology was used to create a frightening task for one member of each couple and to experimentally manipulate their romantic partner's attentiveness and emotional support in the virtual world (Kane, McCall, Collins, & Blascovich, 2012). Relative to those with an inattentive/neglectful partner in the virtual world, those with an attentive/responsive partner reported lower anxiety, more positive self-evaluations, and increased relationship satisfaction following the frightening task. Also, individuals who had been exposed to an inattentive/neglectful partner kept greater physical distance between themselves and their partner during a subsequent, unrelated task.

These findings suggest that responsive caregiving can reduce stress and foster relationship quality, and that unresponsive behaviors can erode both physical and emotional closeness between partners. The findings also indicate a causal link between receipt of caring support and immediate improvements in personal and relational well-being. This is consistent with research with both

dating and married adults indicating that the extent to which individuals are satisfied and adjusted in their relationship depends in part on whether their partner is a good caregiver who can provide a safe haven of comfort, support, and security (Carnelley et al., 1996; J. A. Feeney, 1996).

In addition, researchers have shown that the provision and receipt of responsive care within a close relationship, particularly emotional/esteem support, is one of the best predictors of satisfaction in those relationships (Buhrmester, Furman, Wittenberg, & Reis, 1988; Katz, Beach, & Anderson, 1996; Kotler, 1985). In fact, Barbee and Yankeelov (1992; cited in Barbee & Cunningham, 1995) found that the lack of an attempt to support a partner and the use of dismissing behaviors (e.g., minimizing the importance of the problem) during a support interaction were significant predictors of later romantic relationship dissolution. And other research has shown that caregiving patterns observed in the laboratory (and reported by both couple members) predict the quality, functioning, and stability of relationships concurrently (Collins & Feeney, 2000) and over time (Feeney & Collins, 2001).

Additional evidence for the importance of responsive caregiving in adult relationships comes from studies showing that cardiovascular reactivity is buffered in individuals who experience a stressor in the presence of a close, nonevaluative support provider relative to individuals who experience the stressor alone, with a stranger, or with an evaluative other (e.g., Allen, Blascovich, Tomaka, & Kelsey, 1991; Edens, Larkin, & Abel, 1992; Kamarck, Manuck, & Jennings, 1990; Snydersmith & Cacioppo, 1992). Negative and unsupportive interactions, however, predict slower recovery (Fritz, Nagurney, & Helgeson, 2003). In addition, soothing touch or close physical contact (with a close relationship partner) during a stressful task has been found to decrease heart rate and blood pressure (e.g., Ditzen et al., 2007; Fishman, Turkheimer, & DeGood, 1995; Grewen, Anderson, Girdler, & Light, 2003; Lynch, Thomas, Pasketwitz, Katchar, & Weir, 1977; Whitcher & Fisher, 1979) and to attenuate neural activation in brain regions associated with emotional and behavioral responses to threat (Coan, Schaefer, & Davidson, 2006; see also Coan, Chapter 12, this volume).

Finally, a large literature that is beyond the scope of this chapter indicates that social support in times of stress is associated with better mental and physical health outcomes (e.g., Cohen,

1988, 2004; Cohen & Syme, 1985; Cohen & Wills, 1985; Kawachi & Berkman, 2001; Sarason, Sarason, & Gurung, 1997; Uchino, Cacioppo, & Kiecolt-Glaser, 1996). This literature generally indicates that people with satisfying levels of social support are healthier (both psychologically and physically); they recover from illness more quickly (have better immune functioning) and are better adjusted (both personally and socially). It is important to note that in these studies, "social support" is typically conceptualized and assessed via reports of general perceptions of available support, social network size, and support received within a certain period of time. Very few of these studies have included observations of caregiving behaviors (and related interpersonal processes) as they unfold during actual support interactions with close relationship partners, nor have they followed people over time to assess the extent to which specific caregiving dynamics predict health outcomes.

Individual Differences in Outcomes of Safe-Haven Caregiving

Some research has considered individual differences in outcomes of safe-haven caregiving. Two studies examined attachment differences in the extent to which the presence of a supportive other buffers autonomic reactivity to stress (Carpenter & Kirkpatrick, 1996; Feeney & Kirkpatrick, 1996). One study indicated that separation from a partner during a stressful situation had adverse effects on insecure individuals' cardiovascular reactivity (Feeney & Kirkpatrick, 1996), and the other indicated that for insecure (avoidant and anxious) participants, physiological reactivity in response to a stressor was greater when the partner was present than when absent (Carpenter & Kirkpatrick, 1996). For both types of insecure individuals, the partner's presence resulted in a negative immediate outcome—perhaps because these individuals were dealing with not only the stressful laboratory task but also the prospect of being rejected by their partners while trying to cope with this threat. In contrast, partner proximity had no discernible effect on secure individuals' autonomic responses to stress—perhaps because the psychological availability of the partner transcends physical separation in secure relationships because secure individuals may be confident of their ability to cope with stress, or because they have a higher threshold for attachment system activation.

Other research that considers the moderating effects of attachment on caregiving outcomes during a stressful situation demonstrated that avoidant women were more calmed than secure women by the supportive comments of their male partners, despite the fact that they were less likely to mention the stressful impending event to their partners (Simpson et al., 1992). The researchers suggested that supportive behaviors may have a stronger and more positive impact on avoidant than on secure individuals because they do not typically expect to receive support. These findings are noteworthy because they indicate that avoidant individuals do benefit from receiving support, even though they are unlikely to seek it out.

Another study examining individual differences in the effects of experimentally provided social support showed similar effects (Sarason & Sarason, 1986). Participants who scored high and low in general perceptions of available support were either provided with support or given no special intervention before working on a difficult task. Interestingly, individuals who were low in perceived support (characteristic of insecure individuals) performed significantly better when support was experimentally offered to them. However, individuals who were high in perceived support (characteristic of secure individuals) performed similarly regardless of the experimental support manipulation. These results point to a facilitative effect of manipulated caregiving for individuals low in perceived support.

More research is needed to specify outcomes of safe-haven caregiving for individuals with different attachment characteristics. In particular, it will be important to identify the conditions under which insecure adults are able to derive comfort/security from their partners. Most research on this topic has been conducted with children and has shown that attachment security predicts the ability to be soothed by caregivers: Secure children seek support when distressed and are easily comforted; avoidant children fail to seek proximity to caregivers and do not derive comfort; and although anxious/ambivalent children seek proximity to caregivers, they are difficult to soothe (Ainsworth et al., 1978). Similarly, research has shown that when highly anxious adults discuss relationship conflicts with their partners, they are more distressed relative to less anxious people, and remain more distressed even when their partners are rated as behaving positively toward them (Simpson, Campbell, & Weisberg, 2006). Likewise, research with adolescents has shown that

anxious individuals exhibit heightened heart rate and blood pressure during interactions with peers, whereas avoidant adolescents experience fewer overall interactions with peers and heightened heart rate and blood pressure during experiences of conflict (Gallo & Matthews, 2006). However, much remains to be discovered about the ability of adults with different attachment characteristics to derive comfort from relationship partners. Individuals with different attachment characteristics may require different forms of responsive care in order to feel soothed. For example, Simpson, Winterheld, Rholes, and Orina (2007) found that secure individuals are more calmed when their partners provide emotional care, whereas insecure (dismissive) individuals react more favorably to instrumental support.

Research on Secure Base Support Processes: Support of Exploration

Although adults routinely assign credit for their accomplishments to the support of the significant people in their lives (people who have encouraged them to grow as individuals and strive to reach their full potential), empirical investigations of this caregiving function represent a newer and less developed aspect of the adult caregiving literature.

Links between Exploration Behaviors and Secure-Base Caregiving

As described earlier, three important characteristics of a secure base include supporting exploration by (1) being available in the event that the base is needed, (2) not unnecessarily interfering with exploration, and (3) being encouraging and accepting of exploration. In an initial test of the idea that these three components predict exploration behavior in adulthood, Feeney and Thrush (2010) created a laboratory situation to permit the observation of one couple member's exploration behavior as a function of the other couple member's secure-base behavior (by giving the "explorer" a novel exploration activity to try out in the presence of his or her spouse). Results indicated that spouse availability was associated with greater persistence at the exploration task, whereas spouse interference predicted less persistence, poorer performance, and less enthusiasm in the process of the task. Spouse encouragement predicted better performance and greater expressed enthusiasm for the task. Taken together, these results indicate

that availability and encouragement facilitate exploration, whereas interference is an inhibitor of exploration (Feeney & Thrush, 2010).

Results of this investigation also revealed an ambivalent behavioral pattern for explorers with interfering spouses. Specifically, although explorers with interfering spouses expressed greater concern about the spouse watching their explorations, they also sought task assistance from them. In addition, explorers with interfering spouses were receptive to both solicited and unsolicited task assistance, and they were simultaneously rejecting of both solicited and unsolicited task assistance. This seems to reflect a fundamental tension that individuals with interfering spouses experience in exploration contexts: People with interfering caregivers may come to believe that they are incapable of successful independent exploration, and these self-doubts may make them receptive to task assistance. However, they may be simultaneously rejecting of this assistance because the negative messages conveyed by spouse interference are likely to feel demeaning, and because spouse interference impedes one's own goals/efforts.

Another study examined links between secure-base behavior and exploration behavior in the context of discussing personal goals (Feeney, 2004). Caregivers who were coded by observers as being supportive of and comfortable with their partners' autonomous goals had partners who discussed their goals openly, confidently explored avenues for achieving their goals, and were receptive to support attempts. In contrast, caregivers who were coded by observers as avoiding discussion of their partner's goals had partners who did not discuss their goals openly, did not confidently explore avenues for achieving their goals, were not receptive to support attempts (when they occurred), and avoided discussion of the goals themselves. Interestingly, caregivers who were intrusive and controlling during the discussion had partners who modified and minimized the importance of their original goals.

Individual Differences in Secure-Base Caregiving

To date, not much research has considered individual differences in secure-base caregiving within adult relationships. One study has shown that avoidant spouses are less available to their partners during exploration, whereas anxious spouses are more interfering with, and less encouraging of, exploration (Feeney & Thrush, 2010). These

findings are consistent with the infant literature indicating that insecure parents tend to interfere with their baby's exploratory activity (Cassidy & Berlin, 1994; Grossmann, Grossmann, & Zimmermann, 1999). With regard to who is more or less likely to receive secure-base support from their partners, results indicated that both types of insecure individuals (avoidant and anxious) had spouses who were less available to them during exploration, and attachment avoidance was specifically linked with the receipt of less encouragement for exploration. Thus, the characteristics of both interaction partners matter in predicting the provision and receipt of secure-base support.

Secure-Base Caregiving as a Predictor of Important Outcomes for Recipients

Given that research on secure-base caregiving in adult relationships is in its infancy, the research that has been conducted thus far primarily has considered immediate outcomes of receiving (or failing to receive) this important type of care. Initial studies have focused on state self-esteem and mood as important immediate outcomes. One study revealed that when recipients felt that their goals were supported by their partners (during a discussion of personal goals), they experienced increases in self-esteem and positive mood after the discussion (Feeney, 2004). Similarly, spouses' secure-base behavior during an exploration activity, in which "explorers" worked on a novel and challenging task, predicted changes in the explorer's mood and state self-esteem from before to after the activity (Feeney & Thrush, 2010). Specifically, spouse encouragement predicted increases in positive mood, decreases in concerned mood, and decreases in frustrated mood from before to after the activity. Although spouse availability also predicted decreases in concerned mood, spouse encouragement was the component of secure base support that was most strongly predictive of emotionality. This suggests that encouragement may serve an important emotional and motivational function that the other components of secure-base caregiving (availability and nonintrusiveness) do not serve. With regard to self-esteem, spouse interference during exploration predicted significant decreases in self-esteem, whereas spouse encouragement predicted increases in self-esteem. Finally, experimental evidence for the detrimental effect of intrusive support on self-esteem and positive affect was obtained in a study that manipulated intrusive support during a computer exploration activity

(Feeney, 2004). Individuals who received intrusive support, and who perceived their partners' support as being intrusive and insensitive, experienced decreases in state self-esteem and positive mood from before to after the activity.

Another immediate outcome of intrusive support is poor performance on exploration tasks (Feeney, 2004; Feeney & Thrush, 2010). This may reflect the fact that explorers with interfering partners are interrupted frequently and less able to concentrate on performing well. Also, because explorers with interfering partners perform poorly even when given the answers to challenging tasks (Feeney, 2004), they may be rejecting their partners' intrusive assistance. Although these speculations await future investigation, it is noteworthy that these results with adults are consistent with research showing that parental interference in children's exploratory activities is associated with a variety of negative outcomes for children, including disrupted concentration, less persistence and enthusiasm in exploration, more passivity, more negative emotion, less competence, and less curiosity (e.g., Ainsworth, Bell, & Stayton, 1974; Cassidy & Berlin, 1994; Egeland & Farber, 1984; Main, 1983; Matas, Arend, & Sroufe, 1978).

Perceptions of exploration, and of one's ability to explore successfully, are additional immediate outcomes of receiving secure-base support. In one study, spouse encouragement during exploration predicted subsequent perceptions that exploration is enjoyable and that one is smart and competent to engage in it, whereas spouse interference had the opposite effect (Feeney & Thrush, 2010). Another study showed that when recipients felt that their goals were supported by their partners (during a discussion of personal goals), they rated their likelihood of achieving their goals to be greater after the discussion than before the discussion (Feeney, 2004).

With regard to longer-term outcomes, in one observational/longitudinal study, individuals whose partners exhibited availability to them (during goal discussions) at one point in time were more likely to have accomplished their goals 6 months later, and they showed greater evidence of increases in independent functioning over this period of time (Feeney, 2007). Corroborating these findings using self-report methods, Brunstein, Dangelmayer, and Schultheiss (1996) found that reports of the amount of goal support received from romantic partners predicted the enactment of both relationship and individual goals over a 4 week period of time. A longitudinal investigation

of newlyweds showed that a spouses' secure-base support during the first year of marriage predicts increases in personal growth and relationship quality, as well as reports of better psychological and physical health 1 year later (Van Vleet & Feeney, 2011).

There are also some studies indicating that the successful pursuit of personally meaningful goals is related to indicators of well-being including elated rather than depressed mood and satisfaction with life (Brunstein, 1993; Brunstein, Schultheiss, & Grassman, 1998; Emmons, 1986; Emmons & King, 1988; Omodei & Wearing, 1990; Palys & Little, 1983; Ruehlman & Wolchik, 1988; Yetim, 1993; Zaleski, 1987). As a whole, these studies have shown that individuals with high well-being, in contrast to those with low well-being, pursue goals that are important, fulfilling, challenging, fueled by optimistic expectations, and assisted by others. This is consistent with attachment theory's notion that it is the interpersonal dynamics surrounding the *assistance by others* that is responsible for driving the effects of goal strivings on personal well-being. In longitudinal studies that support this idea, Brunstein and colleagues (1996) found that perceptions of goal attainability and social support for personal goals were predictive of changes in subjective well-being over time, and Brunstein (1993) showed that favorable conditions to attain personal goals led to more progress in goal achievement that translated into enhanced well-being. In fact, of all the personal goal variables assessed in their study, support of personal goals by significant others was the most powerful predictor of subjective well-being (Brunstein, 1993).

Studies have shown that support for personal goals by intimate partners accounts for how satisfied people feel with their relationship (Brunstein et al., 1996; Kaplan & Maddux, 2002). The idea is that perceiving high goal support from a partner should facilitate the enactment of personal goals, thereby enhancing the individual's relationship satisfaction. In contrast, perceiving a partner as undermining the pursuit of personal goals should impair relationship satisfaction by posing a threat to the accomplishment of highly valued goal states. Consistent with attachment-theoretical propositions regarding the importance of the secure-base caregiving function, this research showed that reports of goal support received from dating partners predicted increases in relationship satisfaction over a period of 4 weeks, and that both receiving and giving personal goal support were

systematically linked to spouses' marital satisfaction. These findings suggest that personal goal attainment and relationship outcomes are linked in important ways (Gore & Cross, 2006).

Overall, this work provides important evidence for attachment-theoretical propositions regarding the importance of secure-base caregiving in adulthood. However, more research is needed to assess a variety of potential long-term outcomes of secure-base caregiving, including effects on learning/knowledge/discovery, global self-esteem, achievements, approach to challenges, and changes in exploration behavior over time.

Individual Differences in Outcomes of Secure-Base Caregiving

Although all individuals are expected to benefit from secure-base caregiving, it is possible that the care receiver's attachment characteristics will moderate this link and influence the degree to which he or she benefits. For example, the exploration behavior of avoidant individuals may be less tied to the support they receive (given that they have learned not to depend on it). Moreover, even if anxious individuals receive secure-base caregiving, their fear of failure and chronic attachment system activation may inhibit their ability to fully embrace the value of exploration. These possibilities await future investigation.

Directions for Future Research on Caregiving in Adult Relationships

In addition to future research directions we have already discussed, there is a need for theoretical elaboration and research that considers the interrelations among the attachment, caregiving, and exploration systems as they play out in dyadic interactions. For example, researchers must consider ways in which caregiving processes might change when the attachment and caregiving systems are simultaneously activated in the same individual (e.g., when relationship partners are simultaneously distressed). It is also noteworthy that our discussion of secure-base caregiving processes emphasizes explorations of the external world that are likely to have important implications for the inner self in terms of self-esteem, perceptions of self-competency, and so on. However, effective secure-base caregiving should include not only the support of a relationship partner's exploration of the physical world but also the explora-

tion of his or her inner psychological world (e.g., exploration of thoughts, feelings, and emotions related to self-understanding and self-discovery). In fact, Main and her colleagues have described the uninhibited exploration of attachment-related events, thoughts, and emotions as a hallmark of secure attachment (Main, 1995; Main, Kaplan, & Cassidy, 1985). Thus, the support of this type of exploration, in particular, may have important implications for the development of secure attachment orientations in adulthood (e.g., Byng-Hall, 1999). Finally, it will be important to consider the ways in which the attachment, caregiving, and exploration systems function together in the context of everyday interactions between relationship partners. Attachment theory predicts that a delicate balance of encouraging autonomy (secure-base caregiving) yet accepting dependence when needed (safe-haven caregiving) is vital for healthy personal and relationship functioning. Thus, studies that simultaneously consider both caregiving functions will be important in advancing this research area.

Concluding Statement

Our goal in this chapter has been to consider caregiving from an attachment-theoretical perspective by reviewing theory and research on caregiving in both parent-child and adult relationships. Safe-haven and secure-base caregiving represent two complementary caregiving functions, and they are connected in the sense that attachment figures will be unable to effectively provide a secure base (and support exploration behavior) unless they understand and respect that attachment behavior is a part of human nature (even in adulthood), and is not a negative sign of dependency that should be outgrown (Bowlby, 1969/1982, 1988; Feeney, 2007). Good caregivers must have a genuine understanding and respect for not only individuals' need to grow, learn, discover, and accomplish personal goals but also the ingrained need of all individuals for affection, intimacy, and comfort in times of stress. Although it requires effort to provide a sensitive and responsive safe haven and secure base (and to balance these caregiving responsibilities), attachment theory highlights that the rewards of such care are likely to be great: Recipients of such care are likely to be happy and trusting, confident that others will be helpful when needed, confident in their own abili-

ties and capabilities, self-reliant and bold in their explorations of the world, cooperative with others, effective citizens who are unlikely to break down in adversity, active contributors to society, sympathetic/helpful to others in distress, and capable of maintaining healthy/stable relationships.

Chapter 37

Cross-Cultural Patterns of Attachment

Universal and Contextual Dimensions

Judi Mesman
Marinus H. van IJzendoorn
Abraham Sagi-Schwartz

It was in Uganda, a former British protectorate in East Africa, that Mary Ainsworth (1967) began to create the famous tripartite classification system of infant–mother attachment relationships. In her short-term longitudinal field study, carried out in 1954–1955, she found three patterns of attachment behavior in a small sample of 28 infants. The “securely attached group” of 16 infants cried infrequently, seemed especially content when they were with their mothers, and used their mothers as a secure base from which to explore the environment. The “insecurely attached group” of seven infants cried frequently, not only when left alone by their mothers but also in the mothers’ presence; they cried to be picked up, cried when they were put down, and wanted continuous physical contact with their mothers, mingled with ambivalence about their mothers’ presence. A “nonattached” group of five infants responded similarly to their mothers and to other adults, were not upset about being left alone by their mothers, and avoided interaction with the mothers upon their return. From Ainsworth’s detailed case studies of these infants, it can be inferred that in the Strange Situation procedure (Ainsworth, Blehar, Waters, & Wall, 1978) they would have been classified as “avoidant.”

The Uganda study laid the foundation for not only the notion of attachment classification but also the development of the sensitivity construct that would later be captured in the still widely used Sensitivity–Insensitivity to Infant Signals and Communications Observational Scale (Ainsworth, Bell, & Stayton, 1971, 1974). Ainsworth described how it was not warmth that seemed to distinguish between the different attachment classifications because almost all of the observed mothers in the Uganda sample showed warmth in interaction with their babies, but rather the amount of caregiving for the baby, and the mother’s excellence as an informant about the baby. From Ainsworth’s descriptions it becomes clear that these two factors amount to a pattern of proximity and availability, interest in the baby, perceptiveness about the baby’s needs, and prompt responsiveness to the baby’s signals. Ainsworth’s work in a context with multiple caregivers in the non-Western setting of Uganda was the starting point from which she initiated a replication study in a Western setting, as described in her Baltimore study (Ainsworth & Wittig, 1969). Thus, the Uganda study provided all the main ingredients for decades of research and theorizing about attachment and the role of parental sensitivity

in predicting differences in the quality of attachment.

Bowlby (1969/1982) suggested that the formation of an attachment relationship between infants and their protective caregivers is the outcome of evolution; “inclusive fitness” (Trivers, 1974) was deemed to be facilitated by an ethologically based innate bias to become attached to a conspecific (see Simpson & Belsky, Chapter 5, this volume). Therefore, a core element of attachment theory is the universality of this bias in infants to become attached, regardless of their specific cultural niche. Furthermore, secure attachment is expected to be normative within contexts that are not inherently threatening to human health, survival, and successful reproduction. In circumstances not too strongly deviating from the “environment of evolutionary adaptedness” (Bowlby, 1969/1982), it is assumed to be most adaptive to develop an attachment pattern that allows for exploration of the environment from the security of a safe haven in case of distress. However, if a cultural niche is harsh and socioeconomic circumstances are extremely stressful for parents, infants may be prepared by their parents to develop, for example, an avoidant attachment pattern to cope with the socioeconomic stresses. In such a niche, the avoidant attachment pattern may well be normative in that it promotes inclusive fitness by stimulating a quantitative strategy of procreation with lower investment in more offspring at an earlier age (Simpson & Belsky, Chapter 5, this volume). Similarly, a resistant attachment pattern may be more common in environments that induce stress associated with intractable wars (Belsky, 2008). Evolution may not have equipped human beings with rigid behavioral strategies that would have made it difficult to adapt to changing (natural and social) environments (Hinde, 1982; Simpson & Belsky, Chapter 5, this volume). According to Hinde’s (1982) position on conditional strategies, both mothers and babies are equipped to elicit not one set of interactions but a wide range of potential relationships compatible with specific environmental requirements. Nevertheless, one may wonder whether the secure attachment pattern is the primary strategy for adapting to a social environment that is basically supportive of the infant, and whether the insecure strategies should be considered as secondary, in that they constitute deviating but adaptive patterns provoked by less supportive contexts (Main, 1990). Although insecure attachments may emerge to the benefit of inclusive fitness, the long-term costs for

the individual’s psychological and physical well-being might be considerable.

Regarding the antecedents of attachment, consistent responsive care is expected to foster a secure attachment bond, converging with observational studies of both human and nonhuman primates (e.g., Harlow, 1958; Nelson, Fox, & Zeanah, 2014; Van IJzendoorn, Bard, Bakermans-Kranenburg, & Ivan, 2009). Even in rodents it is found that early-life stress is provoked by fragmentation and unpredictability of parental care and signaling, and such stress leads to persistent emotional dysfunction in offspring (Baram et al., 2012; Meaney, 2010). Indeed, the role of parental sensitivity is to provide a secure base from which the child can explore in the secure knowledge that the caregiver will be physically and emotionally available in case of distress, and will alleviate this distress (Ainsworth et al., 1974, 1978). Genetics seems to play only a minor role in forming variations in attachment patterns (Bakermans-Kranenburg & Van IJzendoorn, Chapter 8, this volume).

It can be argued that when the broader childrearing context allows for consistent responsive care, the formation of a secure attachment to this responsive caregiver is most likely to result in adaptive development and inclusive fitness. Similarly, in environments not deviating strongly from the environment of evolutionary adaptedness (Bowlby, 1969/1982), secure attachment is expected to lead to positive child outcomes across domains given that attachment security has been found to predict more optimal basic human prerequisites for adaptive functioning such as stress regulation (Lupien, McEwen, Gunnar, & Heim, 2009), nutritional status (Black & Aboud, 2011), and immune system functioning (Ehrlich, Miller, Jones, & Cassidy, Chapter 9, this volume; Miller, Chen, & Parker, 2011; see also Thompson, Chapter 16, this volume).

These universality assumptions have been widely tested and confirmed in North American and European samples, but the question is: What has nearly half a century of cross-cultural attachment research yielded regarding these issues? In this chapter, we describe and evaluate the cross-cultural attachment studies that have followed Ainsworth’s Uganda example. We limit our discussion to cultures other than the Anglo-Saxon and European cultures because these are amply represented in other chapters in this volume (e.g., Fearon & Belsky, Chapter 14; Thompson, Chapter 16; Lyons-Ruth & Jacobvitz, Chapter

29; DeKlyen & Greenberg, Chapter 28; Chase-Stovall & Dozier, Chapter 31). We discuss the following hypotheses (originally suggested by Van IJzendoorn, 1990):

1. The *universality hypothesis*: When given an opportunity, all infants without severe neurophysiological impairments will become attached to one or more specific caregivers.
2. The *normativity hypothesis*: The majority of infants are securely attached in contexts that are not inherently threatening to human health and survival.
3. The *sensitivity hypothesis*: Attachment security is dependent on childrearing antecedents, particularly sensitive and prompt responses to infant attachment signals.
4. The *competence hypothesis*: Secure attachment leads to positive child outcomes in a variety of developmental domains.

Attachment and Sensitivity in Africa: A Network of Caregivers

In her Uganda study, Ainsworth (1967, 1977) described the development of attachment in a multiple-caregiver context. Since then, it has also been established that in a Western context, infants' attachment to their mothers does not impede attachment relationships with other caregivers, such as fathers and professional caregivers in day care (Ahnert, Pinquart & Lamb, 2006; Goossens & Van IJzendoorn, 1990; Lucassen et al., 2011; Sagi et al., 1995). Thus, even in a childrearing environment in which mothers share their caregiving responsibilities with several other adults (and in Uganda also with older children), infants nevertheless become attached to their mothers and use them as a secure base to explore the world. The Uganda study, however, was rather small and exploratory, and certainly not representative of the various African cultures, each with its own patterns of multiple caregiving. In this section we discuss studies of attachment in Africa conducted in the years following Ainsworth's (1967) research. We place special emphasis on child development in a network of (child and adult) caregivers, in order to examine whether a multiple-caregiver environment is compatible with a unique attachment relationship between child and parent. Attachment in a network of multiple caregivers (or *alloparents*) is of crucial im-

portance because cross-cultural evidence indicates that in most societies, nonparental caretaking is either the norm or a common form (Hewlett & Winn, 2014; Hrdy, 2009), although this view has been contested (Bogin, Bragg, & Kuzawa, 2014), and paternal grandparents in a patrilineal society are likely to compete for the same resources as the child, challenging the often hypothesized benefits of alloparenting (Strassman, 2011). In this section we discuss ethnographic studies and studies using standardized instruments addressing attachment in the African context, which often involves multiple caregivers.

Ethnographic Studies of Attachment and Sensitivity in Africa

We start by describing five studies of multiple caregiving in African societies that provide ethnographic descriptions of secure-base behavior and discriminative attachment to one or more caregivers, and patterns of sensitive responsive care. Four of these studies concern hunter-gatherer societies, characterized by small seminomadic groups with a fluid group structure, absence of strict social rules, and flexible subsistence strategies (Lee & Daly, 1999). Bowlby (1969/1982) developed his evolutionary theory of attachment on the basis of speculations about child development and childrearing in the original environment in which the human species spent about 99% of its historical time as hunters and gatherers. In this "environment of evolutionary adaptedness" an infant would be protected against predators and other dangers by staying in close proximity to a protective adult. The four societies resembling this original way of living are described here.

Konner (1977, 2005) studied the !Kung San or Bushmen of northwestern Botswana, and described the general rules of childrearing in the !Kung society as reflecting indulgence, stimulation, and nonrestriction (Konner, 1977). The !Kung infants were fed whenever they cried and reached for the breast. At night they slept in close proximity to their mothers and were also fed on demand—even without the mothers' awakening. An infant was carried around in a sling, giving the infant constant access to the mother's breast and to decorative objects hanging around her neck. The infant could look around freely and experience extensive physical and cognitive stimulation. The 2- and 3-year-old children studied by Konner were involved in multiage peer groups, spending

more time there than with their mothers, and readily establishing new bonds. Nevertheless, !Kung mothers were most comforting in response to infant crying, even when excluding breast feeding, always responding to crying bouts lasting longer than 30 seconds (Konner, 2005). The !Kung study showed that there is room for both multiple attachment relationships and a preferred primary bond with the mother. It further highlights that sensitive responsiveness is an integral part of infant care within a multiple-caregiver context.

Morelli and Tronick (1991) studied the Efé of the Ituri forest in northeastern Zambia, a group that employs a system of multiple caregivers throughout the first few years of life, with newborns allowed to suckle other adult females even when their mothers are present (Tronick, Morelli, & Winn, 1987). Even the physical care is shared with other caregivers. Morelli and Tronick reported that the number of caregivers in the first 18 weeks amounted to 14.2 on average. This extremely dense social network led to prompt responses to any sign of infant distress. During the second half of the first year, the infants began to show preference for the care of their own mothers, were more likely to protest against their mothers leaving, and wanted to be carried by their mothers on trips outside the camp. Morelli and Tronick pointed to the 1-year-olds' interference with adults' work activities, which prevented nonmaternal caregivers from taking on caregiving responsibility during work. They also noted that at night, only the mothers cared for their infants, and sleep was regularly interrupted by episodes of playful interaction exclusively between infants and their mothers (Morelli & Tronick, 1991), which may have facilitated the emergence of a special infant–mother bond. From the perspective of attachment theory, the night may be an especially stressful time, during which infants need a protective caregiver the most (see description of Israeli communal kibbutzim, below). The Efé study supports the universality hypothesis, also suggesting that sensitive responsiveness at night fosters attachment relationships.

The child care pattern among the Hadza of Tanzania also consists of multiple caregivers, with close, indulgent, and affectionate physical caregiver–infant proximity and responsiveness in the first years of life (Marlowe, 2005). Hadza women usually forage in groups containing only women and children, taking young infants with them and leaving toddlers at the camp. Marlowe (2005) found that mothers held infants more often than

all other caregivers combined, also showing how despite mothers' willingness to hand their children over to other available caregivers, the child was not always equally willing, signifying a preference for mothers as primary attachment figures. When a child started crying when handed over to another caregiver, the mother usually took the child back, which is consistent with the notions of secure-base behavior and maternal sensitive responsiveness. In addition, Marlowe noted how all caregivers seemed to be equally sensitive to fussing and crying, but that mothers, compared with other caregivers, were generally much more effective at soothing and calming their child. Thus, descriptions of Hadza child care are consistent with the universality and sensitivity hypotheses.

For part of the year, the Bofi live in settlements near farming villages in the southwest region of the Central African Republic, and live in camps in the forest for the other part of the year. In their study of 22 Bofi children who also experienced multiple caregiving, Fouts and Lamb (2005) reported that the average length of bouts of crying and/or fussing was substantially longer when the mother was absent than when she was present. The difference was not statistically significant, but given the small sample size, this is not surprising. Calculating the effect size reveals a large one ($d = 0.70$), suggesting that in maternal absence, children try to elicit the mother's presence and care, which is consistent with other descriptions of attachment behavior. Furthermore, crying children were more likely to be responded to when the mother was present than when she was absent, and context- and caregiver-specific patterns of sensitive responsiveness appeared to explain individual differences in crying frequency. These findings confirm the universality hypothesis concerning a preferential attachment bond with the mother within a multiple-caregiving context, and they also support the sensitivity hypothesis, in that patterns of responsive caregiving, albeit specific to the ecology of each child's family circumstances, were predictive of less crying.

In contrast to these four societies, the Hausa in Nigeria represent a polygynous culture that practices mostly agriculture. An average of four caregivers share the tasks of social, verbal, and playful interactions with children, but the biological mothers take almost complete responsibility for physical care activities, such as feeding and bathing (Marvin, VanDevender, Iwanaga, LeVine, & LeVine, 1977). In their ethnographic study of 18 infants, Marvin and colleagues found that

Hausa infants were almost always in close physical contact with or close proximity to available adult caregivers, while not allowed to explore the wider environment alone because of the dangers involved. The high social density of the Hausa compound led to prompt adult or older sibling responses to any infant attachment signals, such as crying. The Hausa caregivers therefore appeared to be indulgent and sensitive, and at the same time restrictive toward their infants. The restriction of locomotion also led to a different use of adult caregivers as a secure base: Hausa infants explored their immediate environment in visual and manipulative ways, but only in close proximity to an attachment figure, and they ceased to explore as soon as the caregiver left. Nevertheless, Hausa infants clearly used adult caregivers as safe bases from which to explore, and they differentiated between attachment figures and strangers. Furthermore, all infants displayed attachment behavior toward an average of three to four different figures. Although being raised in an attachment relationships network, most Hausa infants were principally attached to one adult (generally the one holding the baby and interacting with him or her most often, whether or not this was the mother) to whom they addressed their attachment behavior most frequently (Marvin et al., 1977). This study provides evidence for the universality hypothesis and suggests that sensitive responsiveness is part of routine care for infants.

Standardized Observations of Attachment and Sensitivity in Africa

Only a few studies in multiple-caregiver African societies have used standardized procedures such as the Strange Situation procedure (Ainsworth et al., 1978) or the Attachment Q-Sort (AQS; Vaughn & Waters, 1990) to classify infants formally as securely or insecurely attached. This is, of course, due to the substantial practical barriers to conducting standardized procedures in contexts lacking laboratory facilities. The four studies that successfully did so are therefore very important and are discussed further here.

Childrearing among the Gusii of Kenya is characterized by alloparenting, but the division of tasks between mothers and other caregivers is rather strict. Mothers provide most of the physical care and are responsible for their children's health, whereas the activities of child caregivers are limited to social and playful interactions

(Kermioian & Leiderman, 1986). In their study, Kermioian and Leiderman (1986) included 26 infant-caregiver dyads. Outside each mother's hut, a modified Strange Situation procedure was implemented, with two separation-reunion episodes for mother, caregiver, and stranger each. The extra separations were meant to compensate for the lack of a Strange Situation laboratory environment. Gusii infants are used to being greeted with a handshake by their mothers and caretakers, and during the reunions, the Gusii infants anticipated the handshake in the same way as North American or European infants anticipate a hug. The secure Gusii infants would reach out to an adult with one arm, to receive the handshake enthusiastically, whereas the insecure infants would avoid the adult or reach and then pull away after the adult approached. The distribution of patterns of attachment was comparable with Western findings: Secure attachment was found in 61 and 54% of infants to mothers and to nonmaternal caregivers, respectively. The authors concluded that the development of differential or person-specific attachment behaviors for "polymatric" infants is similar to that observed in "monomatric" Western societies; that is, infants do become uniquely attached to a protective adult caregiver, regardless of the presence of one or more mother figures (Reed & Leiderman, 1981). This study also provides evidence for the universality and normativity hypotheses. Interestingly, positive nutritional or health status of the infants was related to the security of the infant-mother bond, whereas the infants' cognitive development was related to the security of attachment to the nonmaternal caregiver. These findings might be expected given the clear task division between mothers (physical care, focus on health) and other caregivers (social and playful interactions), and provide evidence also for the competence hypothesis.

Attachment classifications based on the traditional Strange Situation procedure were available in a study of 26 mothers and their 1-year-old infants among the Dogon subsistence farmers in Mali, among whom maternal care is flexibly supplemented with care from siblings and other family members (True, 1994; True, Pisani, & Oumar, 2001). The Dogon mothers breast-fed their infants on demand very frequently and kept them in close proximity almost all the time. The percentage of secure infant-mother dyads was high (69%), whereas the avoidant classification appeared to be absent, and few resistant infant-mother dyads were found (8%). The percentage of disorganized

infants was high (23%) compared to percentages in normal Western samples (15–20%). The study supports the universality hypothesis in showing how the Strange Situation procedure is classifiable with the ABCD (anxious-avoidant, secure, anxious-resistant, disorganized) coding system in an African culture, and supports the normativity hypothesis, because the majority of infants were securely attached (True et al., 2001). To explain the lack of avoidant attachments, True (1994) hypothesized that the Strange Situation procedure in the Dogon society may have been experienced as highly stressful instead of mildly stressful, forcing avoidant infants to seek proximity, and may also have increased the number of disorganized infants. Finally, True also found that infant attachment security was related to caregiving patterns characterized by sensitivity, a lack of frightening/frightened behaviors, and fewer violations of communication coherence and cooperativeness. This seminal study among the Dogon therefore provides evidence for the universality hypothesis, the normativity hypothesis, and the sensitivity hypothesis. Importantly, it also shows that contrary to some claims (e.g., Otto [2014], who calls the procedure “cruel”), it is possible to find creative and culture-sensitive ways of administering the Strange Situation procedure that are not overly stressful for the infants.

There is some evidence that the extensive shared infant care in forager communities might influence infant behavior in separation–reunion situations. In a study among the Aka foragers of the Central African Republic, sensitive responsiveness by nonmaternal caregivers negatively predicted infant’s distress during mother’s absence (Meehan & Hawks, 2013), and positively predicted infant engagement of mother upon her return (Meehan & Hawks, 2015), suggesting that infant behavior toward mothers in separation–reunion situations needs to be interpreted with consideration for the caregiving context.

In South Africa, Tomlinson, Cooper, and Murray (2005) studied attachment in a black sample of 98 mother–infant dyads, and assessed them at 2, 6, and 18 months postpartum. Families were living in Khayelitsha, an impoverished black settlement close to Cape Town. Only 5% lived in brick houses, and 49% of the houses were without modern plumbing, 58% of the families had no regular income, and 51% of the pregnancies were unplanned. The researchers undertook the challenging job of conducting the Strange Situation, observing the quality of the home environment

and maternal sensitive responsiveness. Despite the poor living circumstances, the majority of infants were securely attached to their mothers (62%), although a rather large number of infants did develop a disorganized attachment (26%). Only 4% were avoidantly attached, and the remaining 8% were resistantly attached (Tomlinson et al., 2005). Furthermore, a remarkably high incidence of postpartum depression was found in the mothers (35% when infants were 2 months old), compared to similar samples in Western countries (with about 10% of mothers experiencing postpartum depression). The presence of postpartum depression was strongly associated with attachment insecurity and disorganization, and sensitivity at 2 months, as well as at 18 months, predicted attachment security significantly and independently of depression. The study therefore provides support for the universality hypothesis, the normativity hypothesis, and the sensitivity hypothesis.

In another South African study by Minde, Minde, and Vogel (2006), 46 mother–child dyads (children ages 18–40 months) living in an impoverished black township of Johannesburg were observed using the AQS. The results showed a roughly equal distribution of secure attachment (47%) and insecure attachment (53%), although we should mention that the AQS was not designed to yield attachment classifications. The relatively low rate of secure attachment is likely to be due to the extremely disadvantaged nature of the sample. Not only did all mothers report financial problems but also almost half of them reported a history of abuse, and about one-third had been placed away from home for prolonged periods before they were 5 years old (Minde et al., 2006). Furthermore, the sample’s depression and anxiety levels were just under the 90th percentile of the norm distribution, and similar to findings in Western countries, both the severity of financial problems and the experience of abuse were related to lower rates of attachment security (Minde et al., 2006). The AQS was successfully applied in this South African sample, providing evidence in support of the universality hypothesis. The normativity hypothesis was not properly tested because the AQS was not designed to yield classifications. The sensitivity hypothesis was indirectly confirmed, as higher rates of problems known to adversely affect maternal sensitivity (financial problems and a history of abuse) were related to insecure attachment.

Family life in Africa has changed drastically in the past decades, due to the HIV/AIDS pandemic; many infants of infected mothers are born with

HIV. Peterson, Drotar, Olness, Guay, and Kiziri-Mayengo (2001) investigated a Ugandan sample of 35 HIV-positive mothers with or without AIDS, and 25 HIV-negative mothers, all with infants in their first year of life, 10 of whom were HIV-infected themselves. The researchers used the AQS to rate the attachment security of the infants during a 4-hour home visit. The average AQS score reflecting infants' secure-base behavior in the subsample of 50 infants who were not infected with HIV (.35) was very similar to those found in other countries in different parts of the world (average of 34 samples = .31; Van IJzendoorn, Vereijken, Bakermans-Kranenburg, & Riksen-Walraven, 2004). Peterson and colleagues also found that 32% of the variance of AQS attachment security in the Ugandan sample was predicted by maternal affect, which consisted of ratings of expressivity and affective involvement, stimulation and activity, and responsiveness and sensitivity. Thus, almost half a century after the original Uganda study, the new Ugandan findings support Ainsworth's (1967) observations of attachment bonds within a multiple-caregiver context (universality hypothesis) and her suggestion that sensitive parenting fosters a secure attachment relationship (the sensitivity hypothesis). Furthermore, the normativity hypothesis was supported by showing that security scores were similar to those found elsewhere.

Attachment and Sensitivity in East Asia

Countries in East Asia have been described as favoring the cultural model of *interdependence* (Kagitcibasi, 2007) and have been labeled as having a *collectivistic culture* (Oyserman, Coon, & Kemmelmeier, 2002). Both terms refer to a cultural context in which the importance of the group and social harmony are emphasized more than the needs of the individual, and in which adherence to group norms, filial piety, and self-sacrifice are expected (Hofstede, 1984). The label *autonomous-relatedness* has been coined to describe cultural groups that allow room for a focus on autonomy within an interdependent context, which generally characterizes urbanized or migrated groups that originally came from collectivistic cultural backgrounds but now reside in a more individualistic context (Kagitcibasi, 2007). Indeed, the rapid urbanization, globalization, and increased wealth in

several regions of East Asia may have moved the social and psychological identities of its (urban) inhabitants closer to those of Western countries (e.g., Naftali, 2010). Consistent with this idea, a recent meta-analysis showed that urban Chinese parents display lower levels of authoritative parenting (i.e., warmth and support for autonomy) than parents from North American countries, but not necessarily higher authoritarian parenting in terms of a focus on unquestioning obedience (Wang & Mesman, 2015).

Multiple caregivers are also common in most East Asian cultures, although nonparental care is mostly restricted to care by grandparents, who often coreside with the nuclear family and tend to provide extensive care for their grandchildren when both parents are working (e.g., Nauck & Suckow, 2006), and may in those situations be the primary attachment figures for the children. Grandparental coresidence is also fostered by housing shortages in urban areas and the absence of professional child care facilities for families in which both parents work outside the home (Goh & Kuczynski, 2010). Sibling care is very uncommon given the one-child policy in China and the very low fertility rates in Japan and South Korea. However, we note that demographic and cultural differences within the East Asian region are substantial. For instance, in a country such as Indonesia, fertility rates are higher than elsewhere in the region (although declining fast), and the relatively recent colonial past of this country and its current predominant Muslim identity also sets it apart from countries such as China and Japan. A total of 18 studies using standardized observational instruments focusing on attachment are available from Papua New Guinea, China, Taiwan, Japan, South Korea, and Indonesia. We discuss these in some detail below.

Attachment among the Trobriander

In a unique study among 20 mother-toddler dyads living in the horticulturalist village of Tauwema on the Trobriand Islands (part of Papua New Guinea), written ethnographic records were collected, as well as standardized observations in the Strange Situation procedure (Grossmann, Grossmann, & Keppler, 2005). All observed toddlers showed attachment behavior and used their mothers as safe havens in times of distress in both field observations and the standardized Strange Situation, supporting the universality hypothesis.

In addition, all toddlers showed separation distress when involuntarily separated from their mothers (Grossmann et al., 2005). Secure attachment was normative, with 16 of the 20 infants falling into this category, supporting the normativity hypothesis. Maternal sensitivity was not systematically observed, but the ethnographic records suggest that mothers of insecure infants were less accessible to their toddlers, and slower and harsher in their responses (Grossmann et al., 2005), which indicates tentative support for the sensitivity hypothesis.

Attachment in China and Taiwan

Nine studies of attachment have been conducted in normative urban samples in China, but only three were published in English, and only one obtained attachment classifications by coders officially trained by experts (Archer et al., 2009). In that study, 62 infants and toddlers were examined in the Strange Situation procedure, yielding a distribution of 57% secure, 13% avoidant, 16% resistant, and 13% disorganized (with forced classification: B = 62%, A = 15%, C = 23%). The other two studies found a rate of 68% of securely attached infants (Ding, Xu, Wang, Li, & Wang, 2012; Hu & Meng, 1996), which is very similar to results from studies conducted in other parts of the world (Van IJzendoorn & Kroonenberg, 1988). The pattern within the insecure category was somewhat different, with Hu and Meng (1996) reporting 16% avoidant and 16% resistant (disorganized was not coded), whereas Ding and colleagues (2012) reported 7.5% avoidant and 21.8% resistant (and 2.5% disorganized). The six studies published in Chinese yielded the following distributions: B = 65%, A = 17%, C = 13%, D = 4% (Li et al., 2004); B = 73%, A = 11%, C = 7%, D = 9% (Liang, Chen, & Chen, 2000); B = 53%, A = 13%, C = 27%, D = 7% (Hu & Meng, 2003); B = 72%, A = 10%, C = 10%, D = 8% (Yue, Zhang, Chen, Liang, & Zhang, 2010); B = 68%, A = 6%, C = 26%, D = 0% (Ding et al., 2008); and B = 67%, A = 6%, C = 23%, D = 4% (Gu et al., 1997). As can be readily noticed, all studies conducted in China confirm both the universality hypothesis (by successfully classifying all children into one of the attachment categories) and the normativity hypothesis (by showing that the majority of children are securely attached).

What is also notable is the relatively low prevalence of avoidant attachment in the majority of these studies compared to the rates of avoid-

ance reported in Western studies (Van IJzendoorn & Kroonenberg, 1988; Van IJzendoorn, Sagi, & Lambermon, 1992). Hu and Meng (1996) expressed doubts about the validity of the avoidant category, noting that the avoidant infants did not show stranger anxiety, and expressed indifference toward their mothers at reunion. The Chinese mothers' stress on early independence in their infants, as well as their reliance on nonparental caregivers, may have been responsible for this pattern. In some cases, grandparents may have served as the primary attachment figures. An alternative interpretation, however, might be based on the subtle avoidant behaviors that are difficult for even well-trained coders to observe in infants. However, as we see later, the lower prevalence of the avoidant category is in line with findings of other studies in non-Western cultures and may reflect the cultural context of parenting.

In view of the (until recently) strict birth control policy in China and the traditional preference for a male child, it is important to note that the distributions of attachment classifications for male and female infants were virtually the same in the two studies that reported gender (Ding et al., 2012; Hu & Meng, 1996). It has been suggested that firstborn daughters who "survive" parental choices regarding gender-driven abortion or postnatal abandonment are apparently welcome (Short, Fengying, Siyuan, & Mingliang, 2001) and have indeed been shown to have been treated better than those with a male sibling (Fong, 2002). Regarding the role of grandparents, all but one family in the Hu and Meng study (1996) co-resided with one or more grandparents. The rate of grandparental coresidence was not reported in the Ding and colleagues study (2012), but they did report that infants with an insecure attachment to their mothers were also more likely to sleep with nonmaternal caregivers at night. In both studies, the possibility that a grandparent was the primary caregiver of the infants in those samples was suggested as a potential explanation for the results, namely, the high rate of avoidance and what appeared to be infant indifference toward the mothers (Hu & Meng, 1996), and the lower rate of security in infants with more caregivers during the day and at night (Ding et al., 2012). The issue of sleeping arrangements is also discussed in the section on the Israeli kibbutz below.

Of the nine studies conducted in China, none examined the sensitivity hypothesis using observational studies. However, three studies ex-

amined the competence hypothesis and reported evidence to support this assumption. In one study, securely attached 2-year-old children exhibited fewer internalizing and externalizing problems than nonsecurely attached children both concurrently and at ages 4 and 7 years (Yue et al., 2010). In the second study, securely attached infants possessed more advanced cognitive skills than insecurely attached infants, but there were no differences in physical development (Ding, Wang, Li, Chi, & Xu, 2008), and the final study to examine outcomes of attachment found that secure toddlers had fewer behavior problems and displayed better self-regulation (Gu et al., 1997).

Posada and colleagues (2013) conducted a cross-cultural study involving nine countries, including a sample of 68 mothers and their 4-year-old children in Taiwan, which we discuss under the same heading as the studies from mainland China because of geographical and cultural proximity. Importantly, Taiwan does not have a one-child policy, but its fertility rate is also very low. In the Posada and colleagues study, 3-hour home observations were conducted, and the AQS was used to rate the child's secure-base behavior. The results showed that the average security scores for the Taiwanese sample (.32) were similar to scores found in other studies (.31; see Van IJzendoorn et al., 2004).

The Japanese Case: Amae, Dependence, and Attachment

One of the most severe critiques of attachment theory has come in the form of an accusation of "cultural blindness" among attachment researchers to alternative conceptions of relatedness (Rothbaum, Weisz, Pott, Miyake, & Morelli, 2000). This "cultural blindness" accusation of a Western bias in attachment theory was based specifically on the Japanese case (rebutted in Van IJzendoorn & Sagi, 2001). The Japanese case can indeed be considered a real challenge to attachment theory's universality, normativity, and sensitivity hypotheses, and we address these challenges below.

It has been argued that the concept of attachment may not be relevant to the Japanese culture, in which the idea of *amae* (Doi, 1973, 1992) seems to play a more prominent and effective role in describing family relationships and their societal implications (Emde, 1992). (*Amae* refers to relational dependence, including aspects such as the desire for interpersonal closeness, the presence of

indulgence, and relying on the other person [Behrens, 2004].) Furthermore, it has been argued that "*Amae* has an advantage over attachment because it implies a psychological dependence" (Doi, 1989, p. 350). Vereijken (1996) asked eight native Japanese behavioral scientists to describe the concepts of *amae*, attachment, and dependence with the help of the AQS. The descriptions of *amae* and dependence were very similar, whereas the descriptions of attachment security and *amae* were not associated (Vereijken, 1996). Furthermore, when the descriptions of the ideal child according to Japanese mothers were compared with the Japanese experts' definitions, only attachment security (and not *amae*) appeared to be desirable (cf. Posada et al., 1995). Furthermore, an observational study of Japanese sojourners in the United States by Mizuta, Zahn-Waxler, Cole, and Hiruma (1996; see also Nakagawa, Teti, & Lamb, 1992) confirmed Vereijken's (1996) conclusion that *amae* and attachment are orthogonal dimensions that can be reliably distinguished. Furthermore, Behrens (2004), a psychologist of Japanese origin, analyzed the use of the term and related terminology in natural Japanese discourse. She concluded that for many native Japanese speakers, *amae* has a negative connotation involving social enforcement of obligations, and that *amae* lacks the biological roots of the attachment concept, is not associated with the regulation of stress, but can occur any time there is a desire or a motive on the part of the *amae* provider (Behrens, 2004; Behrens, Main, & Hesse, 2007). Because of the fundamental conceptual, linguistic, and biological differences between the two constructs, attachment research in Japan cannot be considered a challenge to the concept of *amae*, and *amae* cannot be considered a refutation of the concept of attachment.

Studies Using the Strange Situation Procedure in Japan

We now turn to observational studies of attachment in Japan. Three studies using the Strange Situation procedure to assess attachment security in Japan have been reported in the international literature. The first was conducted by Durrett, Otaki, and Richards (1984), who studied a middle-class sample of 39 intact families with their 12-month-old firstborns in Tokyo. This study showed a pattern of avoidant, secure, and resistant infant-mother attachments, consistent with the global distribution, with 13% A, 61% B, 18%

C, and 8% unclassifiable cases. The Tokyo study confirms the universality and normativity hypotheses because the authors did not report difficulties in applying the attachment coding system to this population, and because the normative “modal” category was secure. The unclassifiable cases could be a sign of culture-specific problems in applying the tripartite model but could also be due to the fact that the disorganized (D) classification was not yet available (notably, the D category was particularly instrumental in solving unclassifiable cases; Main & Solomon, 1990; see also Lyons-Ruth & Jacobvitz, Chapter 29, and Solomon & George, Chapter 18, in this volume). Furthermore, the mothers of securely attached infants indicated that they felt more supported by their husbands than did the mothers of avoidantly attached infants, but they did not differ in this regard from the mothers of resistantly attached infants (Durrett et al., 1984). This finding provides indirect support for the sensitivity hypothesis because partner support has been found to foster maternal sensitivity (e.g., Van Bakel & Riksen-Walraven, 2002).

The second Japanese study, conducted in Sapporo (Miyake, Chen, & Campos, 1985; Nakagawa, Lamb, & Miyake, 1992; Takahashi, 1986), was unfortunately weakened by some methodological flaws and unclear reporting (see Van IJzendoorn & Sagi-Schwartz, 2008, for a full discussion of this study) and is therefore not discussed further in this section. The third Japanese study was also conducted in Sapporo with 43 mother–child dyads (Behrens, Hesse, & Main, 2007). Attachment distributions were based on Main and Cassidy’s sixth-year reunion assessment procedure (see Solomon & George, Chapter 18, this volume). In contrast to the previous Sapporo study, children’s three-way or forced “organized” attachment classification distribution did not differ from the global distribution: 68% secure, 22% avoidant, 10% resistant (three children remained unclassified). The ABCD distribution was 49% B, 2% A, 0% C, and 49% D. The high proportion of D could be due to the fact that the non-Japanese coders had to judge maternal talk from translated transcripts and may have missed important cues from the tone of voice (Behrens et al., 2007). Furthermore, maternal attachment representations as measured with the Adult Attachment Interview (AAI; see Hesse, Chapter 26, this volume) predicted child reunion classification (Behrens et al., 2007), with proportions very similar to matches reported worldwide. This is indirect support for the sensitivity hypothesis because adult attach-

ment representations have been found to predict maternal sensitivity (also in Asian samples, see, e.g., Liang et al., 2015), which in turn is known to predict infant attachment security (De Wolff & Van IJzendoorn, 1997). Thus, maternal sensitivity is likely to have (partially) mediated the relation between maternal attachment representations and infant attachment security. Notably, mothers’ unresolved attachment status strongly predicted child D status ($r = .65$).

Studies Using the Attachment Q-Sort in Japan

Three studies using the AQS have been conducted in Japan. Vereijken (1996) studied a Tokyo sample of 48 families with 14-month-old infants. More sensitive mothers had more secure children, and the association between sensitivity and attachment was impressively strong (all correlations—based on reports from independent coders—were .59 or higher). In a follow-up study 10 months later, the association between sensitivity and attachment was replicated (Vereijken, 1996). In another study, 50 Japanese mothers and their preschool children were observed (Kazui, Endo, Tanaka, Sakagami, & Suganuma, 2000). The results showed that the children of secure mothers (as assessed with the AAI) had the highest security scores on the AQS, whereas children of unresolved mothers had the lowest AQS scores. The children of the dismissing and preoccupied mothers scored in between. The majority of the mothers were classified as secure (66%). Knowing that secure mothers generally have more sensitive interactions with their children than do insecure mothers, this outcome represents another indirect confirmation of attachment theory’s sensitivity hypothesis. The last Japanese study was conducted in the context of a larger cross-cultural context (Posada et al., 2013). In a sample of 45 infants, the average security score was the lowest (.19) of those reported for nine countries in total, but the majority of scores were positive, indicating a predominance of secure-base behavior. The low average score appeared to be predominantly due to lower scores on the Smooth Interactions with Mother and the Interactions with Other Adults scales (and not the scales reflecting physical proximity and contact with the mother). These findings may reflect the potential discomfort that Japanese mothers convey when observed in the home (Nakagawa, Lamb, et al., 1992).

Attachment and Sensitivity in South Korea

In the first and only study to use the Strange Situation procedure in South Korea, Jin, Jacobvitz, Hazen, and Jung (2012) observed 87 mother–infant dyads. The results showed that 70% of the infants were classified as securely attached, 1% as avoidant, 17% as resistant, and 9% as disorganized. Jin and colleagues noted that in the reunion episodes of the Strange Situation, the mothers were more likely to approach their infants immediately and sit beside them than was the case in Ainsworth's Baltimore sample, even when the infants were no longer distressed. The authors also discussed the low prevalence of avoidant attachment in their sample by pointing to the generally lower percentage of infants in the avoidant category in other studies of East Asian samples, such as those from Indonesia (Zevalkink, Riksen-Walraven, & Van Lieshout, 1999) and China (e.g., Archer et al., 2015; Ding et al., 2012). Jin and colleagues (2012) speculated that a caregiving context in which mother–infant relationships are generally characterized by physical closeness, indulgence, and the discouragement of mother–infant separation is very unlikely to produce avoidant children. As they put it, “Instead, when insecure attachment occurs, it is more likely to be resistant, since mothers are more likely to err on the side of being overly enmeshed, overprotective, or overinvolved, rather than rejecting” (p. 41). As we see later in this chapter, this may be relevant even for other non-Western cultures outside of East Asia. Finally, observations of maternal sensitivity during free play in this study revealed that infants of more sensitive mothers were more likely to be securely attached than infants of less sensitive mothers. Thus, this unique study in South Korea confirmed the universality hypothesis, the normativity hypothesis, and the sensitivity hypothesis.

Muslim Families in Indonesia

Indonesia is the fourth most populous country in the world and has the largest Islamic population of any country in the world. Zevalkink (1997) conducted the first attachment study on Islamic families of Sundanese Indonesian origin in West Java. Sundanese Indonesian children generally experience relatively extensive periods of close physical proximity to their mothers because they are carried in a carrying cloth, or *slendang*, during the first year. They are breast-fed on demand until 2 or 3 years of age and sleep in the same beds as

their mothers during the first 4 years of life. When an infant is fussy or cries, the mother promptly responds with soothing or feeding. Sundanese Indonesian women, however, marry at a very young age, and their divorce rate is high. A stable income and permanent job are rare, which adds to the instability of family life. Poverty and health problems lead to rather high infant mortality (Zevalkink et al., 1999). Zevalkink and colleagues (1999) reported Strange Situation assessments of 46 children, ages 12–30 months. They also conducted extensive home observations on maternal sensitivity and observed maternal support in structured play sessions. The distribution of attachment classifications was as follows: 52% secure, 7% avoidant, 20% resistant, and 22% disorganized (Zevalkink et al., 1999). More maternal support in structured play sessions was associated with attachment security; disorganized children received low maternal support. In addition, a higher-quality home caregiving environment was related to higher rates of secure attachment (Zevalkink, Riksen-Walraven, & Bradley, 2008). Thus, in these Muslim families, the universality hypothesis was confirmed because all children could be classified based on the Strange Situation procedure. Furthermore, a majority of children were securely attached (supporting the normativity hypothesis), and secure attachment was associated with the quality of caregiving in the predicted way (supporting the sensitivity hypothesis).

Attachment and Sensitivity in Latin America

In this section, we examine the four hypotheses of attachment theory within the Latin American cultural context, mostly reflecting urban parenting, but also in one case of rural parenting. We found seven studies using standardized methods to assess attachment conducted in Latin American countries, including studies from Chile, Colombia, Peru, and Mexico. Each is discussed below.

Chile: A Study on Malnourished Infants

The first study using the strange situation procedure in a Latin American context was conducted in Chile by Valenzuela (1997) among 84 mother–infant dyads living in poverty, with half of the infants classified as chronically underweight. For the

total sample, only 27% of infants were categorized as securely attached, 26% as avoidant, 25% as resistant, and 21% as A/C (probably classifiable now as D). However, when distinguishing two groups based on infant nutritional status, the results revealed that the attachment distribution was much closer to the global distribution in the adequately nourished infants: 50% secure, 23% avoidant, 22% resistant, and 2% A/C (Valenzuela, 1997). Indeed, consistent with findings in the Gusii study (Kermoeian & Leiderman, 1986), attachment security was significantly related to infant nutritional status. Finally, in the Chilean study, observations of maternal sensitivity were also significantly related to attachment security in the expected direction (Valenzuela, 1997). This set of findings is consistent with studies showing that responsive feeding (which basically refers to sensitivity during feeding) is related to children's more optimal weight status (Black & Aboud, 2011). In fact, both the World Health Organization and United Nations International Children's Emergency Fund (Who/UNICEF; 2003) have incorporated responsive feeding into their guidelines for promoting healthy child development. In summary, the study provides evidence for all four key hypotheses formulated to represent the key tenets of attachment theory.

Studies from Colombia and Peru

The AQS was used to assess child secure-base behavior in four studies from urban Colombia (the first three with partially overlapping samples), each of which revealed high average security scores (comparing to the average of .31 across 34 samples in Van IJzendoorn et al., 2004). First, an average security score of .43 was found by Posada and colleagues (2002) in a sample of 61 infants, and observed maternal sensitivity was positively related to attachment security in this study. Second, an average AQS score of .46 was found in a sample of 30 infants (Posada, Carbonell, Alzate, & Plata, 2004). Third, Vaughn and colleagues (2007) reported an average score of .48 for a sample of 25 Colombian infants; they found that maternal secure-base narratives were related to attachment security in the expected direction. Finally, Posada and colleagues (2013) report an average score of .32 in a group of 83 toddlers. In one of these four studies, ethnographic descriptions of maternal care were analyzed to examine the appropriateness of attachment theory's con-

ceptualization of early care (Posada et al., 2004). The authors concluded that "most of the domains of maternal behavior found in this study matched well those identified by Ainsworth; our characterization of maternal early care displays a direct relation to that of attachment theory (e.g., Ainsworth et al., 1978)" (p. 516). Within the cross-cultural study by Posada and colleagues (2013), an urban sample of 30 mothers and preschoolers from Peru was also included, showing an average AQS security scores of .30, similar to that found for the Colombian sample reported in the same article. Given the positive and moderate-to-high security scores found in the five studies described here, support is provided for the universality and normativity hypotheses. Furthermore, the results of two studies directly support the sensitivity hypothesis, and another provides indirect support by showing that maternal secure-base narratives (conceptually relevant to sensitive parenting) relate positively to infant secure attachment.

Attachment and Sensitivity in Urban and Rural Mexico

In a study by Gojman and colleagues (2012), intergenerational relations of attachment and caregiving quality were investigated in a sample of 35 urban, upper-middle-class Mestizo families, and a sample of 31 rural poor Indian families in Mexico. For the urban middle-class families, the Strange Situation procedure revealed a rate of 77% secure attachment, 3% avoidant, 3% resistant, and 14% disorganized (Gojman et al., 2012). In the poor rural sample, rates of security (32%) were clearly lower, and disorganization (35%) was more prevalent than in the upper-middle-class urban sample. The finding that attachment security is less common in poor rural samples than in more affluent urban samples is consistent with the family stress model, which describes how financial strains lead to parental stress, which in turn compromises family functioning in general and parenting quality in particular, leading to unfavorable child outcomes (Conger & Donnellan, 2007). This indirect evidence for the sensitivity hypothesis was corroborated by results showing a partial mediation model, with maternal autonomous attachment representations, as measured with the AAI, predicting observed maternal sensitivity, which in turn predicted infant attachment security (Gojman et al., 2012). As noted by the authors, these results clearly support the cross-cultural robustness of core features of attachment theory.

Attachment in Israel

For the purpose of this chapter, we include Israel within the Anglo-Saxon and European cultures, and therefore do not review urban-normative samples that have been studied with similar outcomes as those found in many Western countries (e.g., Sagi, Koren-Karie, Gini, Ziv, & Joels, 2002). We focus on two unique samples in Israel: infants raised in kibbutzim and the Arab minority.

Attachment and Collective Sleeping Practices

Following a visit to Israeli kibbutzim in the early 1950s, Bowlby (1951) noted the rich opportunities for research provided by kibbutz upbringing and predicted that this childrearing context, though clearly different from institutional care, might produce higher rates of attachment insecurity. The communal bedrooms in the children's house were shared by three or four children, who each had private corners in which they kept their personal things, and which were decorated according to each child's preference. When collective sleeping was still in effect (starting a few months after birth), family time was in the afternoon and evening, and children were returned to the children's house for the night by their parents, who put them to bed. A caregiver or a parent then remained with them until the night watchwomen took over (Aviezer, Van IJzendoorn, Sagi, & Schuengel, 1994). Whereas most institutionalized childrearing in Western cultures involves multiproblem populations, the collective sleeping arrangements in the kibbutzim were designed for middle-class, well-functioning families. Although the system of multiple caregiving in the kibbutz was in many ways similar to multiple-caregiver contexts elsewhere (Rabin & Beit-Hallahmi, 1982), a worldwide sample of 183 societies showed that in none of them did infants sleep away from their parents (Barry & Paxton, 1971).

In support of the universality hypothesis, several studies of the attachments of communal-sleeping kibbutz children to their parents and caregivers revealed that they do form attachment bonds with their caregivers, and most often with their mothers (Aviezer & Sagi-Schwartz, 2008). The first communal kibbutz study conducted with the ABC system found 57% of securely attached infants (Sagi, Lamb, Lewkowicz, Shoham, Dvir, & Estes, 1985). Using the ABCD system in a more

recent sample, a rate of 26% secure infant-mother attachment was found (Sagi, Van IJzendoorn, Aviezer, Donnell, & Mayseless, 1994). In the ABC classification system D/B cases could have been classified as secure, hence inflating the rate of security. The rate of security in the communal sleep kibbutz was lower than that found in Israeli nonkibbutz samples (e.g., 66% in Koren-Karie, Oppenheim, Dolev, Sher, & Etzion-Carasso, 2002; 70% in Sagi, et al., 2002), and lower than that in a kibbutz sample with family-based sleeping (60% in Sagi et al., 1994). To rule out alternative explanations for the effect of communal sleeping arrangements, assessments were also made of the ecology of the children's house during the day, maternal separation anxiety, infants' temperaments, and mother-infant play interactions. The two groups (i.e., family-based and communal sleepers) were found to be comparable on all of these variables. Thus, it was concluded that collective sleeping, experienced by infants as a time when mothers were largely unavailable and inaccessible, was responsible for the greater insecurity found in this group.

Interestingly, resistant attachment was found to be overrepresented in the communal-sleeping kibbutz samples (Sagi et al., 1985, 2002). Inconsistent responsiveness was inherent in the reality of these infants, given that sensitive responding by a mother or caregiver during the day contrasted sharply with the presence of an unfamiliar person at night. This supports the sensitivity hypothesis because inconsistent responsiveness has been described as an important antecedent of resistant attachment (Ainsworth et al., 1978; Cassidy & Berlin, 1994). The rate of disorganized infants was also rather high for the second communal-sleeping kibbutz sample (44%), which could be attributed to the unpredictable circumstances that these children experienced, especially during the nights. It should also be noted that in several Israeli studies (Jewish sample: Koren-Karie et al., 2002; Sagi et al., 1985, 1994, 1997, 2002; Sagi-Schwartz, Van IJzendoorn, & Bakermans-Kranenburg, 2008; Arab sample: Zreik, 2014; see details below), the resistant classification appeared to be overrepresented and the avoidant classification to be underrepresented compared to the global distribution (Van IJzendoorn & Kroonenberg, 1988). We speculate that the resistant attachment strategy may be elicited in the context of continual threats to national and personal security more readily than the avoidant strategy—the threat is external to the family. Parental preoccupation with these daily

stresses may lead to exaggerated overprotectiveness and impaired sensitivity to children's attachment signals (see Belsky, 2008, for an evolutionary perspective).

Networks of Attachment Relationships

The kibbutz context has also made a unique contribution to the evaluation of the competence hypothesis. In a follow-up of most of the subjects in the Sagi and colleagues' (1985) sample when they were 5 years old, Oppenheim, Sagi, and Lamb (1990) found that secure attachment to a nonparental caregiver (the *metapelet*) during infancy was the strongest predictor of a child's being empathic, dominant, independent, achievement-oriented, and behaviorally purposive in kindergarten. No significant associations were found between these socioemotional developments and the quality of children's attachment to their parents, suggesting that the influence of attachment relationships may be domain-specific (see also the Gusii study described earlier). Because the infants' relations with caregivers had been formed in the context of the infant house, those relationships were the best predictor of children's socioemotional behavior in similar contexts. Furthermore, the extended network of infants' attachments to the three types of caregivers (i.e., mothers, fathers, and *metapelet*) was a better predictor of later functioning than attachments in the family network only (attachments to mothers and fathers) and the attachment to mothers only (Sagi & Van IJzendoorn, 1996; Van IJzendoorn et al., 1992), which is consistent with findings in other samples (Howes, Rodning, Galluzzo, & Myers, 1988; Tavecchio & Van IJzendoorn, 1987). This outcome may be interpreted as support for the integration model, which assumes that in a network of multiple-attachment relationships, secure attachments may compensate for insecure attachments in a linear way (Van IJzendoorn et al., 1992). Beyond kindergarten, however, networks of infant attachment relations did not contribute as much to the explanation of later behavior (Sagi-Schwartz & Aviezer, 2005). Instead, the data were more supportive of the hierarchy model (Van IJzendoorn et al., 1992), suggesting that early relations with mother as the primary caregiver contributed most to later adaptive functioning at all ages (except in kindergarten), even in the kibbutz environment (Aviezer, Resnick, Sagi, & Gini, 2002).

Ecological Constraints on Intergenerational Transmission of Attachment

Intergenerational transmission of attachment refers to the process through which parents' mental representations of their past attachment experiences influence their parenting behavior and the quality of their children's attachment to them (Bowlby, 1969/1982; see Hesse, Chapter 26, this volume). In several studies of Western cultures, a concordance rate of about 75% has been found between the security of the parents' mental representation of attachment and the security of the child-parent attachment (for a review, see Van IJzendoorn, 1995). In an Israeli study, Sagi and colleagues (1997) administered the AAI to 20 mothers from kibbutzim maintaining collective sleeping arrangements and to 25 mothers from home-sleeping kibbutzim. Parent-child concordance in attachment classifications was low for the communally sleeping group (40%), whereas it was rather high for the home-sleeping group (76%). Thus, contextual factors such as communal sleeping may override the influence of parents' attachment representation and their sensitive responsiveness. This finding indicates the limits of a context-free, universal model of transmission.

Attachment in the Arab Minority Residing in Israel

In a unique study on attachment in Arab families, infant-mother attachment relationships among Arabs living in Israel were assessed (Zreik, 2014; Zreik, Oppenheim, & Sagi-Schwartz, 2015). The sample included 85 Arab mother-infant dyads, and attachment was assessed using the Strange Situation Procedure. Maternal sensitivity was assessed using the Emotional Availability Scales (Biringen, Robinson, & Emde, 2000) and the Maternal Behavior Q-Sort (Pederson & Moran, 1995). Secure attachment was found to be the modal classification, with a rate of 67%, which supports the universality and normativity hypotheses. Moreover, similar to the studies involving Jewish infants in Israel, the ambivalent classification (13%) also appeared to be overrepresented in this Arab sample, with an underrepresentation of the avoidant classification (4%). Perhaps the fact that both groups live in a similar stressful geopolitical ecology contributed to this finding. Sixteen percent of the sample was classified as disorganized. The expected association between sensitivity and attachment

security is not clear-cut when religion, maternal education, and measurement of sensitivity are taken into consideration, thus only partially supporting the sensitivity hypothesis (see Zreik, 2014, for details).

Universal and Contextual Dimensions of Attachment

Figures 37.1 and 37.2 provide overviews of the results presented in each of the earlier sections. In this section, we review the findings of cross-cultural attachment research in relation to the four core hypotheses of attachment theory, discussing both their universal and their contextual aspects.

The Universality Hypothesis

The universality hypothesis appears to be supported most strongly. In every study on attachment(-related) caregiving patterns in non-Anglo-Saxon and European countries, children were observed to show attachment behavior in stressful circumstances and to have a preferential bond with one or more caregivers, based on both ethnographic descriptions and standardized assessments. The cross-cultural studies included here support Bowlby's (1969/1982) idea that attachment is indeed a universal phenomenon, and an evolutionary explanation seems to be warranted. Although in many cultures children grow up with a network of attachment figures, the parent or caregiver who takes responsibility for the care of a child during part of the day or the night becomes the favorite target of infant attachment behaviors. Not only the attachment phenomenon itself, but also the different types of attachment, appear to be present in various Western and non-Western cultures. Avoidant, secure, and resistant attachments have been observed in the African, East Asian, and Latin American studies, in samples ranging from hunter-gatherer societies characterized by high levels of alloparenting to affluent and deprived urban contexts. Even in the extremely diverging childrearing context of the Israeli kibbutzim with communal sleep at night, the differentiation between secure and insecure attachment could be made.

These results do not, however, preclude culture-specific patterns. Several studies have noted the attachment to multiple caregivers, and the identity of those caregivers depends on the specific

caregiving arrangements that are common in a given cultural context. For instance, infant secure attachment was found in relation to not only the infant's mother but also nonmaternal caregivers (Goossens & Van IJzendoorn, 1990; Kermoian & Leiderman, 1986; Sagi et al., 1995). In addition, infants' ways of expressing attachment and exploration behaviors have been found to vary depending on cultural norms and customs. Hausa infants are generally physically restricted in their locomotion by their caregivers and are thus less free to explore the environment by themselves (Marvin et al., 1977). Instead, these infants explored their immediate environment in visual and manipulative ways, but only in close proximity to an attachment figure, and they ceased to explore as soon as the caregiver left. Nevertheless, the Hausa infants clearly used adult caregivers as secure bases from which to explore, and they differentiated between attachment figures and strangers (Marvin et al., 1977). Among the Gusii, culture-specific modes of attachment behavior were described, in that infants are accustomed to greeting their caregivers with a handshake, which was differentially observed depending on attachment classifications (Kermoian & Leiderman, 1986), showing how local cultural customs can be taken into account in attachment research using standardized assessments.

The Normativity Hypothesis

The cross-cultural evidence for the normativity hypothesis is rather strong as well. In almost all cross-cultural studies included here, the majority of infants were classified as securely attached. Figure 37.2 summarizes the attachment classification distributions found in the studies discussed earlier. When these are combined with AQS findings about the cross-cultural preference among experts, as well as mothers, for securely attached children, we may be confident that secure attachment is not just a North American invention or a Western ideal, but instead is a rather widespread and preferred phenomenon. As we described early on in this chapter, the category of secure attachments emerged from Ainsworth's Uganda study, not from her Baltimore study (as is often suggested). In further support of the normativity hypothesis, Posada and colleagues (1995, 2013) showed that maternal beliefs about ideal child behavior overlapped considerably with attachment theory's notion of the secure-base phenomenon, and that the secure-base phenomenon is clearly present in maternal

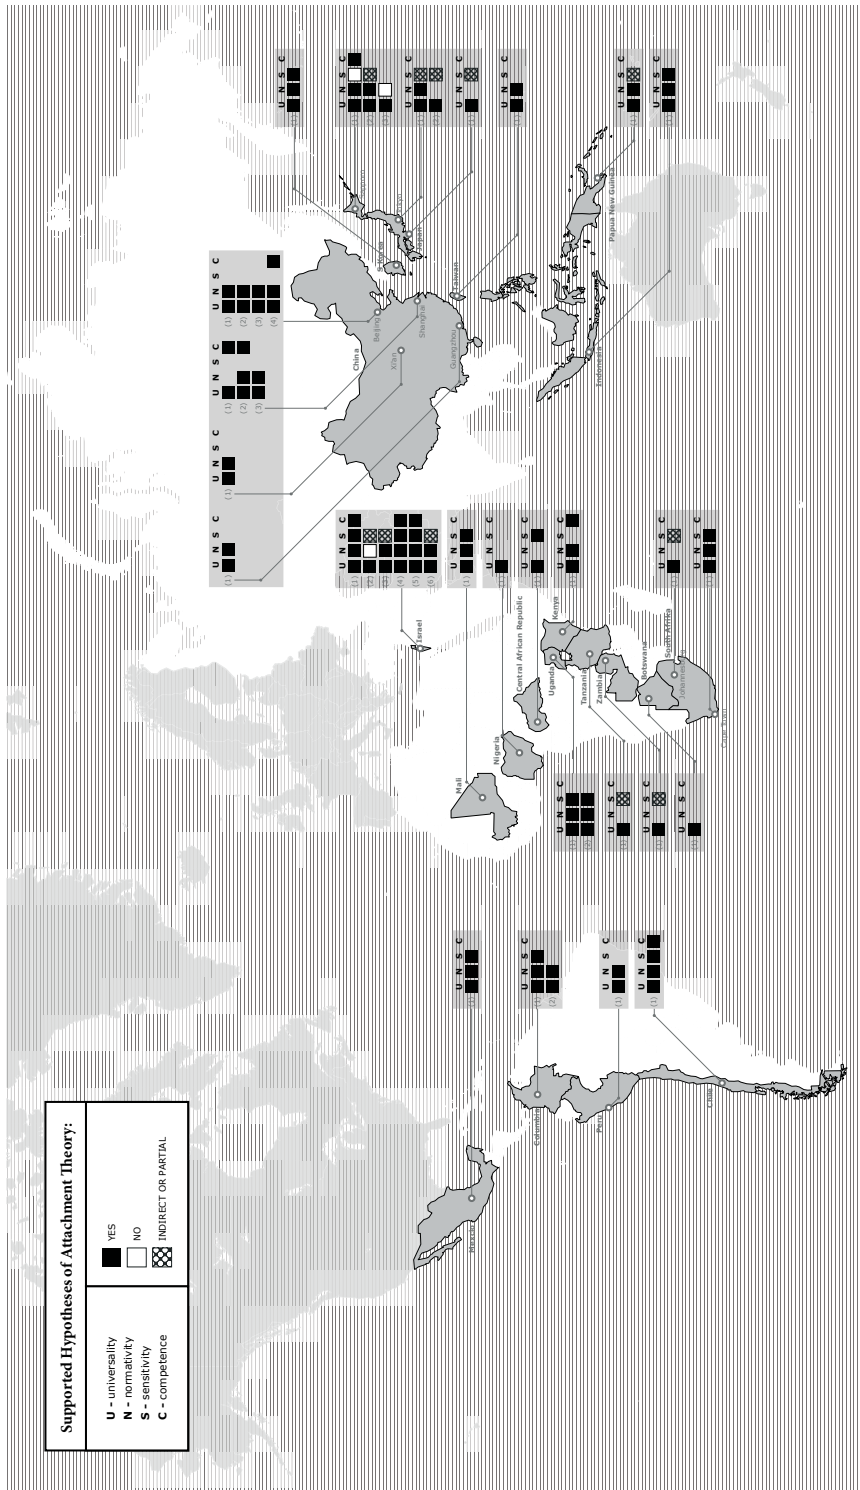

FIGURE 37.1. Results of studies testing attachment theory hypotheses.

Africa: Botswana-1 (Kung San; Konner, 1977); Central African Republic-1 (Bofi; Fouts & Lamb, 2005); Kenya-1 (Gusii; Kermoin & Leiderman, 1986); Mali-1 (Dogon; True et al., 2001); Nigeria-1 (Hausa; Marvin et al., 1977); South Africa, Cape Town-1 (Tomlinson et al., 2005); South Africa, Johannesburg-1 (Minde et al., 2006); Tanzania-1 (Hadza; Marlowe, 2005); Uganda-1 (Canda; Ainsworth & Wittig, 1969); Uganda-2 (Peterson et al., 2001); Zambia-1 (Efé; Morelli & Tronick, 1991).

East Asia: China, Beijing-1 (Hu & Meng, 1996); China-Beijing-2 (Liang et al., 2000); China-Beijing-3 (Hu & Meng, 2003); China, Beijing-4 (Yue et al., 2010); China, Guangzhou-1 (Li et al., 2004); China, Shanghai-1 (Gu et al., 1997); China, Shanghai-2 (Ding et al., 2008); China, Shanghai-3 (Ding et al., 2012); China, Xi'an (Archer et al., 2009); Indonesia-1 (Zevalkink et al., 1999); Japan, Tokyo-1 (Durrett et al., 1984); Japan, Tokyo-2 (Kazui et al., 2000); Papua New Guinea-1 (Trobriand Islands; Grossmann et al., 2005); Japan, Sapporo-1 (Takahashi, 1986; Nakagawa et al., 1992); Japan, Sapporo-2 (Behrens et al., 2007); Japan, Sapporo-3 (Posada et al., 2013); South Korea-1 (Jin et al., 2012); Taiwan-1 (Posada et al., 2013).

Latin America: Chile-1 (Valenzuela, 1997); Colombia-1 (Posada et al., 2002, 2004; Vaughn et al., 2007); Colombia-2 (Posada et al., 2013); Mexico-1 (Gojman et al., 2012); Peru-1 (Posada et al., 2013).

Israel: Israel-1 (first kibbutz cohort communal sleeping; Sagi et al., 1985); Israel-2 (second kibbutz cohort communal sleeping; Sagi et al., 1994); Israel-3 (second kibbutz cohort family sleeping; Sagi et al., 1994); Israel-4 (first urban cohort; Sagi et al., 2002); Israel-5 (second urban cohort; Koren-Karie et al., 2002); Israel-6 (Arabs; Zreik, 2014).

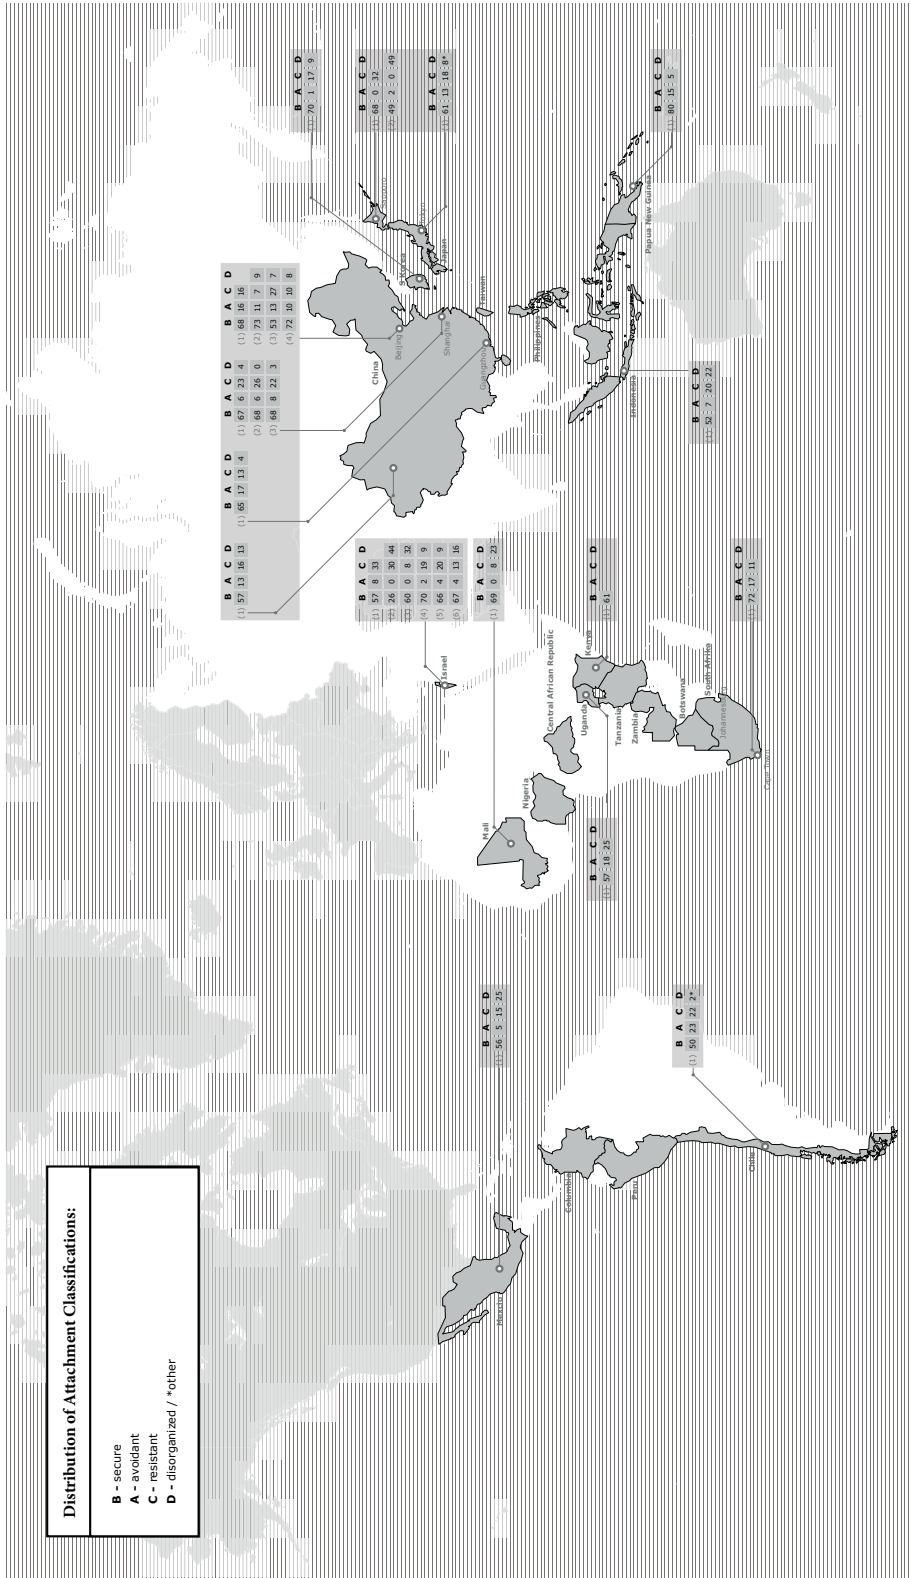

FIGURE 37.2. Results of studies examining the distribution of attachment classifications. See paragraphs that follow the caption in Figure 37.1.

descriptions of the behaviors of their own children across different cultural contexts (Posada et al., 1995).

Even though secure attachment appears to be the norm across cultures, there are variations in the rates of secure attachment reported in the studies in non-Anglo-Saxon and European contexts. For instance, rates of security were particularly low in the rural poor Mexican sample (32%; Gojman et al., 2012) and in the undernourished Chilean sample (7%; Valenzuela, 1997). These findings emphasize the importance of socioeconomic circumstances in shaping family life and parenting patterns. This is consistent with the family stress model, which describes how adverse economic circumstances interfere with optimal parenting through their influence on parental stress, ultimately leading to negative effects on child development (Conger & Donnellan, 2007; see also McLoyd, 1998). Not having the economic resources to reliably provide basic care for children in terms of nutrition, health care, safe housing, and clothing is likely to be universally stressful for parents. We suggest investing in studies on the relation between economic stress and attachment-related processes across cultures to evaluate the family stress model. In many studies comparing parent-child relations in different cultural groups, cultural and socioeconomic variables are confounded (e.g., Bakermans-Kranenburg, Van IJzendoorn, & Kroonenberg, 2004). Therefore, as also shown by the Mexican and Chilean studies, it is pivotal for future cross-cultural studies of attachment to examine different socioeconomic groups within cultures.

The normativity hypothesis does not address the distribution of classifications within the insecure category. However, interesting patterns of the prevalence rates of avoidant versus resistant attachment emerge from the studies discussed in this chapter (see Figure 37.2). Whereas results from Anglo-Saxon and European samples generally show a higher rate of A than C classifications, with A mostly (well) above 20% (Van IJzendoorn et al., 1992; Van IJzendoorn & Kroonenberg, 1988), the range of avoidant attachment classifications in the studies discussed in this chapter lies between 0 and 23%, with only two studies reporting a rate higher than 20% (Behrens et al., 2007; Valenzuela, 1997), and half of the studies reporting a rate lower than 10% in a variety of non-Western countries. Because avoidant attachment is generally associated with consistently unresponsive parenting, we hypothesize that in countries empha-

sizing relatedness, customs of highly proximal and indulgent parenting may be responsible for the low rates of avoidance. As Jin and colleagues (2012) noted, insensitive care in these cultures may be more likely to be intrusive rather than unavailable (and therefore potentially inconsistently sensitive as well), which is generally found to foster resistant attachment rather than avoidance.

The Sensitivity Hypothesis

The sensitivity hypothesis was not tested in most of the studies, but when examined, the data almost invariably supported it (except for the procedurally flawed first Sapporo study). Indirect support for the sensitivity hypothesis comes from studies reporting that secure attachment was related to factors known to be associated with maternal sensitivity. Furthermore, several ethnographic studies provide accounts of sensitive parenting as apparently normative in hunter-gatherer societies. It is also interesting to note that in a sample of no less than 1,150 Asian families living in the United States, 87% of whom were born in Asia, observations of maternal sensitivity were significantly related to observations of infant attachment security (Huang, Lewin, Mitchell, & Zhang, 2012). Further support for the cross-cultural relevance of the sensitivity construct was provided by Mesman and colleagues (2015), who reported strong convergence between maternal beliefs about the ideal mother and attachment theory's description of the sensitive mother across 26 cultural groups from 15 countries (see also Emmen et al., 2012).

The potentially universal role of sensitive caregiving in fostering attachment security is consistent with the idea that when the socioeconomic context allows for sensitive care, the formation of a secure attachment to a sensitive caregiver is most likely to result in adaptive functioning and inclusive fitness. Notably, the function and outcome of the parental behaviors are more important than their specific manifestation, which is consistent with the form-function distinction drawn by Bornstein, Cote, Haynes, Suwalsky, and Bakeman (2012), which states that different parental behaviors can have the same function in different cultural contexts. As such, the sensitivity construct reflects an organizational approach to the attachment relationship in that neither parent nor child behaviors can be captured by a predefined and exhaustive set of concrete behaviors (Sroufe & Waters, 1977), but reflect a history of patterns of interaction rather than individual

behaviors (Weinfield, Sroufe, Egeland, & Carlson, 2008). Indeed, there is evidence that whereas the rates of contingent responding are very similar across very different cultures, the modalities through which responsiveness is channeled are culture-dependent (e.g., Kärtner, Keller, & Yovsi, 2010). In some cultures, appropriate responding to infant vocalization may consist of touching or stroking the infant, whereas in other cultures it may be to imitate the sound that the infant made or to smile at the infant (Kärtner, Keller, & Yovsi, 2010; Keller, Borke, Yovsi, Lohaus, & Jensen, 2005; Keller et al., 2009). Similarly, infant distress may be dealt with appropriately in many different ways. For instance, soothing through nursing/feeding is much more common in non-Western than in Western cultures (e.g., Ainsworth, 1967; True et al., 2001). Many more concrete aspects of responsiveness may be examined to fine-tune our understanding of what it means to be sensitive in different cultures both in infancy and beyond, to paint a comprehensive picture of the similarities and differences in the concrete behavioral characteristics of sensitive responsiveness across cultures and their particular role in fostering secure attachment.

The Competence Hypothesis

The competence hypothesis has been tested only sporadically in cross-cultural research; this concurs with the relative lack of Western studies on the association between attachment and (later) competence (Groh et al., 2014; Sroufe, Egeland, Carlson, & Collins, 2005; Van IJzendoorn, Dijkstra, & Bus, 1995). In the Gusii study (Kermoian & Leiderman, 1986), the nutritional status of the secure infants was better than that of the insecure infants. This outcome has been replicated by Valenzuela (1997) in her Chilean study of undernourished infants. Although the relation between attachment and health status is truly remarkable, it is still not clear whether attachment security serves only as the cause and nutritional status only as the effect. It may be that more healthy infants evoke more care in general and more sensitive care in particular, especially in situations of economic deprivation when parents are forced to be selective in their investment of time and energy (Finerman, 1994; Scheper-Hughes, 1993). A more intricate causal pattern cannot be completely excluded on the basis of the correlational evidence

that Kermoian and Leiderman (1986) and Valenzuela (1997) have provided. The Dogon study (True, 1994; True et al., 2001) does not allow for differentiation between cause and effect, either. Only the Israeli studies on children raised in a kibbutz and city children showed some longitudinal relations between secure attachment and future adaptive functioning (Aviezer, Sagi, & Van IJzendoorn, 2002; Gini, Oppenheim, & Sagi-Schwartz, 2007; Oppenheim, Koren-Karie, & Sagi-Schwartz, 2007; Sagi-Schwartz & Aviezer, 2005). We should therefore conclude that the cross-cultural support for the competence hypothesis is still insufficient. Given the convincing support for the other three key hypotheses postulated by attachment theory, it seems more than feasible to extend attachment research in non-Western countries to children's developmental outcomes. Furthermore, the concept of attachment networks may be fruitfully applied in studies of the competence hypothesis in societies where multiple caregivers are the norm.

Conclusions

Our analysis and integration of cross-cultural attachment research suggest a balance between universal trends and contextual determinants. Attachment theory without contextual components is as difficult to conceive of as attachment theory without a universalistic perspective. If all infants across cultures used the same fixed strategies to deal with attachment challenges, it would leave no room for adaptation to dynamic changes in the environment (Hinde & Stevenson-Hinde, 1990) and to the constraints imposed by different developmental niches (DeVries, 1984; Harkness & Super, 1992, 1996; LeVine & Miller, 1990; see Simpson & Belsky, Chapter 5, this volume). Without variation, selection of optimal behavioral strategies would become obsolete (Darwin, 1859/1985; see Van IJzendoorn, Bakermans-Kranenburg, & Sagi-Schwartz, 2006, for an evolutionary attachment model integrating universal and contextual dimensions of attachment).

The studies reviewed in this chapter emphasize the importance of investigating attachment within the wider social networks in which children grow and develop. In Western as well as non-Western cultures, most children communicate with several attachment figures, including siblings. Examining the competence hypothesis

only on the basis of infant–mother attachment may decrease predictive power substantially, and more conceptual and empirical work is needed to determine how experiences with different attachment figures become organized to form a coherent internal working model (Sagi-Schwartz & Aviezer, 2005). Furthermore, several studies reviewed here emphasize the importance of including variations in the socioeconomic context within countries, so that attachment patterns can be elucidated from both a cultural and a resource perspective.

Last, the current cross-cultural database is almost absurdly small compared to the domain that should be covered. Data on attachment in a populous country such as India and most Islamic countries are still lacking, and large parts of Africa, Asia, and Latin America are uncharted territories with respect to the development of attachment. Although the studies including samples from these parts of the world represent admirable contributions to the attachment literature, they cannot be considered to be representative of their respective continents. This lack of studies outside of North America and Europe, of course, is partly due to the difficulties of conducting standardized research in countries where facilities and resources are lacking. And even if researchers manage to, for instance, conduct the Strange Situation procedure, in many cases the coding is done by researchers who have not been formally trained by experts, which makes the quality of the classifications unclear. It is also the task of Western attachment researchers to provide adequate and affordable training opportunities to those researchers in other parts of the world who want to study attachment.

In our chapter of this third edition, which includes attachment data from five new countries or cultures compared to the previous edition (Van IJzendoorn & Sagi-Schwartz, 2008), we pay special attention to cross-cultural beliefs about attachment and sensitivity, and we provide more details on attachment and sensitivity in Latin America and with Arabs living in Israel. What has not changed since 2008 is that the available cross-cultural studies have not refuted the bold conjectures of attachment theory about the universality of attachment, the normativity of secure attachment, the link between sensitive caregiving and attachment security, and the competent child outcomes of secure attachment. In fact, taken as a whole, the studies are remarkably consistent with the theory. Until further notice, attachment theory may therefore claim cross-cultural validity.

Acknowledgments

Support for the preparation of this chapter was provided by the Spinoza Prize of the Netherlands Foundation for Scientific Research (NWO) to Marinus H. van IJzendoorn, and by NORFACE (New Opportunities for Research Funding Agency Cooperation in Europe, Grant No. 292) to Judi Mesman.

Chapter 38

A Lifespan Perspective on Attachment and Care for Others

Empathy, Altruism, and Prosocial Behavior

Phillip R. Shaver
Mario Mikulincer
Jacquelyn T. Gross
Jessica A. Stern
Jude Cassidy

Attachment theory (Bowlby, 1969/1982, 1973, 1980) is, at its core, a theory of prosocial behavior. It explains how, in early childhood, interactions with mindful, caring, and supportive parental figures (“attachment figures”) create and solidify children’s positive mental representations of others (as competent, dependable, and well intentioned), their pervasive sense of safety and security, and their ability to recognize, acknowledge, and regulate emotions. The theory has been supported by decades of developmental research, summarized in this volume, which implies the existence of an intergenerational transmission of security (or insecurity) that potentially creates a continuing cross-generational stream of prosocial behavior—or its absence. The extension of the theory to some of the topics encountered in the broader psychological literature on prosocial behavior—empathy, compassion, generosity, forgiveness, and altruism (Mikulincer & Shaver, 2010, 2012)—is quite natural, and in recent years it has been accomplished in studies of the prosocial behavior of children, adolescents, and adults.

Our purpose in this chapter is to highlight attachment-related research on prosocial behavior in different phases of the lifespan. We begin with a brief explanation of how the theory’s basic concepts relate to prosocial attitudes, motives, emotions, and behavior. This explanation is summarized in a conceptual model of the association between parental sensitive responsiveness on one hand, and a child’s empathy and prosocial behavior on the other, mediated by the child’s attachment security, internal working models (IWMs), and effective emotion regulation. We follow the theoretical introduction with two major sections on prosocial emotions and behavior in childhood and in adulthood. We conclude the chapter with suggestions for future research involving children and adults.

Basic Concepts of Attachment Theory in Relation to Prosociality

As explained more fully in other chapters of this volume, attachment theory is organized in terms of

several basic concepts: the attachment behavioral system, the caregiving behavioral system, the felt sense of security, working models of self and others, and emotion regulation (see, in this volume, Cassidy, Chapter 1; Bretherton & Munholland, Chapter 4; B. C. Feeney & Woodhouse, Chapter 36; and Mikulincer & Shaver, Chapter 24). The attachment behavioral system was postulated by Bowlby (1969/1982) to explain the observable tendency of primate infants to maintain proximity to their mother, especially in novel or unpredictable environments, and to cling to her when threats arise (often, in the natural environment, as she moves into and through trees to avoid predators). In the human case, although we are born with a grasping reflex that allowed our primate ancestors to cling to a mother's fur, the attachment system emerges slowly during the first months of life, but it gradually matures sufficiently to orient a baby to its familiar caregivers, to move the baby closer to them in response to threats and fears, and to regulate the baby's sense of safety in response to a caregiver's protection, support, and soothing.

Bowlby (1969/1982) also postulated the existence of a caregiving behavioral system to explain humans' seemingly natural capacity for empathy, compassion, and care—features evident in the behavior of parents who respond sensitively to their children's signs of vulnerability and need. These features are not limited to parental behavior but also are evident in the observable tendency of children and adults to become concerned when they encounter other people who are suffering or in need and, often, to be motivated to relieve this suffering or respond to others' needs. Within a person's developmental history, parameters of the universally present attachment behavioral system are modified in response to caregivers' behavior, and the same experiences affect the caregiving behavioral system, causing a complex web of connections between the person's attachment and caregiving cognitions, emotions, and behavior.

According to Bowlby (1969/1982), the caregiving system is designed to provide protection and support to others who are either chronically dependent or temporarily in need. It is inherently altruistic in nature, being aimed at the alleviation of others' distress, although the system itself presumably evolved because it increased inclusive fitness by making it more likely that children and tribe members with whom the individual shared genes would survive and reproduce (Batson, 2010; de Waal, 2008; Hamilton, 1964; MacLean, 1985). Within attachment theory, the caregiving system

provides an entrée to the study of compassion and altruism; moreover, understanding this system provides a foundation for devising ways to increase people's compassion and effective altruism.

The caregiving system is focused on the welfare of others and therefore directs attention to others' distress rather than to one's own needs. In its prototypical form—that is, in the parent-child relationship—the goal of the child's attachment system (proximity that fosters protection, reduces distress, increases safety, and establishes a secure base) is also the goal of the parent's caregiving system. Extending this conceptualization to the broader realm of compassion and altruism, we view the caregiving system as activated by the presence of a distressed person, even a stranger in need, its aim being to alter the needy person's condition until signs of increased safety, well-being, and security appear. This system's functioning can be undermined by anxiety and self-concern on the part of the potential care provider, which is why attachment insecurity often undermines or interferes with effective care. In contrast, a sense of attachment security allows a person to attend less to his or her own concerns and shift attention to providing care.

Theoretically, being secure implies that one has witnessed, experienced, and benefited from generous attachment figures' sensitive and effective care, which provides a model to follow when one encounters a vulnerable or needy other. Secure individuals also feel more comfortable than insecure ones with intimacy and interdependence, so they can more readily accept other people's needs for closeness, sympathy, and support. The positive mental representations (working models) of others that are associated with attachment security (see Bretherton & Munholland, Chapter 4, this volume) make it easier to construe others as deserving of sympathy and support, hence compelling one to care for them. Moreover, secure individuals' positive model of self (Bartholomew & Horowitz, 1991; Bowlby, 1969/1982) allows them to feel more confident about their ability to handle another person's needs while effectively regulating their own emotions (e.g., Batson, 2010).

In contrast, an insecure person is likely to have vulnerable, defended self-esteem, if not an outright negative model of self. He or she is likely to be wary of others' potential for neglect, harsh criticism, rejection, or abuse. Stated this baldly, it is clear why security might be conducive to empathy and prosocial behavior, whereas insecurity might be conducive to self-concern, self-protect-

tion, defensive rejection of others' needs, and mistimed or misguided efforts to understand and help others.

As explained in other chapters in this volume (e.g., Solomon & George, Chapter 18), Ainsworth, Blehar, Waters, and Wall (1978) established methods for identifying and categorizing different patterns of attachment (secure, anxious/ambivalent or resistant, and avoidant) that emerge during the first two years of life as a result of caregivers' behavior. In their book, Ainsworth and colleagues (1978) also demonstrated that two main dimensions, anxiety and avoidance, underlie the three patterns of attachment. Subsequent research on adult attachment established similar categorization schemes for adults, using either interviews (e.g., the Adult Attachment Interview [AAI]; Hesse, Chapter 26, this volume) or adult self-report measures of attachment anxiety and avoidance (e.g., the Experiences in Close Relationships scale [ECR]; Brennan, Clark, & Shaver, 1998; see Crowell, Fraley, & Roisman, Chapter 27, this volume). In the following section, we explore attachment-related childhood roots of care for others.

Childhood Roots of Care for Others

The capacity to care for others' well-being is rooted in early development. Children as young as 8 months of age display concern for others' suffering and in some contexts will act to relieve their pain (Roth-Hanania, Davidov, & Zahn-Waxler, 2011; Zahn-Waxler, Radke-Yarrow, Wagner, & Chapman, 1992). Among the multiple factors that comprise care for others, two of the most important are empathy and prosocial behavior. *Empathy* is an experience of affective resonance with another's emotions, along with a sense of concern for his or her welfare; it may also include cognitive apprehension of another's condition or needs (Decety & Meyer, 2008; Eisenberg, 2000; Hoffman, 1984, 2001). *Prosocial behavior* is voluntary behavior intended to benefit others (Grusec, Hastings, & Almas, 2011); like empathy, prosocial behavior may occur in response to distress, but it may also arise in response to other cues such as instrumental or material need (Dunfield & Kuhlmeier, 2013). In addition to these dimensions, *compassion* refers to the feeling of care for others' suffering, as well as the intention to relieve their suffering (Dalai

Lama, 2001; Gillath, Shaver, & Mikulincer, 2005; Halifax, 2012; Siegel & Germer, 2012). Compassion is similar in many respects to empathy, but it involves a sense of acceptance, tenderness, and motivation to act to relieve suffering, and it tends to result in more positive affect than does empathy (Klimecki, Leiberg, Richard, & Singer, 2014). Despite its clear connection to concern for others, virtually no research has specifically examined the development of compassion in children, although some classroom interventions cite compassion as a desired outcome (Greenberg & Harris, 2012).

Together, empathy and prosocial behavior have been the foci of most of the empirical and theoretical work on children's capacity to care. Because this chapter is concerned with care for others, we focus on empathy and prosocial behavior in this section, emphasizing children's comforting of others in response to distress and/or global measures of prosociality, and omit discussion of specific noncaring social capacities such as compliance, cooperation, social competence, affection, and moral reasoning (but see Thompson, Chapter 16, this volume).

Although concern for others' welfare is part of normative development, clear individual differences in empathy and prosocial behavior are evident across childhood, with some children responding to a peer's distress with immediate and overt concern and helpful overtures, and others responding with wariness, hostility, indifference, or distress of their own. These differences are linked to important developmental outcomes, such as peer acceptance, friendship quality, school performance, loneliness, and aggression (Asher & McDonald, 2009; Cassidy & Asher, 1992; Clark & Ladd, 2000; Findlay, Girardi, & Coplan, 2006; Ladd, Birch, & Buhs, 1999; Wentzel, 2003). Given the theoretical basis for expecting a link between attachment and care for others described in the previous section, a key question becomes: Are individual differences in children's empathy and prosocial behavior related to attachment?

We begin by exploring theoretical considerations regarding the link between attachment security and children's emerging capacity to care for others, first by exploring potential mediators of this link, then by discussing the role of parental sensitivity in supporting the development of both security and care for others. We then discuss definitions and operationalizations of empathy and prosocial behavior. Next, we review empirical investigations of the attachment-care link from infancy through adolescence.

Theoretical Considerations

Mediators

As mentioned earlier, Bowlby (1973) proposed that security provides a foundation for the development of children's emotional functioning, particularly the capacity to regulate emotions. Ainsworth's (1969) observations suggested that individual differences in children's attachment representations guide specific patterns of behavior, and that a secure IWM provides the blueprint for mutually responsive social interaction. Both of these concepts—emotion regulation and the secure IWM—are relevant to empathy and prosocial behavior, and provide potential mediating mechanisms in the link between attachment and care for others.

With regard to children's emotional functioning, researchers studying empathy and prosocial behavior in children have long recognized that multiple emotional competencies underlie the capacity to care for others, including emotion recognition and understanding, intersubjectivity, affective resonance, distinction between self and other, perspective taking, and effortful control (Batson, 1991; Davis, 1996; Decety & Jackson, 2004; Ickes, 2003; Kochanska, 1993; Laible, 2004). Attachment has been empirically linked to many of these, with securely attached children consistently showing, for example, better emotion understanding (Denham, Blair, Schmidt, & DeMulder, 2002; Laible & Thompson, 1998; Raikes & Thompson, 2006; see also Thompson, Chapter 16, this volume) and better effortful control compared to their insecure peers (Viddal et al., 2015).

One of the most important and well researched of these competencies is *emotion regulation* (e.g., Eisenberg & Fabes, 1992; Trommsdorff, Friedlmeier, & Mayer, 2007), which allows children to perceive and respond to others' distress without becoming overly distressed themselves. Research has shown that behavioral and physiological indicators of self-regulation are related to children's empathy and prosocial behavior, whereas personal distress (i.e., self-focused, dysregulated negative emotion) is inversely related to or unassociated with empathy and prosocial behavior (Eisenberg, 2000; Eisenberg & Fabes, 1990, 1991, 1995; Fabes, Eisenberg, & Eisenbud, 1993).

The extent to which emotion regulation capacities are linked to individual differences in attachment is striking. Attachment theory holds that emotion regulation arises from repeated experiences of caregivers' sensitive coregulation

of children's distress, and views this capacity as a major mediating mechanism explaining how early experience affects later functioning (Bowlby, 1973, 1980, 1988; Calkins & Leerkes, 2011; Cassidy, 1994; Hofer, 1994; Mikulincer, Shaver, & Pereg, 2003; Schore, 2000; Sroufe, 1996, 2000; Thompson, 1994; see Mikulincer & Shaver, Chapter 24, this volume). Considerable research has demonstrated that securely attached infants, children, and adolescents are better able to regulate emotional arousal (Contreras, Kerns, Weimer, Gentzler, & Tomich, 2000; Kerns, Abraham, Schlegelmilch, & Morgan, 2007; Kobak, Cole, Ferenz-Gillies, Fleming, & Gamble, 1993; Kopp, 1989; Leerkes & Wong, 2012; Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996; Sroufe, 1983, 2005; see Thompson, Chapter 16, this volume). Thus, based on theory and empirical evidence, we join others who have proposed a model in which emotion regulation mediates the link between attachment security and care for others (e.g., Panfile & Laible, 2012).

With regard to cognition, a second pathway by which attachment may be linked to care for others is via the IWM. Through repeated experiences with a responsive caregiver, secure attachment provides children with a mental representation of the self as worthy of and effective in eliciting care, of others as available and responsive to distress, and of the world as a generally safe and caring place. One line of evidence for this part of the model comes from visual habituation studies of infants' responses to geometric representations of a caregiver and child: a large oval and a small oval (Johnson, Dweck, & Chen, 2007; Johnson et al., 2010). In these studies, securely attached infants looked longer at visual displays in which the "caregiver" oval was unresponsive to the "child" oval's distress upon separation, whereas insecure infants looked longer at displays in which the "caregiver" oval was responsive. In each case, infants attended longer to visual displays that were presumed to violate their expectations—that is, their mental representations—that distress would be met with responsive care (in the case of secure infants) or unresponsive care (in the case of insecure infants) (Johnson et al., 2007, 2010). These findings provide evidence for the existence of attachment-based expectations about how social actors respond to others' distress. Specifically, the secure child develops a representation of others as caring, attuned, and responsive (in addition to a representation of the self as likely to receive empathic care from others; Bowlby, 1973; Bretherton, Ridgeway,

& Cassidy, 1990). (For discussions of topics related to the concept of the IWM, see Lyons-Ruth et al., 1998, for the idea of *implicit relational knowing*, and Waters & Waters, 2006, for the idea of *secure-base scripts*.)

The precise mechanism by which the secure model of others as caring becomes integrated into a model of the self as caring for others remains unclear; however, Sroufe and Fleeson (1986) proposed that care leading to secure attachment shows children both sides of a responsive relationship, and that children can draw upon both representations when responding to the needs of others. Empirically, securely attached children tend to have more positive, reciprocal friendships in childhood (Elicker, Englund, & Sroufe, 1992; Shulman, Elicker, & Sroufe, 1994) and more secure IWMs of romantic relationships in adolescence (Furman & Wehner, 1997), suggesting that implicit knowledge of what it means both to give and to receive responsive care is conserved as children enter into close relationships with peers. It is also possible that children incorporate behavioral routines for care in the same way they model other kinds of behavior, such as eating with a spoon, brushing teeth, dancing, or throwing a ball.

Parental Sensitivity

Beyond the roles of emotion regulation and a secure IWM as mediators of the link between attachment and care for others (see solid lines in Figure 38.1), there are other conceptual models that may further illuminate this link. One model

to consider is one in which security and care for others share common developmental antecedents (see dashed lines in Figure 38.1). A wealth of research demonstrates that caregivers' emotionally attuned, consistent responsiveness predicts attachment security in young children (Ainsworth, 1969; Ainsworth et al., 1978; Egeland & Farber, 1984; Isabella, 1993; van den Boom, 1994), and theories of empathic development posit that sensitive parental behavior also contributes to the development of children's care for others (Hoffman, 1977; for evidence, see Eisenberg, Fabes, & Murphy, 1996; Eisenberg et al., 1992, 1993; Garner, 2006; Hastings, Utendale, & Sullivan, 2007; Taylor, Eisenberg, Spinrad, Eggum, & Sulik, 2013).

In addition to being influenced by parental sensitivity, children's care for others appears to be guided by *rules* for responding to distress. According to recent empirical work, even young children (age 3 years) appear to decide which emotional displays are "appropriate" or "inappropriate" and show greater empathy and willingness to help an adult experimenter whose distress is perceived as appropriate to the harm that caused it (Hepach, Vaish, & Tomasello, 2013b). Thus, children assess the appropriateness of emotions and use this assessment to guide their empathy and prosocial responses. It is reasonable to suspect that children learn these decision rules for what constitutes "appropriate" distress through experiences of how their own distress was responded to, which is a key contributor to secure child attachment (e.g., Beckes & Coan, 2015; Leerkes, 2011).

FIGURE 38.1. Model of the link between secure attachment and care for others (i.e., empathy and prosocial behavior) in childhood. Solid lines represent the principal model presented in this chapter, in which the link between secure attachment and care for others are mediated by (1) secure internal working models (IWMs) of self and other, and (2) emotion regulation. Dashed lines represent an additional model, in which caregiver sensitivity provides a common developmental antecedent for both security and care for others.

The perspective of attachment theory on the role of parenting in the development of concern for others differs from that of other conceptual models. Traditional theories of socialization, social learning, and conditioning tend to rest on a top-down, behaviorally oriented approach in which parents' instruction, modeling, reinforcement, and punishment shape children's desired social behavior and the internalization of parental values (Maccoby, 1992). In fact, historically, much of the research on parents' role in the development of concern for others has focused on socialization practices such as discipline and modeling of prosocial action (Hoffman, 1970). In support of these theories, considerable evidence indicates that adults' gentle discipline, inductive reasoning, emotion-focused dialogue, prosocial modeling, and authoritative, noncontrolling parenting style promote children's empathy and prosocial behavior (e.g., Grusec, 1972; Krevans & Gibbs, 1996; Perry, Bussey, & Frieberg, 1981; Rushton, 1975; also see Hastings, Utendale, & Sullivan, 2007). More recently, these models have included the child's role in socialization, with a focus on how children's temperament and view of their parents influence their receptivity to the socialization efforts (e.g., Grusec & Goodnow, 1994; Kochanska, 1997; Maccoby, 1992).

According to Ainsworth, Bell, and Stayton (1974), attachment theory offers a different view. Rather than requiring parents' active socialization efforts, children are thought to be inherently social, biologically predisposed to respond to the social signals of members of their species, and intrinsically motivated to comply with maternal requests, especially within the context of a sensitive, trusting relationship. For instance, Ainsworth and colleagues proposed that the greater compliance with maternal requests that is characteristic of securely attached infants reflects the mutual responsiveness inherent to their IWMs of relationships. (In other words, secure children represent relationships as contexts within which recognition of and responsiveness to the needs of other people are the norm.) The central thesis of this argument is that "socialization results from reciprocal mother-infant responsiveness. When the mother is less sensitive and less responsive to her infant than is expected in the social environment of evolutionary adaptedness, the infant more than likely will be less responsive and hence less compliant to the signals of his mother and other social companions" (pp. 118–119). Extending this view to care for others, we can speculate that empathy and prosocial behavior need not be explicitly taught, but

instead develop naturally in the context of a mutually responsive relationship. Such a relationship provides the repeated firsthand, felt experience of having a secure base and safe haven in times of distress, which may then allow secure individuals to extend such care to distressed others. For recent similar viewpoints about a biologically based predisposition toward caring for others, see Bartal, Decety, and Mason (2011), de Waal (2008), and Warneken and Tomasello (2006).

To point out these distinctions between the attachment and socialization perspectives is not to discount the unique contributions of each to the development of care for others in children. Kochanska (2002) suggested that attachment and socialization work in concert in fostering children's conscience, with security representing a "mutually responsive orientation" that renders children more willing to accept and integrate parents' socialization influence. In support of this view, she observed that the effects of positive parenting on children's conscience held only for securely attached children (Kochanska, Aksan, Knaack, & Rhines, 2004). Similarly, Zahn-Waxler, Radke-Yarrow, and King (1979) posited that children must not only witness parents' prosocial modeling and be exposed to prosocial values but must also *experience parents' empathy and prosocial actions themselves* in order to develop these capacities. Thus, socialization may be important, but it does not provide a full picture of parents' role in the development of children's care for others; crucially, the lived experience of having a secure base and safe haven in times of distress provides the foundation for children's ability to regulate emotion and care for others, upon which socialization influences can build.

In summary, multiple theoretical pathways link attachment security to a child's capacity to care for others. Here we focus on how security may contribute to the development of empathy and prosocial behavior, particularly in response to others' distress.

Definitions and Operationalization

In childhood, the definition and operationalization of care for others is particularly complex. As described earlier, *empathy* is the felt, emotional dimension of concern for others' welfare, whereas *prosocial behavior* is the active, behavioral manifestation of that emotion, which encompasses actions intended to benefit others. A critical distinction is that the former refers to an internal state,

the latter to expressed behavior. Thus, a key issue for researchers is how to measure each construct with sensitivity and specificity in young children, before self-reports of internal experience are possible.

Relatedly, some prosocial behavior may be motivated by empathy, but not in every case (Hastings et al., 2007). For example, a child may share a toy with a sad peer out of compliance with a teacher's expectations, or out of deference to the peer's social dominance, rather than out of genuine concern for the peer's well-being (see Hepach, Vaish, & Tomasello, 2013a, for consideration of empirical methods for examining children's underlying motivations for prosocial behavior). Furthermore, children's internal experiences of empathy may not always manifest in prosocial behavior, particularly when the situation is complex or when prosocial intervention would be especially difficult. Therefore, one can neither measure children's prosocial behavior and infer that it reflects empathy, nor measure empathy and assume that prosocial behavior will follow.

Researchers mindful of this distinction have developed separate criteria to measure each dimension (e.g., Zahn-Waxler, Radke-Yarrow, et al., 1992): Empathy is reflected in young children's looks of concern ("concerned attention") or expressions of sadness in response to a sad peer, adult, or parent; prosocial behavior takes the form of helping, sharing, or comforting (among other behaviors), but may or may not be a response to others' distress (Dunfield & Kuhlmeier, 2013). Understanding the link between attachment and children's capacity to care for others requires specificity in measurement and attention to the unique contributions of both empathy and prosocial behavior. With this in mind, we review empirical work on the links between attachment and both empathy and prosocial behavior in childhood.

Empirical Work

Several studies have examined attachment-related differences in care for others from infancy through adolescence. In this section, we divide these studies by developmental period (based on the age of the children when care for others was assessed), and further by the measurement of care (i.e., empathy, prosocial behavior, or a composite). For each developmental period, we begin with a brief summary of age-related changes in attachment relationships, care for others, or both. Then, after reviewing studies of the link between attachment

and care for others within each age group, we discuss evidence for the purported mediational role of child emotion regulation.

Infancy and Toddlerhood

Children's initial attachment relationships develop during their first year of life (Bowlby, 1969/1982; see Marvin, Britner, & Russell, Chapter 13, this volume). Early precursors of empathy are evident during this time as well, such as affect mirroring and "empathic distress" (Hoffman, 2001), as are early indications of empathy (e.g., Roth-Hanania et al., 2011, who noted modest levels of affective and cognitive empathy as early as 8 months). Prosocial behaviors are rare in the first year of life (Roth-Hanania et al., 2011) but become increasingly common between ages 1 and 2 (Zahn-Waxler, Radke-Yarrow, et al., 1992). By their second birthday, almost all infants readily provide instrumental help (Warneken & Tomasello, 2006, reported that 92% of 18-month-old infants provided help in at least one simple situation), and some show concerned attention or provide comfort in response to the distress of peers, siblings, strangers, or their mother (Eisenberg, Fabes, & Spinrad, 2006). In addition, even young infants are able to make social evaluations of others based on their prosocial and antisocial behaviors. For example, 6- and 10-month-old infants show a preference for actors (represented by colored shapes) who helped compared to those who hindered another actor's attempt to attain a goal, an evaluation that may serve as the foundation for later moral action (Hamlin, Wynn, & Bloom, 2007).

Surprisingly, only a handful of studies have investigated attachment-related differences in empathy and/or prosocial behavior among infants and toddlers. In one study, 36-month-olds' attachment security (assessed with mothers' ratings using the Attachment Q-Set [AQS; Waters & Deane, 1985]) was linked to mother-rated empathy, yet was linked only indirectly to observed prosocial behavior through empathy (Panfile & Laible, 2012). In another study, mothers' reports of neither their 1-year-old infants' empathy nor prosocial behavior were associated with infant behavior in the Strange Situation (Carter, Little, Briggs-Gowan, & Kogan, 1999).

Two additional studies used composite measures containing elements of both empathy and prosocial behavior. One longitudinal study of 22- to 23-month-olds recorded empathic responses toward an experimenter who was simulating distress

(Bischof-Köhler, 2000). Toddlers who had been classified as securely attached in the Strange Situation as infants were more likely to show concern and provide help than those who had been classified as insecurely attached. Additional longitudinal evidence came from a study measuring infants' attachment and observed care for others at both 16 and 22 months, toward both the mother and an experimenter simulating distress. Only one of the eight potential associations (two behaviors, two care recipients, two time points) was significant: Infants' security in the Strange Situation at 22 months was positively related to their concurrent empathic concern for the experimenter (van der Mark, Van IJzendoorn, & Bakermans-Kranenburg, 2002). We also mention a third study that, although it lacks a measure of attachment security, seems relevant to the links considered here. Main and George (1985) observed children in a day care setting and reported that abused toddlers (who typically are insecurely attached; Cyr, Euser, Bakermans-Kranenburg, & Van IJzendoorn, 2010) never reacted to a peer's distress with concern, but instead often reacted with physical attacks, fear, or anger.

In contrast to the mixed evidence concerning infants' and toddlers' *behaviors* and *emotions*, studies of their *expectations* about the concern that will be shown in response to the distress of others reveal more consistent attachment-based differences. In a series of studies using a visual habituation paradigm (briefly described earlier), Johnson and colleagues (2007, 2010) demonstrated that securely attached infants expected others (i.e., a large oval) to help someone in distress (i.e., a small oval simulating distress), whereas insecure-avoidant and insecure-resistant infants expected others to withhold comfort. These studies suggest that infants' attachment patterns influence their representations of the ways in which people treat each other, including whether caring and comforting are typical responses to distress.

Earlier, we described a mediation model (Figure 38.1) in which attachment security supports the development of effective emotion regulation, which in turn underlies children's ability to show concern for others without becoming overly aroused with personal distress. The evidence for each of these pathways in infancy and toddlerhood (from attachment to emotion regulation, and from emotion regulation to empathy and prosocial behavior) supports the possibility that such a mediating pathway exists during this developmental period. As noted earlier, several investigators have

argued that the quality of infants' developing attachments contributes to individual differences in emotion regulation (e.g., Cassidy, 1994), and several studies provide empirical evidence (e.g., Hill-Soderlund et al., 2008; Kim, Stifter, Philbrook, & Teti, 2014; Sherman, Stupica, Dykas, Ramos-Marques, & Cassidy, 2013). Infants' greater regulatory skills, in turn, have been associated with prosocial behaviors and empathy (e.g., Carter et al., 1999), as well as the ability to maintain an optimal level of arousal in the face of others' distress (Geangu, Benga, Stahl, & Striano, 2011), a crucial part of empathic concern (Davidov, Zahn-Waxler, Roth-Hanania, & Knafo, 2013). A recent test of this mediation model revealed that toddlers' emotion regulation mediated the association between attachment security and empathy (all mother-reported variables), such that more secure toddlers were better able to regulate their emotions, which then predicted greater empathy (Panfile & Laible, 2012). Furthermore, greater empathy in this study predicted more prosocial behavior toward an experimenter seeking a pacifier to soothe the (recorded) cries of a nearby baby.

In summary, few studies have examined the link between attachment and caring for others during the infancy/toddler period. The mixed evidence that emerges from these studies suggests that other factors may relate to empathy and prosocial behavior more than attachment during this period. Such factors may include genetics (Zahn-Waxler, Robinson, & Emde, 1992, reported modest evidence for heritability of empathy and prosocial behavior at 14 and 20 months) and temperament (van der Mark et al., 2002, found that temperamental fearfulness in 16-month-old girls predicted less empathic concern for a distressed stranger at 22 months). The possibility that infants and toddlers are too young to experience complex social feelings such as empathy in the ways that become more evident by the preschool years may also influence the consistency of the link between attachment and caring for others during this period.

Preschool

The preschool period ushers in developmental changes that affect both children's attachment relationships, such as the emergence of a goal-corrected partnership (see Marvin et al., Chapter 13, this volume), and factors underlying care for others, such as maturing emotion regulation and enhanced executive functioning (Eisenberg & Sulik, 2012; Rothbart, Sheese, Rueda, & Posner,

2011). Opportunities to care for peers in the classroom or for younger siblings in the home increase as preschoolers spend more time in the company of other children.

Evidence for attachment-related differences in care for others during this developmental period emerges from some studies and not from others. Two longitudinal studies of attachment found links with later empathy. In one of these, 1-year-old infants who were classified as secure in the Strange Situation were later rated by their mothers as more sympathetic to their peers' distress at age 3 compared to children who were insecure as infants (Waters, Wippman, & Sroufe, 1979). In the other study, secure attachment (mother-reported with the AQS) and care for others were measured at both 42 and 48 months. Although neither concurrent link was significant, attachment security at 42 months predicted concerned facial expressions during a baby-cry procedure at 48 months, even after researchers controlled for earlier empathy (Murphy & Laible, 2013). In contrast, in a third longitudinal study, attachment quality in the Strange Situation at age 2 did not predict children's reports of their affective responses to emotional photographs at age 5 (Iannotti, Cummings, Pierrehumbert, Milano, & Zahn-Waxler, 1992).

Studies of prosocial behavior are also somewhat mixed. For example, when children (ages 2–7) were left alone in an unfamiliar room with their younger (toddler) sibling, children rated as more secure by their mothers on the AQS were more likely to respond to the sibling's distress with comfort (Teti & Ablard, 1989); however, Volling (2001) found no differences in sibling comforting between 4-year-olds previously classified as secure or insecure in the Strange Situation (with both mother and father) at 12 months. Additionally, in two studies of preschool children, child attachment (mother-reported AQS) was related to concurrent mother-reported prosocial behavior directly (Laible, 2006) and, in a separate sample, indirectly via child effortful control (Laible, 2004).

When peers are the targets of children's prosocial behavior, evidence is similarly mixed, although the inconsistencies may be due to differences in the measurement of attachment. For example, security in the Strange Situation at age 2 predicted observed prosocial behavior toward a peer 3 years later (Iannotti et al., 1992). In contrast, security assessed with an observer-rated AQS did not relate to naturalistic observations of preschoolers' prosociality in the classroom (Mitchell-Copeland, Denham, & DeMulder, 1997), nor did

mother- and father-reported AQS relate to teacher-reported prosociality (Lafrenière, Provost, & Dubeau, 1992). There is also some evidence that secure children are more prosocial with peers than are avoidant, but not resistant, children, a finding that is only possible using a measure of attachment that differentiates the two insecure subtypes (e.g., the Strange Situation). Children who had been secure in the Strange Situation at 12 and 18 months were observed to be more prosocial and empathic in the classroom as preschoolers than those who had been avoidant, but not more than those who had been resistant (Kestenbaum, Farber, & Sroufe, 1989). In the same sample, Sroufe (1983) found that teacher reports of empathic responding were "characteristic" of children who had been secure infants and "uncharacteristic" of children who had been avoidant. The children who had been classified as resistant were between these other two groups.

Turning again to the model wherein the link between attachment and children's care for others is mediated by emotion regulation, we note that emotion regulation continues to develop throughout preschool and remains an important contributor to social interactions. Preschoolers vary widely in their ability to self-regulate, with individual differences in this ability relating to differences in empathy (e.g., Eisenberg & Fabes, 1995). Well-regulated preschoolers can focus on the distress of others in need and respond with empathy because they are better able to control their own emotional arousal (Eisenberg et al., 1990). A recent longitudinal study provides some additional evidence for preschoolers' emotion regulatory capacities predicting concern for others using physiological measures of respiratory sinus arrhythmia (RSA), an indicator of heart rate variability thought to underlie individual differences in emotion regulation and arousal (Taylor, Eisenberg, & Spinrad, 2015). In this study, baseline RSA (for girls and boys) and RSA suppression (for boys only) at 42 months were positively correlated with concurrent mother-reported sympathy. Moreover, a marginally significant indirect path was evident from baseline RSA, at 42 months, to greater mother- and teacher-reported sympathy, at 72 and 84 months, through effortful control at 52 months.

In summary, the majority of studies support a link between secure attachment and care for others among preschoolers, although some inconsistent findings highlight the need for further research. It is worth noting that longitudinal studies provide more consistent evidence than concurrent

studies when care for others is measured during the preschool period and attachment is measured during infancy/toddlerhood, particularly when peers are the targets of care. This pattern could be due to chance, methodological constraints (e.g., perhaps prosocial behavior and empathy are more easily measured in preschoolers), or developmental realities (e.g., early attachment may play a larger role than current attachment in preschoolers' care for others, particularly their peers in the classroom); future research could help tease apart these possibilities. We also note that some studies using the Strange Situation as the measure of attachment quality provide evidence for differential relations between the insecure subtypes, with secure children showing more care for others than avoidant, but not resistant, children.

Early and Middle Childhood

By early and middle childhood, peers begin to play a greater role in children's social development, and demonstration of empathy and prosocial behavior toward peers contributes to friendship formation and popularity (Eisenberg et al., 2006). Developmental advances in theory of mind (i.e., understanding that other people have minds), emotion regulation, and cognitive flexibility allow for enhanced understanding of others' needs (e.g., Devine & Hughes, 2013; Murphy, Eisenberg, Fabes, Shepard, & Guthrie, 1999; Piekny & Maehler, 2013). The attachment behavioral system makes significant developmental advances as well: Its goal shifts from caregiver *proximity* to caregiver *accessibility*, as children are able to handle longer separations with the knowledge that attachment figures will be available if needed (see Kerns & Brumariu, Chapter 17, this volume).

Studies examining attachment-related differences in care for others during early and middle childhood generally assess only behavior (e.g., volunteering to help others, kindness to younger children), rather than empathic internal states. In fact, all but one study assessed care for others using parent or teacher reports of prosocial behavior. The single exception contained observations of 6-year-olds' unsolicited prosocial interactions with their younger siblings in the home and found no behavioral differences between children with secure and insecure attachment histories (assessed at 12 months with the Strange Situation; Volling & Belsky, 1992).

Among the studies using parent and teacher reports of prosocial behavior, the evidence favors

a positive link between security of attachment and prosocial behavior. Two longitudinal studies provide evidence that children who were securely attached earlier in life are more prosocial than children who had been avoidant, but not more than children who had been resistant. In one of these studies, 8- and 9-year-old children who had been secure in the Strange Situation at 15 months were rated as more prosocial (based on a composite of parent and teacher reports) than those who had been avoidant, but not those who had been resistant (Bohlin, Hagekull, & Rydell, 2000). A concurrent link between attachment and prosocial behavior was absent in this study, however, when childhood attachment was assessed with the Separation Anxiety Test (SAT; Slough & Greenberg, 1990; adapted from Klagsbrun & Bowlby, 1976), a measure that does not differentiate insecure subgroups. In the other study, 5-year-olds responding to a modified version of the Attachment Story Completion Task (ASCT; Bretherton & Ridgeway, 1990), with themes indicative of secure attachment representations to parents were rated as more prosocial by their teachers 1 year later than children who had responded with avoidant (but not resistant) themes (Rydell, Bohlin, & Thorell, 2005). An additional longitudinal study suggests that children with secure attachment histories are more prosocial than those with disorganized, but not avoidant or resistant, attachment histories (Seibert & Kerns, 2015). In this study, third- and fifth-grade children who had been classified disorganized at 36 months in the Strange Situation were rated as less prosocial by their mothers than children who had been secure; ratings of previously avoidant and resistant children did not differ from those of any other group. Teacher ratings in this study followed a similar trend, with secure children given the highest ratings and disorganized children given the lowest; however, although omnibus analyses revealed significant differences in prosocial behavior among the four classifications, post hoc tests to clarify the nature of these differences were not significant. In contrast to these three studies, a fourth longitudinal study reported no concurrent or longitudinal associations between attachment (measured at 6 years with observed separation and reunion behavior; Main & Cassidy, 1988, and at 8 years with a modified version of the ASCT) and teacher reports of prosocial behavior at 6 and 8 years (Bureau & Moss, 2010).

Two studies with concurrent measures of attachment and care for others offer mixed findings. First, in a sample of low-income, ethnically diverse

families, 5-year-olds' attachment-related narratives in a story stem task were related to teacher reports—but not mother reports—of the children's prosocial behavior controlling for verbal IQ and sociodemographic risk (Futh, O'Connor, Matias, Green, & Scott, 2008). Second, late elementary school children's perceived attachments to both mother and father (assessed with the self-report Security Scale; Kerns, Klepac, & Cole, 1996) were associated with prosocial behavior (a composite of mother, father, and teacher reports), but only in an overall model that also included "positive parental affection," and only for girls (Michiels, Grietens, Onghena, & Kuppens, 2010). When child-reported attachment was tested as a unique predictor, the association disappeared.

In considering which factors may explain these attachment-based differences in care for others, we once again turn to the example of the emotion regulation mediation model (Figure 1). The evidence supporting this model in early and middle childhood comes from several studies showing that children's ability to regulate emotional arousal predicts greater empathy and prosocial behavior, whereas their dysregulated emotions in response to others' distress (i.e., personal distress) relate negatively to their concern for others (e.g., Eisenberg, Fabes, et al., 1996; Eisenberg et al., 1995, 1998; Fabes, Eisenberg, Karbon, Troyer, & Switzer, 1994; Rothbart, Ahadi, & Hershey, 1994). Additionally, a few studies can be viewed as providing evidence relevant to the full mediational model because they indicate that sensitive parenting (which is consistently linked to attachment security) predicts emotion regulation during early and middle childhood, which in turn predicts child prosocial behavior during this developmental period (see, e.g., Chan, 2011; Davidov & Grusec, 2006).

In conclusion, studies of attachment and care for others in early and middle childhood, as is the case in other developmental periods, are few. In fact, studies of attachment-related differences in empathy during early and middle childhood do not, to our knowledge, exist. The research on prosocial behavior, however, supports a modest association. As with the preschool period, some evidence points to diminished care for others among insecure-avoidant but not insecure-resistant children. We also note another pattern similar to that evident in the preschool period: Longitudinal associations between early-life attachment security and care for others in early and middle childhood are more likely to be present than links between attachment and prosocial behavior when mea-

sured concurrently. Once again, more research is needed, particularly studies using more diverse measures of children's care for others, beyond parent or teacher reports of behavior.

Adolescence

As children enter adolescence, close, intimate friendships and romantic relationships begin to form, opening the possibility of attachment to peers, as well as the potential for practicing the provision of care within these new relational contexts. Significant advances in cognitive and brain development (Paus, 2009; Piaget, 1972), provide adolescents with a more complex understanding of others' emotions and needs, and sophisticated meta-awareness allows adolescents to report more accurately on their own empathy and prosocial behavior. Moreover, adolescents' representations of specific previous and current attachment relationships are gradually joined to form a more global, integrated attachment organization (see Allen & Tan, Chapter 19, this volume). Adolescent attachment is typically examined through self-report measures of attachment to parents (e.g., the Inventory of Parent and Peer Attachment [IPPA]; Armsden & Greenberg, 1987), self-report measures of attachment style more broadly (e.g., the ECR (Brennan et al., 1998), or an interview-based measure of "state of mind with respect to attachment" (the AAI; George, Kaplan, & Main, 1985).

Given the similar methods used for assessing attachment and care for others in adults and adolescents, and the multitude of studies on attachment-based differences in care for others in adulthood (reviewed in the next section), it is surprising that few studies have examined this link during adolescence. The existing studies, however, consistently find that secure adolescents are more empathic and prosocial than insecure adolescents, which provides a point of continuity with the adult literature. Using the IPPA (Armsden & Greenberg, 1987) and the Interpersonal Reactivity Index (IRI; Davis, 1980), Laible, Carlo, and Raffaelli (2000) found that 16-year-olds reporting higher secure attachment to peers (but not to parents) also reported being more empathic, and a combination of high attachment security scores in relation to both peers and parents predicted the highest levels of empathy (although see Andretta et al., 2015, for evidence with African American adolescents involved in the juvenile criminal justice system indicating that, using the same mea-

tures, secure adolescents were not more empathic than their insecure peers; they were, however, substantially more prosocial on the self-reported Adolescent Prosocial Behavior Scale [APBS; Andretta, Woodland, & Worrell, 2014]). In a similar study, Thompson and Gullone (2008) found that 12- to 18-year-old adolescents reporting higher scores on a measure of secure attachment to parents (the parent scale of the revised IPPA; Gullone & Robinson, 2005) also reported being more empathic (using the Index of Empathy for Children and Adolescents; Bryant, 1982) and prosocial (using the Strengths and Difficulties Questionnaire; SDQ; Goodman, 2001). In that study (Thompson & Gullone, 2008), empathy partially mediated the link between attachment and prosocial behavior. In a study with 11- to 16-year-old British students using the same measures of attachment (revised IPPA) and prosocial behavior (SDQ), higher attachment security scores were associated with more prosocial behavior (Oldfield, Humphrey, & Hebron, 2015; see also Chan et al., 2013, for similar results in an ethnically and racially diverse sample using a different self-report measure of prosocial behavior). Another study using the IPPA found evidence for a model wherein attachment to mother and/or peers affects bullying behavior in seventh, eighth, and ninth graders indirectly via their self-reported empathy on the Basic Empathy Scale (BES; Jolliffe & Farrington, 2006). For boys, *cognitive* empathy mediated the indirect effects of attachment to both mother and peers on bullying behavior, whereas for girls, *affective* empathy mediated the effect of attachment to peers on bullying (You, Lee, Lee, & Kim, 2015). Consistent with these studies using the IPPA, studies with other measures of attachment demonstrate positive links as well. One such study found that the level of self-reported secure attachment to the mother and to a friend (using the Relationship Questionnaire; Bartholomew & Horowitz, 1991), but not to father, related to self-reported prosocial behavior among youth in middle and early high school (Markiewicz, Doyle, & Brendgen, 2001; see also Keskin & Çam, 2010, for similar evidence among Turkish youth).

Notably, the two studies from this developmental period with measures of attachment that differentiate the insecure subtypes—the observer-rated Attachment Behavior Classification Procedure (ABCP; Cobb, 1996; Hilburn-Cobb, 1998) and the interview-based AAI—found that only dismissing, and not preoccupied, adolescents re-

ported lower empathy/prosocial behavior, mirroring some of the findings from studies of preschoolers and grade school children demonstrating lower empathy/prosocial behavior among avoidant, but not resistant, children. In one of these studies, using the ABCP, both secure and preoccupied adolescents (ages 11–18) reported greater empathy on the IRI than avoidant adolescents (Hilburn-Cobb, 2004). In the other study, using the AAI, 11th-grade students with a secure/autonomous state of mind were more likely than students with an insecure/dismissing state of mind to be nominated by their peers as being prosocial (Dykas, Ziv, & Cassidy, 2008).

We again consider the emotion regulation mediation model described in relation to previous developmental periods. Adolescence is an important period for the development of brain regions involved in emotion regulation and executive functioning, such as the prefrontal cortex and anterior cingulate cortex; it is not until late adolescence that these regions reach full maturity (Decety & Meyer, 2008). In support of our mediation model, evidence suggests that teens who are more effective at regulating their emotions are also more prosocial (Cui et al., 2015; Kanacri, Pastorelli, Eisenberg, Zuffianò, & Caprara, 2013) and empathic (MacDermott, Gullone, Allen, King, & Tonge, 2010), whereas teens who struggle with self-regulation, such as those with conduct disorder, are less empathic than their peers (Cohen & Strayer, 1996). Moreover, considerable research indicates that secure adolescents are more effective at regulating their emotions than insecure adolescents, and use more adaptive forms of emotion regulation (e.g., Cooper, Shaver, & Collins, 1998; Kobak & Sceery, 1988; Zimmermann, Maier, Winter, & Grossmann, 2001).

In summary, the evidence suggests that securely attached adolescents are more empathic and prosocial than their insecurely attached counterparts, mirroring evidence from the adult literature (reviewed in the next section). More studies of this developmental period are needed, especially ones using non-self-report measures, to provide a more fully developed understanding of the role of secure attachment in adolescents' care for others.

Empirical Studies of Children and Adolescents: Discussion

Research to date provides moderate evidence for a link between attachment security and care for others in childhood. The majority of the empiri-

cal work has focused on preschool-age children, utilizing both adult report and observational measures in naturalistic and laboratory settings, with the weight of the evidence in favor of the hypothesized link. In early and middle childhood, studies have employed a wider variety of methods for assessing attachment and care for others and have yielded less conclusive findings. By the time children enter adolescence, however, the use of self-report measures provides a more direct, standardized methodology for tapping children's empathic and prosocial capacities. Accordingly, although studies with adolescents are few, they provide the most consistent support for an association between attachment security and concern for others before adulthood, and these studies offer a point of continuity with findings from the adult literature (Mikulincer & Shaver, 2005).

The inconsistent findings in the research on children merit exploration. Methodological differences across studies, sometimes as a result of child age, may account for some of the inconsistencies. Before the use of self-report measures becomes possible in adolescence, questionnaire measures of care for others alternately tap parents' and teachers' perceptions of children's apparent concern for peer distress, tendency to share with others spontaneously, helpfulness toward adults, or a combination of these. These reports are likely shaped in part by normative levels of care for others in the child's culture or social group, as well as reporter biases, such as teachers' esteem for more compliant children or parents' social desirability tendencies and the degree to which the parents hold prosocial values themselves. When observational measures are used, children's care for others may be influenced by contextual factors such as a child's relationship to the person in distress (e.g., sibling, peer, mother, teacher, experimenter), the presence of other individuals, the salience of emotional cues, and the setting in which observation occurs (e.g., classroom, playground, home, laboratory), which also may influence the degree of *felt* security the child experiences in the moment he or she witnesses others' distress. Both the variety of measures employed and the multiplicity of factors influencing children's emotions and behavior at any one moment are likely to give rise to variability in the data.

Beyond the diversity of measures used, a more fundamental distinction can be made between measures of care for others in the presence-absence of an emotional display (i.e., whether children are responding to distress or to a non-

emotional need, such as a bid for instrumental help). This is an important distinction to make when considering the role played by secure attachment in emotional development. Specifically, security fosters the development of cognitive and regulatory skills that support children's ability to respond to others' distress, such as emotion regulation and emotion understanding (e.g., Panfile & Laible, 2012), which may not play as large a role in children's prosocial response to nondistressed others. Whereas measures of empathy almost always exclusively involve response to emotion, several of the studies of prosocial behavior reviewed here, particularly studies using mother- and teacher-reports, simultaneously assessed children's ability to comfort or demonstrate compassion in response to distress, along with children's responses to instrumental or material needs (e.g., "helps clean up," "shares toys") in the absence of emotional stimuli. Given recent evidence that prosocial behavior is a multifaceted construct, and that comforting, sharing, and instrumental helping behaviors show unique developmental trajectories (Dunfield & Kuhlmeier, 2013), unique neural and parenting correlates (Brownell, Svetlova, Anderson, Nichols, & Drummond, 2013; Paulus, Kühn-Popp, Licata, Sodian, & Meinhardt, 2013), and few intercorrelations among types of prosocial behavior (e.g., Richman, Berry, Bittle, & Himan, 1988), these disparate forms of behavior may have differential relations with attachment. Perhaps, for example, comforting, which typically occurs within an emotional context, relates to secure attachment, whereas other forms of prosocial behavior do not.

An additional explanation for the inconsistent findings in studies of children concerns the possible nonlinear relation between attachment and care for others. Investigators of this topic have observed that children with secure attachment histories score neither extremely high nor extremely low on measures of care for others, and propose that middle scores may be optimal for young children (van der Mark et al., 2002). This may help to account for findings from some studies that the highest frequencies of empathic behavior were from children of severely depressed mothers or from single mothers who depended on their children as a source of comfort (Radke-Yarrow & Zahn-Waxler, 1984; Rehberg & Richman, 1989; Richman et al., 1988). Indeed, young children of depressed mothers are more likely to develop disorganized attachments, characterized by caregiving toward the mother and parent-child

role reversal (Teti, Gelfand, Messinger, & Isabella, 1995; Van IJzendoorn, Schuengel, & Bakermans-Kranenburg, 1999). Relatedly, Eisenberg and colleagues (1995) have argued that maintenance of a moderate, but nonaversive, level of emotional arousal is important for feeling sympathy in the absence of debilitating personal distress; it may be that attachment security helps maintain an optimal level of arousal, such that secure children neither avoid responding to others' distress nor engage in "compulsive caregiving" out of personal distress. Consideration of "compulsive caregiving" may also help to explain why insecure-resistant children sometimes do not show reduced prosocial behavior; for these children, providing care for others may serve as an adaptive strategy for maintaining closeness with others, even if the care is motivated by personal distress rather than genuine, attuned concern for others' welfare (for discussion of compulsive care and adult anxious attachment, see Bowlby, 1980; Feeney & Collins, 2001; Kunce & Shaver, 1994).

Another possibility is that the inconsistent findings are in part due to moderating factors such as parent socialization. As previously mentioned, although attachment and socialization are constructs from distinct theoretical frameworks and have unique pathways to care for others in childhood, there is some evidence that attachment and socialization interact to predict moral development (Kochanska et al., 2004). Security may provide a foundation upon which socialization can build a stronger ethic of care across development. When measured within the same study, the unique effects of attachment and socialization practices (e.g., elaborative discourse, response to distress, gentle discipline) may reveal a more complete and nuanced picture of the roots of care for others in childhood.

Finally, we cannot rule out the possibility that attachment does not, in fact, play a role in children's care for others, and that the links observed thus far are explained by other factors, such as parent socialization, genetics, child temperament, cultural or contextual influences, or interactions with teachers and peers. It may be that parents who use sensitive, warm discipline and reinforce prosocial behavior also use sensitive parenting more broadly, contributing to children's care for others and to secure attachment via independent pathways. Alternatively, there is some evidence that more empathic parents tend to have securely attached children (Oppenheim, Koren-Karie, & Sagi, 2001; Stern, Borelli, & Smiley, 2015), so it

may be that secure children learn to empathize simply by observing empathic adult models, or that empathy is transmitted from parent to child via genetic mechanisms (Knafo, Zahn-Waxler, Van Hulle, Robinson, & Rhee, 2008). It is also possible that children with high negative emotionality (i.e., a fearful temperament) elicit insensitive parental behavior and are more prone to personal distress, limiting their capacity to care for others. These and other pathways merit exploration as we consider new directions for research on the development of children's concern for others.

Caring for Others in Adulthood

Adult attachment researchers in the fields of personality and social psychology have tended to consider prosocial motives, emotions, and behaviors as related to the caregiving behavioral system proposed by Bowlby (1969/1982) in his effort to explain why parents (and also older children, as well as adults other than the parents) respond to an infant's, and indeed to any person's, needs for help, protection, or support (e.g., Mikulincer, Shaver, & Gillath, 2008; Shaver, Mikulincer, & Shemesh-Iron, 2010). Although this reliance on the caregiving system construct is not essential for studying links between attachment orientations and prosocial emotions and behavior (and was not emphasized in the previous section of this chapter), it has proved to be a useful way to conceptualize adults' responses to people in need. That is, caregiving is not only a primary ingredient of parental behavior but also a major part of romantic and marital relationships, and a key to all forms of prosocial behavior in adulthood.

An adult's caregiving behavior is related to his or her attachment orientation because the parameters of the attachment and caregiving systems are shaped by some of the same forces (most notably, parenting), and because attachment insecurity involves a degree of self-focus and self-protection that interferes with attention to others' needs (just as attachment insecurity interferes with curiosity and exploration in infancy, according to Ainsworth et al., 1978). The two major kinds of attachment insecurity, anxiety and avoidance, are therefore expected to have somewhat different implications for providing care and support to a person in need. Anxiety is associated with feelings of vulnerability and a focus on one's own negative feelings (in particular, what empathy researcher

Daniel Batson [1991, 2010] called “personal distress,” as distinct from empathy). Avoidance is associated with not feeling comfortable getting close to other people and attempting to avoid situations that interfere with personal independence (Mikulincer et al., 2008).

Theoretically, the goal of the caregiving system is to reduce other people’s suffering, to protect them from harm, and to foster their growth and development—in other words, to provide a safe haven and secure base for them (Collins, Ford, Guichard, Kane, & Feeney, 2010; B. C. Feeney & Woodhouse, Chapter 36, this volume; Mikulincer et al., 2008). According to Collins and colleagues (2010), the caregiving system is activated in two kinds of situations: (1) when another person has to cope with danger, stress, or discomfort and is either openly seeking help or would clearly benefit from it, and (2) when another person has an opportunity for exploration, learning, or mastery and either needs help in taking advantage of the opportunity or seems eager to talk about it or to be validated for having aspirations or achieving desired goals. In either case, once a person’s caregiving system is activated (whether appropriately or not), he or she calls on a repertoire of behaviors aimed at restoring or advancing another person’s welfare. This repertoire includes showing interest in the other person’s problems or goals; providing an open, accepting space in which the other person’s needs are heard; affirming the other’s competence and ability to cope with the situation; expressing love and affection; providing advice and instrumental aid as needed, without interfering with the person’s own problem-solving efforts or exploratory activities; and admiring and applauding the person’s successes.

Optimal functioning of the caregiving system requires psychological assets associated with attachment security, as explained throughout the earlier sections of this chapter—assets such as emotion regulation strategies that allow caregivers to deal effectively with the discomfort entailed by witnessing another person’s distress. Deficient emotion regulation can cause a caregiver to feel overwhelmed by personal distress, to slip into the role of another needy person rather than occupying the role of caregiver, or to maintain distance from the needy other as a way of reducing his or her own negative emotions. Optimal caregiving also requires effective self-regulation strategies beyond emotion regulation. Addressing another person’s problems often requires temporary suspension of one’s own goals and plans. Moreover,

one has to diagnose the other person’s problem, develop a plan for assisting the person sensitively and effectively, and suppress motives that interfere with effective helping. According to Collins, Guichard, Ford, and Feeney (2006), caregiving can be disrupted by social skills deficits, depletion of psychological resources, lack of a desire to help, and egoistic motives that interfere with empathic sensitivity.

Attachment Orientations and Patterns of Care

Bowlby (1969/1982) noticed that activation of the attachment system can interfere with the operation of the caregiving system because potential caregivers may feel that obtaining safety and care for themselves is more urgent than providing a safe haven or secure base for others. At such times, adults are likely to be so focused on their own vulnerability that they lack the mental resources necessary to attend sensitively to others’ needs. Only when a sense of security is restored can a potential caregiver perceive others as not only potential sources of security and support but also as worthy human beings who themselves need and deserve sympathy and support.

Reasoning along these lines, adult attachment researchers (e.g., Collins et al., 2010; Mikulincer et al., 2008) hypothesized that attachment security is an important foundation for optimal caregiving. Moreover, being *secure* implies (given the theory and the research reviewed in earlier sections of this chapter) that a secure person has witnessed, experienced, and benefited from his or her attachment figures’ effective care (with those figures being either parents or other important care providers), which provides a model to follow when the person comes to occupy the caregiving role. Because secure individuals are more comfortable with intimacy and interdependence (Hazan & Shaver, 1987), they can allow other people to approach them for help and express feelings of vulnerability and need (Lehman, Ellard, & Wortman, 1986). Secure individuals’ confidence about other people’s goodwill makes it easier for them to construe others as deserving sympathy and support, and their positive model of self allows them to feel more confident about their ability to handle another person’s needs while effectively regulating their own emotions and helping behavior.

Adults who are insecure with respect to attachment (i.e., are either anxious or avoidant, or both) are likely to find it difficult to provide ef-

fective care. Although those who suffer from attachment anxiety may have some of the qualities necessary for effective caregiving (e.g., willingness to experience and express emotions, and comfort with psychological intimacy and physical closeness), their deficits in self-regulation make them vulnerable to personal distress, which interferes with sensitive and responsive care. Their tendency to become sidetracked by self-focused worries, misplaced projections, and blurred interpersonal boundaries can interfere with focusing accurately on other people's pain and suffering. Moreover, attachment-anxious adults' lack of confidence can make it difficult for them to adopt the role of "stronger and wiser" pillar of support. In addition, their strong desire for closeness and approval may cause them to become intrusive or overinvolved, blurring the distinction between another person's welfare and their own.

Attachment-anxious individuals may use caregiving as a means of satisfying their own unmet needs for closeness, acceptance, and inclusion. According to Collins and colleagues (2010), these self-centered motives result in intrusive caregiving that is insensitive to a needy person's signals. Anxious people may try to get too close or too involved when an interaction partner does not want help, and this can generate resentment, anger, and conflict, which in turn leave the anxious person feeling unappreciated or falsely accused.

Avoidant adults' lack of comfort with closeness and negative working models of others may also interfere with optimal caregiving. Their discomfort with expressions of need and dependence may cause them to back away rather than get involved with someone whose needs are strongly expressed. As a result, avoidant individuals may attempt to detach themselves emotionally and physically from needy others, may feel superior to those who are vulnerable or distressed, or may experience disdainful pity rather than empathic concern (Mikulincer et al., 2008). In some cases, avoidant people's cynical or hostile attitudes and negative models of others may replace sympathy or compassion with *schadenfreude*, or gloating.

Providing Care in Parent–Child and Romantic Relationships

B. C. Feeney and Woodhouse (Chapter 36, this volume) reviewed studies of caregiving in parent–child relationships, demonstrating that parents' attachment orientations systematically affect their caregiving-related mental representations and be-

haviors (see also Jones, Cassidy, & Shaver, 2015a, 2015b). Secure parents find it easier to perceive their children's needs accurately and to respond sensitively and appropriately. Anxious parents tend to be anxious themselves, and their self-preoccupation and biased perceptions can cause them to miss or misread their children's needs and calls for help. Avoidant parents tend not to be comfortable with children's expressions of need, and they act in ways that lead their children to become more emotionally inhibited and self-reliant. Viewed in terms of empathy or kindness, these insecure parents' attitudes and behaviors are problematic.

In the romantic and marital domains, research and common sense both indicate that a person's ability and willingness to respond sensitively to a relationship partner's needs are major determinants of relationship quality (e.g., Collins & Feeney, 2000). Adult romantic love involves not only the attachment system, which helps maintain proximity to a relationship partner, but also the caregiving system, which motivates one partner to attend and respond to the other's needs (Shaver & Hazan, 1988). As a result, romantic and marital relationships provide good opportunities to discover how attachment patterns shape caregiving orientations. Many of the relevant studies are reviewed by B. C. Feeney and Woodhouse (Chapter 36, this volume); others are discussed in detail by Mikulincer and Shaver (2007a). These studies indicate that attachment insecurity interferes with compassion, empathy, and loving-kindness in couple relationships. A few examples are provided here.

For example, attachment security is associated with care provision by adult spouses of cancer victims—people who are clearly in need. Kim and Carver (2007) found that greater attachment security (assessed with self-report scales) was associated with more frequent provision of emotional support to a spouse with cancer. Attachment security was also associated with favorable motives for providing care, such as accepting the need for caregiving, feeling loving, and respecting the care recipient (Kim, Carver, Deci, & Kasser, 2008). As expected, attachment anxiety was associated with more self-focused motives for caregiving (e.g., providing care in order to be appraised as a good person). In another study, Braun and colleagues (2012) found that avoidant attachment was associated with less responsive and less sensitive care for a spouse with cancer, whereas anxious attachment was associated with more compulsive caregiving (insisting on care, being intrusive, failing to be sensitive to

the spouse's actual needs). This harks back to an early study by Kunce and Shaver (1994) in which anxious adults and their mates both agreed that the anxious adults' caregiving efforts tended to be unempathic, self-focused, and intrusive.

In two laboratory experiments, B. Feeney and Collins (2001) and Collins and colleagues (2010) provided a detailed analysis of avoidant and anxious adults' caregiving deficits. Dating couples were brought to a laboratory, and one member of the couple (the "care seeker") was informed that he or she would perform a stressful task—preparing and delivering a videotaped speech. The other couple member (the "caregiver") was led to believe that his or her partner was either extremely nervous (high-need condition) or not at all nervous (low-need condition) about the speech task, and was given the opportunity to write a private note to the partner. In both studies, the note was coded in terms of the degree of support it conveyed. In addition, the caregiver's attentiveness to the partner's needs was assessed by counting the number of times the caregiver checked a computer monitor for messages from the partner while the caregiver was working on a series of puzzles (in a separate room). To assess the caregiver's state of mind, Collins and colleagues added measures of empathic feelings toward the partner, rumination about the partner's feelings, willingness to switch tasks with the partner, partner-focused attention, and causal attributions regarding the partner's feelings. More avoidant participants wrote less emotionally supportive notes in both high- and low-need conditions, and provided less instrumental support in the high- than in the low-need condition, when the partner most needed support. Moreover, avoidant participants reported less empathy for their partner, were less willing to switch tasks with the partner, and were less distracted by thoughts about the partner while doing puzzles. More anxious participants were easily distracted by thoughts about their partner and reported relatively high levels of empathy and rumination, but failed to write more supportive notes as their partner's needs increased.

Because most such studies of attachment and caregiving in parent-child and adult couple relationships have been correlational rather than experimental, making it impossible to determine causality, Mikulincer, Shaver, Sahdra, and Bar-On (2013) conducted a study, in both the United States and Israel, to see whether *experimentally augmented security* ("security priming"; in this case, subliminal presentation of attachment figures' names) would improve care provision to a roman-

tic partner who was asked to discuss a personal problem. A second goal of the study was to see whether security priming could overcome barriers to responsive caregiving caused by mental depletion or fatigue. Couples came to a laboratory and were informed that they would be video-recorded during an interaction in which one of them (the care seeker) disclosed a personal problem to the other (the caregiver). Caregivers were taken to another room, where they performed a task that induced (or did not induce) mental fatigue, while also being subliminally exposed to either the names of security providers or the names of unfamiliar people. Following these manipulations, couple members were videotaped while talking about the care seeker's problem, and the recording was later coded to assess the caregiver's supportive or unsupportive behavior. As predicted, attachment security (security priming) was associated with greater sensitivity and responsiveness to the disclosing partner, and the priming overcame the detrimental effects of mental depletion on sensitive responsiveness.

Providing Care and Expressing Social Virtues in the Wider Social World

Empathy, Compassion, and Altruism

The discovery of connections between attachment orientation and caregiving in both the parent-child and romantic/marital domains led researchers to explore the possibility that attachment insecurity interferes with compassion toward suffering others, even if the sufferers do not belong to the caregiver's family. If all forms of loving-kindness draw from the same caregiving well, then contamination of that well by attachment-related worries and defenses is likely.

In fact, studies of adult attachment and prosocial attitudes and behavior do show that avoidant people score lower on diverse measures of prosocial reactions to other people's needs. For example, more avoidant adults report less empathic concern (e.g., B. Feeney & Collins, 2001; Joireman, Needham, & Cummings, 2002; Lopez, 2001; Wayment, 2006), less inclination to take the perspective of a distressed person (Corcoran, & Mallinckrodt, 2000; Joireman et al., 2002), less ability to share another person's feelings (Trusty, Ng, & Watts, 2005), less sense of communion with others, and less willingness to take responsibility for others' welfare (Collins & Read, 1990; Shaver

et al., 1996; Zuroff, Moskowitz, & Cote, 1999). Avoidant adults are also less likely to be cooperative and other-oriented (DeDreu, 2012; Hawley, Shorey, & Alderman, 2009; Van Lange, DeBruin, Otten, & Joireman, 1997), to write comforting messages to a distressed person (Weger & Polcar, 2002), to offer help to needy others in hypothetical scenarios (Bailey, McWilliams, & Dick, 2012; Drach-Zahavy, 2004), or to be sensitive to moral transgressions that can damage other people (Albert & Horowitz, 2009). Sommerfeld (2009) also found that more avoidant people (assessed with the ECR) were more likely to feel a sense of burden when acting generously.

With regard to attachment anxiety, research once again suggests a pattern of overinvolvement and intrusiveness during encounters with people in distress. In particular, although Lopez (2001) found a positive association between attachment anxiety and a measure of emotional empathy, people who score relatively high on measures of attachment anxiety also report higher levels of personal distress while witnessing others' suffering (Britton & Fuendeling, 2005; Joireman et al., 2002; Monin, Schulz, Feeney, & Clark, 2010; Vilchinsky, Findler, & Werner, 2010). Moreover, anxious adults score higher on a measure of unmitigated communion, which taps a compulsive need to help others even when they are not asking for assistance, and even when the help comes at the expense of one's own health and legitimate needs (Fritz & Helgeson, 1998; Shaver et al., 1996).

In an observational laboratory study, Westmaas and Silver (2001) videotaped people while they interacted with a confederate of the experimenter who, they thought, had recently been diagnosed with cancer. The authors found that both kinds of attachment insecurity created specific impediments to effective caregiving. As expected, avoidant participants were rated by observers as less verbally and nonverbally supportive and as making less eye contact during the interaction. Attachment anxiety was not associated with supportiveness, but more anxious participants reported greater discomfort while interacting with the confederate and were more likely to report self-critical thoughts after the interaction. These are signs of emotional overinvolvement and self-related worries, which can sometimes interfere with caregiving.

It is worth mentioning, however, that Ein-Dor and Orgad (2012) found that attachment-anxious people acted prosocially when a real danger threatened them and their group. In their

study, participants were led to believe that they accidentally activated a computer virus that erased an experimenter's computer. They were then asked to alert the department's computer technicians to the incident. On their way, they were presented with four decision points at which they could choose either to delay their warning or continue directly to the technicians' office. More anxious individuals (assessed with the ECR) were less willing to be delayed on their way to deliver a warning message. This finding fits with the "sentinel" mental script characteristic of attachment-anxious individuals (Ein-Dor, Mikulincer, & Shaver, 2011), which might automatically cause them to act prosocially in a dangerous situation by rapidly communicating the threat to others. Kogut and Kogut (2013) also found that attachment-anxious people tend to help others when they can identify with the help receiver or feel similar to or specially connected with him or her, probably thereby satisfying unmet needs for merger and love.

There is also evidence that the link between avoidant attachment and unhelpfulness can be mitigated in specific relational contexts. For example, Richman, DeWall, and Wolff (2015) found that when highly avoidant participants were convinced that helping would not increase closeness to the receiver of help or would not change their own emotions, they tended to help others as much as less avoidant participants; that is, by reducing the psychological linkage between helping and emotional closeness, Richman and colleagues reduced avoidant people's fears of becoming more intimate with the needy other, allowing them to act more prosocially toward him or her. This finding fits with our belief that avoidant people's reluctance to help others is in part due to attachment system deactivation and a preference for emotional distance rather than intimacy.

In an influential study of adolescents that spurred similar research with adults, McKinney (2002) found that those who were insecurely attached to their parents were less involved than more securely attached adolescents in voluntary altruistic activities, such as caring for older adults or donating blood. Gillath, Shaver, Mikulincer, Nitzburg, and colleagues (2005) extended this line of research by assessing young adults' motives for volunteering in their communities. Avoidant attachment was associated with engaging in fewer volunteer activities; among those who did volunteer, avoidance was associated with being involved for less altruistic reasons. Attachment anxiety was not directly related to engaging in volunteer ac-

tivities per se, but it was associated with more egoistic reasons for volunteering (e.g., hoping to be socially accepted and receive approval), another indication of anxious people's self-focus. These findings were replicated in a subsequent study with Dutch students (Erez, Mikulincer, Van IJzendoorn, & Kroonenberg, 2008). In all of these studies, more avoidant adults were less likely to volunteer.

Insecure people's relative lack of a prosocial orientation is also manifested in career choice. Using the AAI to measure adult attachment, Horppu and Ikonen-Varila (2004) found that insecure students at a college for kindergarten teachers endorsed less altruistic, less prosocial motives for becoming teachers, compared with more secure students. Similarly, Roney, Meredith, and Strong (2004) found that less secure occupational therapy students (identified with self-report scales) were less likely to say they chose a therapeutic career because they wanted to help people. In a sample of medical students, Ciechanowski, Russo, Katon, and Walker (2004) found that less secure students (based on self-report scales) were more likely not to choose primary care specialties because primary care demands intense patient-physician relationships that can cause patients to become emotionally attached to their physician.

Recently, a number of investigators have examined the effects of security priming on feelings and attitudes toward needy people. For example, Bartz and Lydon (2004) primed attachment-related mental representations by asking people to think about a close relationship in which they felt either secure, anxious, or avoidant, then assessed the implicit and explicit activation of communion-related thoughts (thoughts about devoting oneself to others and maintaining supportive and warm interactions with them). Implicit activation was assessed in a word fragment completion task (which identified the number of word fragments completed with a communion-related word); explicit activation was assessed with the Communion scale of the Extended Personality Attributes Questionnaire. Contextual priming of representations of avoidant attachment led to lower levels of implicit and explicit communion-related thoughts than did contextual priming of secure attachment.

Along the same lines, Mikulincer and colleagues (2001, Study 1) performed an experiment assessing compassionate responses to others' suffering. Dispositional attachment anxiety and avoidance were assessed with the ECR scales, and a sense of attachment security was activated in one condition by having participants read a story about

support provided by a loving attachment figure. This condition was compared with the activation of neutral or positive affect. Following the priming procedure, all participants read a brief story about a student whose parents had been killed in an automobile accident and rated how much they experienced compassion and personal distress when thinking about the distressed student. As expected, dispositional attachment anxiety and avoidance were inversely related to compassion, and attachment anxiety (but not avoidance) was positively associated with personal distress. In addition, enhancement of attachment security, but not enhancement of positive affect, strengthened compassion and inhibited personal distress in reaction to others' distress. These findings were replicated in four additional studies (Mikulincer et al., 2001, Studies 2-5).

In another set of three experiments, Mikulincer, Gillath, and colleagues (2003) found theoretically predictable attachment-related differences in value orientations. Avoidant attachment, assessed with the ECR, was inversely associated with endorsement of two self-transcendent values, benevolence (concern for close others) and universalism (concern for all humanity), supporting our notion that avoidant strategies interfere with concern for others' needs. In addition, experimental priming of mental representations of attachment figure availability, as compared with enhancing positive affect or exposing participants to a neutral priming condition, strengthened endorsement of these two prosocial values. The findings fit well with Van IJzendoorn and Zwart-Woudstra's (1995) discovery that secure attachment (assessed with the AAI) is associated with more humanistic moral reasoning. The conclusion is further supported by Clark and colleagues' (2011) findings that contextual priming of attachment security reduced the endorsement of materialistic values and decreased the importance people assigned to material objects.

Mikulincer, Shaver, Gillath, and Nitzberg (2005) examined the effects of security priming on the actual decision to help or not to help a person in distress. In the first two experiments, participants watched a confederate (an actress) while she performed a series of increasingly aversive tasks. As the study progressed, the confederate became increasingly distressed by the aversive tasks, and the actual participant (who was merely an observer) was given an opportunity to take the distressed person's place, thereby self-sacrificing for the benefit of the distressed confederate. Shortly before

the scenario just described, participants had been exposed to a series of security or neutral primes subliminally (rapid presentation of the name of an attachment figure or a neutral control person) or supraliminally (vividly recalling an interaction with a supportive person), or in the control condition (recalling a neutral person). At the point of making a decision about replacing the distressed confederate, participants completed brief measures of compassion and personal distress. In both studies, dispositional avoidance was related to lower reported compassion and lower willingness to help the distressed confederate. Dispositional attachment anxiety was related to self-reported personal distress but not to either compassion or willingness to help. In addition, subliminal or supraliminal priming of representations of a security-providing figure decreased personal distress and increased participants' compassion and willingness to take the place of the distressed confederate.

In two additional studies, Mikulincer and colleagues (2005, Studies 3–4) examined whether the contextual bolstering of attachment security overrides egoistic motives for helping, such as mood enhancement (Schaller & Cialdini, 1988) or empathic joy (Smith, Keating, & Stotland, 1989), and results in genuinely altruistic (unselfish) helping. Participants were divided into two conditions (security priming, neutral priming), read a true newspaper article about a woman in dire personal and financial distress, and rated their emotional reactions to the article (compassion and personal distress). In one study, half of the participants anticipated mood enhancement by means other than helping (e.g., expecting to watch a comedy film). In the other study, half of the participants were told that the needy woman was chronically depressed and her mood might be beyond their ability to repair (*no empathic joy* condition). Schaller and Cialdini (1988) and Smith and colleagues (1989) had found that these two conditions, expecting to improve one's mood by other means or anticipating no sharing of joy with the needy person, reduced egoistic motives for helping because a potential helper would gain no mood-related benefit from helping. However, these conditions failed to inhibit altruistic motives for helping when helping was augmented by security priming. The security-supported increased willingness to help seemed to be genuinely unselfish. These findings support our theoretical view that a sense of attachment security reduces selfishness (defensive self-protection) and allows a person to activate his or her caregiving behavioral

system, direct attention to others' distress, take the perspective of a distressed other, and engage in altruistic behavior with the primary goal of benefiting the other person.

Generosity

Generous actions are among the building blocks of positive and stable social relations. However, although extensive theoretical and empirical work has been devoted to the study of empathy, compassion, and altruistic helping in adults, there is little systematic research on acts of generosity, the subjective experiences of people when they act generously, or the associations of these experiences with attachment orientations. One preliminary exploration (Sommerfeld, 2009) involved the development of the Experience of Generosity Questionnaire, a measure of the extent to which adults are prosocially oriented when acting generously or feel a sense of burden, self-criticism/guilt, or self-congratulation when being "generous." Sommerfeld (2009) examined associations between these experiential aspects of generosity and ECR attachment insecurity scores (anxiety and avoidance). She found that attachment anxiety was associated with greater feelings of personal burden and self-criticism/guilt, whereas avoidance was associated with a less prosocial orientation, in addition to feelings of personal burden. Much more research is needed on attachment and generosity.

Gratitude

Gratitude has been portrayed in the psychological literature in diverse ways: as a positive emotion, as a personality trait, as a positive attitude toward others, as a moral virtue, and as a constructive approach to interpersonal relations (Emmons & McCullough, 2003; Weiner, 1985). Emmons and McCullough (2003) proposed that gratitude be conceptualized in terms of three propositions. First, the object of gratitude is always an "other," whether a human being, a nonhuman natural being (e.g., an animal, the weather), or a supernatural being (e.g., God). Second, gratitude is a response to a perceived personal benefit (e.g., a material, emotional, or spiritual gain) resulting from another's actions—a benefit that has not necessarily been earned or deserved. Third, gratitude stems from appraising the benefactor's actions as intentionally designed to benefit the recipient, even if the intention is metaphorical, as

in the case of good weather (“Thank you for not raining on my parade”). According to Lazarus and Lazarus (1994), gratitude results from recognizing another’s goodwill and appreciating the other’s generous action as an altruistic gift. Agreeing with this conception, Tsang (2006) defined *gratitude* as “a positive emotional reaction to the receipt of a benefit that is perceived to have resulted from the good intentions of another” (p. 139).

In Peterson and Seligman’s (2004) taxonomy of human strengths and virtues, the capacity for gratitude is viewed as a core strength that improves people’s well-being and mental health (Snyder & McCullough, 2000). Similarly, Emmons and McCullough (2003) portrayed gratitude as a remedy for many of life’s hardships and as a way to achieve peace of mind, happiness, and satisfying interpersonal relationships. In line with this view, Watkins, Woodward, Stone, and Kolts (2003) found that grateful people tend to experience greater “abundance” in their lives, feel more thankful to other people for contributions to their personal well-being, and are more likely than other people to appreciate even the small pleasures in life. Moreover, the expression of gratitude to a generous relationship partner has been found to have beneficial effects on relationship satisfaction, emotional and physical closeness, and positive appraisals of the partner (e.g., Algoe, Gable, & Maisel, 2010; Algoe & Haidt, 2009; Lambert, Clark, Durtschi, Fincham, & Graham, 2010).

From an attachment perspective, the experience of gratitude can be expected to be associated with feelings of being protected, accepted, and valued by others. Warm, comforting interactions with a sensitive, responsive, and supportive caregiver during childhood foster not only positive mental representations (working models) of others but also a feeling that one has received a gift that “keeps on giving” (as advertisers sometimes boast). This feeling makes it easier, in later phases of life, to feel grateful for other people’s kindness and generosity. In other words, attachment security can be expected to correlate with dispositional gratitude. In contrast, attachment-related avoidance may constrict feelings of gratitude in response to others’ generous behavior because avoidant people tend to doubt other people’s good intentions. Moreover, expressions of gratitude toward a relationship partner can be interpreted as a sign of closeness or dependence, which is inconsistent with avoidant people’s preference for emotional distance.

Attachment anxiety may lead to ambivalent reactions to others’ generous behavior. People who

score high on attachment anxiety tend not to believe they deserve others’ kindness and worry that they will not be able to reciprocate adequately or meet a generous person’s needs and expectations (Mikulincer & Shaver, 2007a). This, in turn, may taint gratitude with anxiety. In addition, for attachment-anxious people, positive interpersonal experiences may be reminiscent of previous experiences that began well but ended poorly. Once attuned to negative memories, the anxious mind suffers from a spread of negative affect (Mikulincer & Orbach, 1995), which is likely to interfere with genuine gratitude.

In two studies, Mikulincer, Shaver, and Slav (2006) explored links between attachment scores and feelings of gratitude toward a generous relationship partner. The first study was cross-sectional and correlational; it indicated that secure participants scored higher on a dispositional measure of gratitude than avoidant participants and reported more feelings of security, happiness, love, and generosity—and fewer feelings of narcissistic threat and distrust—when feeling grateful. Attachment anxiety was not significantly associated with dispositional gratitude, but it was associated with a more ambivalent experience of gratitude. People who scored higher on attachment anxiety recalled experiencing security-related feelings (e.g., “I felt there was someone who cared for me”), happiness, and love, together with narcissistic threats and inferiority feelings (e.g., “I felt weak and needy”), which seemed to mar the otherwise positive experience of gratitude.

In a second study (Mikulincer et al., 2006), newlywed couples (both husbands and wives) completed a daily questionnaire each evening for 21 days. In it, they listed positive and negative behaviors exhibited by their partner on a given day and rated the extent to which they felt grateful toward the partner that day. For both husbands and wives, attachment security predicted higher levels of daily gratitude across the 21-day period. Moreover, more secure husbands reported greater gratitude on days when they perceived more positive spousal behavior, whereas more avoidant husbands reported relatively low levels of gratitude even on days when they noticed their wife’s positive behavior.

Attachment insecurities also seem to interfere with the positive effects that gratitude normally has on prosocial behavior. Mikulincer and Shaver (2009) randomly assigned undergraduates to a gratitude condition (“Think about the many things in life for which you might feel grateful”)

or a control condition (“Think about your typical day”). They then measured the extent to which participants helped an experimenter’s confederate, who asked them to complete a cognitively taxing problem-solving survey. The major dependent variable was the time spent working on the survey. The results indicated that participants in the gratitude condition spent more time helping with the survey than did participants in the control condition, and more anxious and/or avoidant participants spent less time helping. However, these effects were qualified by significant interactions between gratitude and attachment insecurity scores: The gratitude exercise led to more helping behavior than the control condition mainly when participants scored relatively low on anxiety and/or avoidance. The prosocial effect of gratitude was lower when attachment anxiety or avoidance was relatively high.

Overall, research findings reported thus far suggest that gratitude and its links with prosocial behavior are complex and moderated by attachment orientations. It seems relatively easy for a secure person to feel grateful, especially after being rewarded by someone else. It is difficult for an insecure person to be unambivalent about receiving a benefit from another person, and to pass the benefit along to someone else. To an important extent, gratitude depends on feeling loved, valued, supported, and cared for, both in the moment and over the years.

Forgiveness

Forgiveness is often key to maintaining relational harmony and affectional bonds following conflicts, offenses, and transgressions in relationships (e.g., Fincham & Beach, 2010; Gordon, Hughes, Tomcik, Dixon, & Litzinger, 2009; Karremans & Van Lange, 2004). In addition, forgiveness contributes to positive emotions toward an offending other, to intimacy and emotional closeness, and to relationship satisfaction and stability (e.g., Finkel, Rusbult, Kumashiro, & Hannon, 2002). Moreover, the ability to forgive is related to psychological and even to physical well-being (e.g., Karremans, Van Lange, Ouwerkerk, & Kluwer, 2003). However, forgiveness is not an automatic response to another person’s offenses and transgressions. It often requires a transformation (or what Rusbult, Verette, Whitney, Slovik, & Lipkus, 1991, called “accommodation”) of interpersonal motives—containment of angry feelings and regulation of the impulse to act destructively,

while finding a constructive way to overcome an impasse created by another person’s hurtful behavior (e.g., McCullough, 2000). According to McCullough, Worthington, and Rachal (1997), forgiveness requires “a set of motivational changes, whereby one becomes decreasingly motivated to retaliate against and maintain estrangement from an offending relationship partner and increasingly motivated by conciliation and goodwill for the offender, despite the offender’s hurtful actions” (pp. 321–322).

From an attachment perspective, the motivational transformation involved in forgiving an offending other is likely to be facilitated by attachment security. Secure people are confident of others’ availability and love, view others as generally trustworthy and dependable, and believe in others’ goodwill (Shaver & Hazan, 1993). In addition, secure people have been found to provide more benign explanations for others’ hurtful actions and attribute them to less intentional and less stable causes. Therefore, they are more inclined to forgive. In contrast, avoidant individuals are likely to be less forgiving because they possess negative working models of others and tend to attribute others’ objectionable behavior to bad intentions.

In the case of individuals who score high on attachment anxiety, reactions to others’ offending behavior are likely to be influenced by two conflicting forces. On the one hand, their inclination to intensify negative emotions and ruminate about threats should fuel intense and prolonged bouts of anger toward an offending other, thereby interfering with forgiveness. On the other hand, such people’s fears of rejection and separation may cause them to suppress or hide resentment and anger and incline them toward self-protective forgiveness. This kind of forgiveness might be accompanied by recurrent intrusive thoughts about the transgression and heightened doubts about others’ availability and dependability. In other words, although attachment anxiety may not preclude forgiveness, it may engender ambivalence about forgiveness and therefore reduce its relational and personal benefits.

Correlational evidence indicates that attachment anxiety and avoidance are in fact associated with lower scores on measures of dispositional forgiveness (e.g., Burnette, Taylor, Worthington, & Forsyth, 2007; Kachadourian, Fincham, & Davila, 2004; Lawler-Row, Younger, Piferi, & Jones, 2006; Mikulincer et al., 2006; Yármoz-Yaben, 2009). Moreover, Mikulincer and colleagues (2006) found that less secure people were more inclined

to report intense feelings of vulnerability or humiliation and a strong sense of relationship deterioration when forgiving a partner. In other words, attachment insecurities were associated with a less constructive experience of forgiveness. Burnette, Davis, Green, Worthington, and Bradfield (2009) provided evidence concerning the potential mediators of such effects: Whereas the link between attachment anxiety and reduced forgiveness was mediated by excessive rumination on relational injuries, the link between avoidance and reduced forgiveness was mediated by lack of prosocial attitudes.

In a diary study of daily fluctuations in the tendency to forgive a spouse, Mikulincer and colleagues (2006) found that attachment insecurities predicted lower levels of forgiveness across 21 consecutive days. Moreover, whereas secure people were more inclined to forgive their spouse on days when they perceived more positive spousal behavior, less secure people reported little forgiveness even on days when they perceived their spouse to be available, attentive, and supportive. In other words, attachment insecurities not only prevented forgiveness but they also interfered with the ability of a partner's positive behavior to restore understanding and empathy.

Beyond these associations between dispositional measures of attachment and forgiveness, there is increasing evidence that state-like senses of security or insecurity can alter the tendency to forgive a hurtful partner. For example, Finkel, Burnette, and Scissors (2007) experimentally enhanced attachment anxiety or measured its natural weekly fluctuations for 6 months and found that heightened attachment anxiety reduced forgiveness for a partner's offenses. In addition, Hannon, Rusbult, Finkel, and Kumashiro (2010) found that a betraying partner's provision of security to the injured partner (by genuinely expressing interest in being responsive to the victim's needs) promoted forgiveness and restoration of relational harmony. Karremans and Aarts (2007) found that security priming (with the name of a loving other) elicited more automatic forgiving responses to interpersonal offenses than neutral priming.

In a series of experimental and longitudinal studies, Luchies, Finkel, McNulty, and Kumashiro (2010) showed that situational *felt security* (the extent to which a partner is perceived to be responsive and able to provide a sense of security and stability) is a prerequisite for the beneficial effects of forgiveness. For example, they found that the association between marital forgiveness and

heightened self-respect over the first 5 years of marriage depended on the extent to which spouses appraised their partners as safe and responsive. Moreover, the positive effects of forgiveness on self-respect and self-concept clarity following an experimentally induced hurtful relational episode depended on the perpetrator's expression of genuine interest in being responsive to the victim's needs. Overall, these findings imply that, under insecurity-heightening circumstances, forgiveness negatively affects feelings about oneself, which may help to explain why dispositionally insecure people are often reluctant to forgive an offending partner.

Empirical Studies of Adults: Discussion

Based on only the relatively small sample of studies of adult attachment and caregiving reviewed here (for a fuller treatment, see Mikulincer & Shaver, 2007a), a clear and quite general pattern emerges. Adults who score high on self-report measures of attachment anxiety have difficulty caring for another person without becoming personally distressed in an unproductive manner, often because they are more focused on their own needs and sense of vulnerability than on the needs of a person who needs their help. They are lacking not in empathy but in what Buddhists call *effective compassion*, which goes beyond empathy to include "skillful" action. Attachment-anxious adults' ineffective compassion is evident in parent-child relationships, romantic/marital relationships, and interactions with peers and strangers. Their failure to take effective action is also affected by their somewhat negative models of self, which includes a sense of poor self-efficacy. It is worth mentioning, however, that although anxious adults' heightened sensitivity to threats (to self) often results in poorly timed or poorly considered efforts to help others, their heightened vigilance can sometimes benefit members of the groups to which they belong because their ability to detect threats can sometimes save their own and other people's lives (Ein-Dor, Mikulincer, Doron, & Shaver, 2010; Ein-Dor et al., 2011).

Adults who score high on self-report measures of attachment-related avoidance are quite different. They are generally less empathic, less compassionate, and less willing to help others. They are often uncomfortable with other people's reliance on them, especially if it requires close physical or emotional contact or prolonged assistance. At the group level, however, their self-preoccupation,

and what Bowlby (1969/1982) called their “compulsive self-reliance,” can sometimes make them quick to figure out, in a threatening situation, how to escape or save themselves, and this can provide a useful model for other members of their group to escape danger (Ein-Dor et al., 2010, 2011).

Both anxious and avoidant adults are capable of feeling and being generous, grateful, and forgiving, but their versions of these feelings are often colored by qualifications, such as feeling depleted, “ripped off,” or overly obligated. Underlying such complicated forms of what would otherwise be positive feelings is a sense of insecurity, doubts about one’s own value to others, and fear of vulnerability.

To date, an advantage of the literature on adult care is the relative ease of conducting experimental studies involving various kinds of security priming: guided imagery or recall of being treated well by attachment figures; pictures of attachment figures’ faces; subliminal stimulation with attachment figures’ names or words such as *being loved*, *hug*, *support*, or *affection* (Mikulincer & Shaver, 2007a, 2007b). This adds considerably to the huge volume of correlational research, which indicates that self-reported individual differences in security, anxiety, and avoidance are associated strongly with many questionnaire and behavioral measures of empathy, compassion, gratitude, and forgiveness. Activating an adult’s network of mental associations related to security (associations that are both cognitive and affective) increases prosocial feelings and motivates prosocial behavior. Fewer studies have been conducted with “insecurity primes,” but those studies show that being reminded of insecurity (e.g., memories of past rejections and hurt feelings) reduces empathy and prosocial behavior. Taken in combination with the developmental studies of children and adolescents reviewed earlier in this chapter, the adult studies offer convincing evidence that attachment security and insecurity influence a wide range of prosocial motives, feelings, and behaviors.

Future Directions

Despite the impressive size of the literature reviewed in this chapter, indicating that attachment orientations are related to various aspects of concern for others, there are still many needs and possibilities for future research. Because our large sections on attachment and care in childhood and

attachment and care in adulthood are somewhat different in focus and methods (because of the different developmental levels of the research participants, requiring different verbal and nonverbal measures, and the different social contexts in which they live; with parents, in university communities, in homes with their spouses, etc.), we consider future directions separately for the two large research domains.

Future Directions for Research on Attachment and Prosocial Phenomena in Childhood

Existing research and its limitations indicate that the field is ripe for further investigation of the link between attachment security and the development of care for others in childhood, when these capacities are first coming online and there is the greatest opportunity to influence their development in the next generation. To do this, a first priority is to improve the sensitivity and specificity of measures used to assess care for others at different developmental stages. When operationalizing constructs, researchers should delineate clear boundaries around empathy and prosocial behavior, so that the unique developmental antecedents and consequences of each can be identified. Further insights may be gained by measuring specific dimensions of both constructs. For example, it may be important to assess both cognitive aspects of empathy (e.g., emotion recognition and understanding, perspective taking) and its affective aspects (e.g., emotional resonance, compassion, concern). Similarly, future research should consider specific dimensions of prosocial behavior such as sharing, helping, and comforting behaviors, verbal versus nonverbal responses, the relative success or effectiveness of prosocial overtures, and whether they occur in the presence or absence of emotional stimuli.

Central to the pursuit of valid measures of care for others is observational research in the home, neighborhood, and school, as well as in laboratory settings. Research has shown that responses to hypothetical situations (e.g., to imagine donating to someone in need) do not always map onto actual behavior (e.g., Ajzen, Brown, & Carvajal, 2004). For example, although children may know that they should share a prized teddy bear with a child who has no toys, they may not do so when faced with the immediate conflict between their own desires and another’s needs. Observational measures used to study the normative

development of children's empathy and prosocial behavior provide creative and ecologically valid tools that can be extended to the study of attachment-related individual differences. These include home-based observations of children's reactions to naturalistic and simulated distress (e.g., Zahn-Waxler, Radke-Yarrow, et al., 1992); laboratory situations in which an adult experimenter displays needs that differentially call for helping, sharing, and comforting (e.g., Dunfield & Kuhlmeier, 2013); and tasks that isolate specific motives (e.g., sympathy vs. seeking social rewards) underlying prosocial behavior (e.g., Hepach et al., 2013a). In addition, observational paradigms used with adults, such as donating behavior and willingness to help a distressed confederate (e.g., Mikulincer & Shaver, 2005), have been used successfully with children (e.g., Benenson, Pascoe, & Radmore, 2007) and provide other valid approaches to the study of attachment-related individual differences in care for others in childhood.

Exploring potential interactions of empathy with other mental capacities such as emotion regulation, theory of mind, and social information processing may illuminate connections that help to explain the development of care for others. Moving beyond cross-sectional, correlational studies toward intervention and longitudinal designs may shed light on questions of continuity and change, sensitive periods, and the temporal sequence of this link. For example, research examining the effects of attachment interventions such as the Circle of Security (Hoffman, Marvin, Cooper, & Powell, 2006) on children's empathy and prosocial behavior may illuminate whether enhancing security might support the development of greater capacities for extending care to others beyond the parent-child relationship.

Furthermore, priming studies of the kinds developed by researchers studying adult attachment provide a promising paradigm for investigating causal pathways in the short term. It is reasonable to hypothesize that experimental priming of attachment security in children will enhance their empathy and prosocial behavior given evidence of this link in the adult literature. Indeed, one study by Over and Carpenter (2009) demonstrated that subliminal priming of affiliation (i.e., a picture of two dolls facing each other) significantly enhanced 18-month-old children's spontaneous helping toward an experimenter who had dropped her pencils. In adult samples, however, attachment priming has been shown to have specific effects beyond those of affiliation in enhancing

empathy and willingness to help a distressed other (Mikulincer et al., 2005). It remains to be seen whether attachment priming has similarly unique effects beyond affiliation in children.

Alongside developmental questions regarding individual differences, future research may be informed by the recent upsurge of creative methods used to examine the normative development of human altruism, which have shed light on contextual, motivational, and evolutionary factors influencing children's care for others (e.g., Warneken & Tomasello, 2009). For example, evidence suggests that toddlers sympathize with and are motivated to help victims of harm, even when the victims show no emotion, suggesting that children's early perspective taking and understanding of harm support their care for others, even in the absence of distress cues (Vaish, Carpenter, & Tomasello, 2009). It may be that the link between attachment and children's care for others is moderated by whether harm occurs in the presence or absence of emotional distress. A study of 5-year-olds demonstrated that children show the bystander effect made famous by social psychologists (Darley & Latane, 1968), helping at high levels when alone but less often when others are available to help (Plötner, Over, Carpenter, & Tomasello, 2015). Attachment security may moderate children's susceptibility to the bystander effect. Other research has shown that children are more prosocial following reciprocal (vs. simply friendly) social interactions with an adult (Barragan & Dweck, 2014) and following synchronous music making (Kirschner & Tomasello, 2010), suggesting that responsive, coordinated social interactions experimentally boost children's care for others. On one level, attachment security involves similar experiences of responsivity and mutual coordination; however, questions remain regarding how specific the role of caregiver-child interactions may be in promoting children's concern for others. Future investigations may benefit from drawing on the novel methods and context-specific paradigms in the emerging literature on child altruism to illuminate the nature of attachment-related individual differences.

In addition, it will be important to continue the search for further mechanisms underlying the link between security and care for others. For example, it may be that security reduces attention to threat to oneself, which allows children to shift mental resources away from the self and toward others in need (as described in this chapter in relation to adults). Examining the parameters of

the automatic nature of some prosocial behavior should also prove useful. Alternatively, security may foster openness to emotional pain and vulnerability (Cassidy, Shaver, Mikulincer, & Lavy, 2009), such that others' suffering need not be defensively excluded. One particularly interesting avenue to explore is the biological basis of the ways in which attachment gets "under the skin" (in this volume, see Polan & Hofer, Chapter 6, and Ehrlich, Miller, Jones, & Cassidy, Chapter 9), and how, in turn, this may influence the capacity to care for others who are suffering. A viable starting point may be to examine the role of oxytocin in the development of children's concern for others, as it has been implicated in attachment and pair bonding (Carter, 1998; Feldman, Weller, Zagoory-Sharon, & Levine, 2007; Young & Wang, 2004), parenting (Bakermans-Kranenburg & Van IJzendoorn, 2008; Feldman et al., 2012; Galbally, Lewis, Van IJzendoorn, & Permezel, 2011), empathy (Bartz et al., 2010; Hurlemann et al., 2010), and altruistic behavior (De Dreu et al., 2010; Zak, Stanton, & Ahmadi, 2007). (See also Hane & Fox, Chapter 11, this volume.) These mechanisms likely interact with emotion regulation in linking security and concern for others.

Pursuing further research along these lines has broader implications for attachment theory. Specifically, a better understanding of attachment-related differences in children's care for others may prove useful in illuminating key processes involved in the intergenerational transmission of attachment. In parents, self-reported attachment security has been linked to their own enhanced emotion regulation capacities, which in turn are associated with parents' more empathic responses to their children's distress (Jones, Brett, Ehrlich, Lejuez, & Cassidy, 2014). A similar model may apply to children, whereby attachment security in childhood supports the development of both emotion regulation capacities and the capacity to care for others, so that, in adulthood, secure individuals are able to extend such care to their own children in the form of sensitive, empathic parenting. Indeed, evidence suggests that empathy and prosocial behavior early in development are carried forward into adulthood (Eisenberg et al., 2002), that adults' empathic concern is positively related to retrospective accounts of their parents' sensitive responses to their distress in childhood (Kanat-Maymon & Assor, 2009), and that parental empathy mediates the link between parent and child attachment security (Stern et al., 2015). Assembling the pieces of the intergenerational puzzle

calls for future longitudinal work on attachment and concern for others across the lifespan.

More broadly, there is a need for a positive psychology of children—encompassing virtues such as compassion, gratitude, mindfulness, and forgiveness (e.g., Froh et al., 2011; Greenberg & Harris, 2012)—that includes the potential influence of attachment. The extensive and exciting findings reported in the adult literature provide an avenue for similar exploration in childhood, with the creative adaptation of existing measures, as well as the development of new paradigms and methods for enhancing concern for others in the short and long term. We echo Greenberg and Turksma's (2015) call for leveraging the unique insights from developmental research to foster kindness and empathy in homes, neighborhoods, and schools, and add that these efforts likely need to be rooted in secure human relationships if they are to be effective, sustainable, and transmitted to the next generation. Understanding the developmental roots of care for others in childhood is central not only to attachment research but also to the broader goal of cultivating a kinder, more compassionate society.

Future Directions for Research on Attachment and Prosocial Phenomena in Adulthood

As demonstrated in this chapter, there is extensive evidence linking attachment security and two major forms of insecurity (attachment anxiety and avoidance) with prosocial motives, emotions, and behavior. The connections between attachment and prosociality have been demonstrated in the laboratory and in the community, using both correlational and experimental designs. It is now important to branch out in new directions.

One rich source for new studies would be a search for both mediating and moderating factors. In particular, future studies should examine times and situations in which secure attachment fails to promote prosocial behavior as well as the conditions that may favor prosocial behavior among insecure people. The priming studies conducted thus far clearly indicate that security can be heightened temporarily by priming. It has been assumed that longer-term priming (1) would produce stronger and more lasting effects on mental and behavioral processes, and (2) might be similar to what happens naturally in security-enhancing close relationships with friends, romantic partners, mentors, leaders, or therapists. But more work is needed to

explore the process of security enhancement in real-world relationships and to determine whether that kind of natural security enhancement results in increased empathy and care for other people. If it does have this bonus benefit, it will be important to learn how the effects are mediated (e.g., through changes in working models of self, such as increased self-esteem and self-efficacy, or changes in working models of others, such as formerly avoidant individuals changing their critical, skeptical working models of others).

In addition, research should examine how cultural settings and variables moderate the link between attachment and prosocial behavior given that physical and cultural settings can shape cognitive representations of people and relationships. For example, although there is evidence to suggest that security priming attenuates hostile attitudes toward outgroup members, even among groups engaged in years of intractable conflict (Mikulincer & Shaver, 2001, 2007c), one pilot study found that more secure Palestinians living in the territories occupied by Israeli soldiers were more, rather than less, hostile toward Israeli Jews and more accepting of violence against them (Mikulincer & Shaver, 2007c). Thus, although the pursuit of the possible benefits of psychological security enhancement is promising, the assumption that security and pacifism are synonymous would be faulty. Achieving a world at peace requires humane ethics, a more tolerant cultural and educational climate, and good judgment and effective political will on the part of leaders, not just securely attached individual citizens.

Because of the growing emphasis in adult attachment research on physiological and neurological underpinnings (in this volume, see Coan, Chapter 12, and Hane & Fox, Chapter 11), it will be important to explore further how the brain and various hormones underlie the link between attachment orientations and prosocial behavior. There are already numerous studies showing that self-reported anxiety and avoidance are related to various neurophysiological processes (e.g., reactions to social rejection; DeWall et al., 2012; Gil-lath, Bunge, Shaver, Wendelken, & Mikulincer, 2005). The next step would be to extend these studies into the realm of prosocial emotions and behavior.

Bowlby (1969/1982) viewed attachment and caregiving as two innate behavioral systems, both of which evolved because they increased the likelihood that primate (including human) infants would survive in a world of full of danger,

despite these infants' immaturity at birth. The attachment and caregiving behavioral systems presumably develop throughout life as a function of experiences in important relationships, and by the time adults enter psychological studies, their dispositional attachment and caregiving orientations, although not identical or totally unified, are clearly intertwined. In adult attachment research, prosocial emotions and behavior have generally been viewed as aspects of the caregiving system, but in the child attachment literature, less attention has been given to the concept of a developing caregiving system. Ideally, future research would involve measurement of both the attachment and the caregiving systems and then would determine, using longitudinal designs, how the two influence each other over time, and how each is influenced, separately or simultaneously, by social experiences of various kinds, with parents, other caregivers, teachers, coaches, and so on.

There might be other kinds of influences worth assessing, such as books, films, television series, and religious practices. Granqvist, Mikulincer, and Shaver (2010; see also Granqvist & Kirkpatrick, Chapter 39, this volume), for example, have reviewed literature showing that religious figures, such as Jesus or the Virgin Mary, can serve as symbolic attachment figures, and many religions encourage their adherents to pray to such figures for help in times of distress or crisis. In Buddhism, there have long been meditation practices that involve imagining being loved by a family member (e.g., one's mother) or a religious figure (e.g., the Buddha), then turning that feeling of love, in one's mind, toward other people, including "difficult" ones, which might make it easier to engage in constructive (prosocial) relationships with such people in real life (e.g., Hoffman, 2015b; Mipham, 2013; Nhat Hanh, 2014). Empirically, these loving-kindness practices have been shown in turn to strengthen feelings of social connectedness (Hutcherson, Seppala, & Gross, 2008) and boost prosocial behavior (Block-Lerner, Adair, Plumb, Rhatigan, & Orsillo, 2007; Kemeny et al., 2012; Leiberg, Klimecki, & Singer, 2011).

The role of the attachment system in prayer and Buddhist loving-kindness meditation is indicated by prayers that stress such factors as being protected in times of danger, and being "nearer" to God. A common Buddhist prayer is "I take *refuge* in the Buddha, the Dharma (the Buddha's teachings and Buddhist practices), and the Sangha (the community of fellow practitioners)." Many of these religious practices are being recast in a more

secular form as Buddhist practices such as mindfulness meditation and self-compassion meditation make their way into Western psychology and psychiatry (e.g., Hoffman, 2015a, 2015b; Miller, 2009, 2015). In the same way that mindfulness meditation is being studied by psychologists and neuroscientists, it should be possible to assess the effects of other forms of meditation—focusing on self-compassion, compassion for others, and loving-kindness—on the brain, and on people’s prosocial emotions and behavior.

Concluding Comments

It is interesting that ideas stemming at first from close scrutiny of the parent–child relationship have proven to apply not only to other close relationships but also to all kinds of social relationships in which concern for others’ welfare arises. It seems that all forms of sensitive, responsive, and compassionate care across the lifespan (e.g., caregiving in parent–child relationships, in adult romantic relationships, in relationships between middle-aged adults and their infirm older adult parents) and in different contexts (e.g., in close relationships and in the wider social world, where thousands of strangers need help and support) have a common basis and resemble each other. This implies that the research literatures on parenting, romantic caregiving, social support, helping, empathy, and counseling and psychotherapy—and even social justice/human rights and peace-building—are fundamentally related, and that further theoretical and empirical efforts should be made to create an overarching perspective on them.

Generous caregivers—human, nonhuman, spiritual, and symbolic—can contribute to a person’s sense of security and to his or her caregiving propensities; they can also provide models of compassion and loving-kindness that can be copied. Thus, if we wish to create a kinder and more peaceful world, we need to foster better parenting, more nurturing romantic relationships, better mentoring, and more positive and prosocial spiritual models. Simply championing virtues in the abstract or using socialization practices alone to encourage virtue, without providing a sense of love and security, is unlikely to be very helpful because, as we have shown here, insecure individuals do not experience opportunities for kindness and virtue in simple, unadulterated ways. They tend not to have confidence in the possibility of goodness.

Chapter 39

Attachment and Religious Representations and Behavior

Pehr Granqvist
Lee A. Kirkpatrick

In my hour of darkness, in my time of need,
Oh, Lord grant me vision.
Oh, Lord grant me speed.

—GRAM PARSONS, “In My Hour of Darkness,”
Grievous Angel (1974)

Although Bowlby’s theorizing about attachment focused largely on the evolutionary origins of the attachment system and its manifestation in infant–mother relationships, he clearly believed from the beginning that the processes and dynamics of attachment have broad implications for social development and psychological functioning across the lifespan. In this chapter we argue that with increased cognitive maturation, people can and do develop attachments to unseen figures (e.g., God). More specifically, we argue that some core aspects of religious beliefs and behavior are interpretable in terms of attachment dynamics.

Serious attachment scholars are well aware of the dangers inherent in extending the theory beyond its valid limits. Bowlby’s choice of the term *attachment* was in one sense unfortunate because of the word’s much broader meaning in everyday language: People speak of feeling *attached* to many things in their lives, from important possessions (cars, smartphones), to locations (home), to social groups, to sports teams, to rock stars. In our view, such phenomena can typically not be understood properly in terms of attachment, as defined by Bowlby. Nevertheless, we argue that some core as-

pects of religious belief and behavior represent real manifestations of attachment processes that may, in fact, provide a unique window into attachment processes in adulthood.¹

This chapter is divided into five major sections. In the first, we argue that people’s perceived relationships with God meet the defining criteria of attachment relationships reasonably well, and hence function psychologically much as other attachments do. We examine in the second section lifespan maturational issues involved in the development of attachment and religion. These first two sections deal with normative/typical aspects of the attachment–religion connection. In the third section, we review empirical connections between religion and individual differences in attachment. This section is subdivided into two subsections—the first focusing on a “compensation” pathway and the second describing a “correspondence” pathway to religion. We address in the fourth major section research findings and implications of the religion-as-attachment model with respect to psychological outcomes. In the final major section, which is new to this edition, we address the current state of theory and research on the attachment–religion connection.

Believers' Perceived Relationships with God in Relation to the Criteria for an Attachment Relationship

The obvious starting point for the application of attachment theory to religion is the observation that central to monotheistic religions, particularly Christianity, is the belief in a personal God with whom believers maintain a personal, interactive relationship. The word *religion* stems from the Latin *religare* or *relegere*, which means “being bound” (see Ferm, 1945). This relationship connotation has a clear counterpart in how people evaluate their own faith. For example, when asked, “Which of the following four statements comes closest to your own view of ‘faith’: a set of beliefs, membership in a church or synagogue, finding meaning in life, or a relationship with God?,” a majority of people in a national (U.S.) Gallup sample chose “a relationship with God” (compared to notably lower proportions for the other alternatives; Gallup & Jones, 1989).

It is also important to note that other supernatural figures may fill this relationship role in addition to or instead of “God.” In many Christian traditions, it is Jesus with whom one maintains an active day-to-day relationship, while “God the Father” remains a more distant background figure. In Roman Catholicism, Mary typically represents the “maternal functions” related to attachment (Wenegrat, 1989). Outside Christianity, the worlds of different groups of believers are populated by a variety of gods and other deities, some (but by no means all) of whom function as attachment figures. Even in countries dominated by Eastern religions such as Hinduism and Buddhism, which Westerners may think of as godless philosophies, believers often focus on the more theistic components of the belief system and on personal gods imported from ancient folk religions (e.g., Kirkpatrick, 1994). In this chapter, we refer to “God” as an attachment figure, but it should be understood that in many cases another supernatural figure may fill this role.

A second point of departure for discussing an attachment–religion connection is the centrality of the emotion of love in people’s perceived relationships with God and in religious belief systems more generally. The powerful emotional experiences associated with religion are often expressed “in the language of human love,” particularly in the writing of mystics (Thouless, 1923, p. 132). Similarly, the process of religious conversion has

been likened frequently, by both scholars and religious writers, to falling in love (James, 1902; Thouless, 1923; Ullman, 1982).

The “love” experienced by a worshipper in the context of a relationship with God is, of course, qualitatively different from that experienced in adult romantic relationships; the latter typically includes sexuality, whereas the former usually does not. The form of “love” experienced in the context of a relationship with God resembles more closely the prototypical attachment of a child to his or her mother. In Greeley’s (1990, p. 252) words, “The Mary Myth’s powerful appeal is to be found . . . in the marvelous possibility that God loves us the way a mother loves her baby.”

The idea that God is experienced psychologically as a kind of parental figure is, of course, hardly new. The most familiar version of this idea is Freud’s (e.g., 1927/1961) characterization of God as an “exalted father figure” (but see Granqvist, 2006). Wenegrat (1989), however, observed that the deities of the oldest known religions were largely maternal figures. Whether images of God more closely resemble maternal or paternal images has been a topic of much empirical research in the psychology of religion, with decidedly mixed results (e.g., Hood, Hill, & Spilka, 2009). The most reasonable conclusion from this research seems to be that images of God combine elements of both stereotypically maternal and paternal qualities (Vergote & Tamayo, 1981): God is neither an exalted father nor a mother figure but rather an “exalted attachment figure.”

There is considerable evidence to support the notion that believers view God as a kind of exalted attachment figure (AF). One line of suggestive evidence comes from religious writings and songs, perhaps most notably in the Psalms (Wenegrat, 1989). God seems clearly to capture the essence of the protective other that a parent represents to a child. As summarized by the theologian Kaufman (1981, p. 67), “The idea of God is the idea of an absolutely adequate attachment-figure. . . . God is thought of as a protective and caring parent who is always reliable and always available to its children when they are in need.”

Similarly, factor-analytic studies of God images consistently find a large first factor laden with attachment-related descriptors (see Hood et al., 2009). For example, Gorsuch’s (1968) first factor (labeled “benevolent deity”) included descriptors such as “comforting,” “loving,” and “protective,” and the reverse of “distant” and “inaccessible.”

In summary, there are several notable parallels between religious belief and experience on the

one hand, and attachment relationships on the other. Below, we argue, using Ainsworth's (1985) and Bowlby's (1969/1982) criteria for distinguishing attachments from other types of relationships, that these resemblances are more than interesting analogies and in fact reflect genuine attachment processes.

Seeking and Maintaining Proximity to God

The biological function of the attachment system, as described by Bowlby (1969/1982), is the maintenance of proximity between an infant and a protective AF. To obtain physical proximity, infants engage in behaviors such as crying, raising arms, and clinging (however, see below for maturational considerations).

Religions provide various ways of enhancing perceptions about the proximity of God. A crucial tenet of most theistic religions is that God is omnipresent; one is always in "proximity" to God. God is frequently described in religious literature as always being by one's side, holding one's hand, or watching over one. Nevertheless, other, more concrete cues may be valuable in enhancing perceptions of proximity to God. For example, virtually all religions provide places of worship where one can go to be closer to God. In addition, a diverse array of idols and symbols (e.g., graven images, crosses on necklaces, paintings) seem designed to remind the believer continually of God's presence.

The most important form of proximity-maintaining behavior directed toward God is prayer (Reed, 1978), which is not coincidentally also "the most often practiced form of religiosity" (Trier & Shupe, 1991, p. 354). Among the major forms of prayer reviewed in the comprehensive psychology-of-religion text by Hood, Spilka, Hunsberger, and Gorsuch (1996, pp. 394ff.), two seem clearly related to proximity maintenance: "contemplative" prayer ("an attempt to relate deeply to one's God") and "meditational" prayer ("concern with one's relationship to God"). Prayer seems analogous to social referencing (Campos & Stenberg, 1981; cf. secure base behaviors) in children; an intermittent checking back to make sure the AF is accessible.

God as a Safe Haven

A second defining aspect of attachment is that an AF serves as a safe haven in times of potential danger, which fulfills the evolutionary function of protecting otherwise defenseless infants from danger.

Bowlby (1969/1982) discussed three sets of natural clues to danger that activate the attachment system and elicit attachment behavior: (1) frightening/alarming environmental events; (2) illness, injury, fatigue; and (3) separation (or threat thereof) from AFs.

As Freud (1927/1961) and many others have long speculated, religion does appear to be rooted at least partly in needs for protection and felt security. Although to be taken with a grain of salt (see Granqvist & Moström, 2014), as the adage goes, there are no atheists in foxholes. Hood and colleagues (1996, pp. 386–387) concluded that people are most likely to "turn to their gods in times of trouble and crisis," listing three general classes of potential triggers: "illness, disability, and other negative life events that cause both mental and physical distress; the anticipated or actual death of friends and relatives; and dealing with an adverse life situation." This list bears a striking resemblance to Bowlby's (1969/1982) discussion of factors postulated to activate the attachment system.

Considerable evidence supports the view that people turn to religion particularly in times of distress and crisis, and it is important to note that they primarily turn at such times to prayer—a form of religious attachment behavior—rather than to church (Argyle & Beit-Hallahmi, 1975). Pargament (1997) has outlined various religious coping strategies that people have employed in stressful situations, including attachment-like responses such as "experienced God's love and care" and "took control over what I could and gave up the rest to God." Furthermore, research undertaken within a coping framework has documented that religious individuals are inclined to turn to God particularly when faced with threats (e.g., danger) and loss (e.g., death of a loved one; e.g., Bjorck & Cohen, 1993).

Frightening or Alarming Events

With respect to environmental stressors, empirical research suggests that there are indeed few atheists in some foxholes: Combat soldiers do pray frequently (Stouffer, 1949). From his interviews with combat veterans, Allport (1950, p. 57) concluded: "The individual in distress craves affection and security. Sometimes a human bond will suffice, more often it will not." As one combat veteran reported to Allport, "There were atheists in foxholes, but most of them were in love" (p. 56).

Although warfare provides an extreme example, other kinds of severe stressors can lead to emotional crises in which other AFs may be per-

ceived as inadequate. A century of research supports the claim that sudden religious conversions are most likely during times of severe emotional distress and crisis (e.g., Galanter, 1979; James, 1902; Starbuck, 1899; Ullman, 1982). According to James (1902), the climax of the crisis-driven conversion process comes when one surrenders oneself to God and places one's problems in God's hands. Hence, even individuals who did not experience a relationship with God prior to a crisis may come to do so if sufficiently distressed. It is also noteworthy that the source of the distress precipitating religious conversions is often relationship-related; in our own studies, relationship problems with parents and romantic partners have been frequently cited (Granqvist, 1998; Kirkpatrick & Shaver, 1990).

Moreover, experimental studies suggest that appraisal of threat does not require conscious processing to result in increased God-related cognitions (Birgegard & Granqvist, 2004; Granqvist, Mikulincer, Gewirtz, & Shaver, 2012). For example, in a recent study explicitly set up to test the religion-as-attachment model in a Jewish sample of Israeli college students, participants showed a greater psychological accessibility of God (or the concept of God) following subliminal exposure to threats (i.e., failure and death) compared to neutral material (Granqvist, Mikulincer, et al., 2012).

Illness, Injury, and Fatigue

Several studies show prayer to be an especially common method of coping with serious physical illnesses of various types (e.g., for reviews, see Koenig, King, & Carson, 2012; Pargament, 1997). For example, O'Brien (1982) observed in his interviews with patients experiencing renal failure that many of them saw God as providing comfort, nurturance, and a source of personal strength for getting through this difficult time. Other studies have shown religion to be particularly helpful to people in coping with *chronic* illness (Mattlin, Wethington, & Kessler, 1990).

Separation and Loss

Research also suggests that religiousness and prayer tend to increase following the death of or (threat of) separation from loved ones, and that religious beliefs are correlated positively with successful coping at these times (e.g., Loveland, 1968; Parkes, 1972). Relevant research has focused

mostly on effects of spousal separation/bereavement (i.e., the ending of the principal attachment relationship in adulthood). Loss of a principal AF is a particularly powerful stressor: Not only is it a stressful event in itself but it also eliminates the availability of the person to whom one would otherwise turn for support in a stressful situation.

We (Granqvist, 1998; Kirkpatrick & Shaver, 1990) have observed that the crises reported retrospectively by religious converts often involved relationship-focused difficulties including loss of or separation from AFs, particularly through relationship breakups and divorce. Similarly, in a prospective study using a population-based sample of older adults—some of whom were destined to suffer bereavement during the course of the study and others who were not—Brown, Nesse, House, and Utz (2004) found a prospective increase in the importance of the religious beliefs for the bereaved compared to the nonbereaved, and specifically as a function of the bereavement. This study also showed that grief over the loss decreased specifically as a function of the increased significance of the bereaved individual's religious beliefs, indicating that the attachment component of the individual's religiousness may be what is activated in such situations and contributes to a more favorable outcome.

In a controlled attachment experiment, theistic believers who were primed with a subliminal separation threat ("Mother is gone") targeting their relationship with their mothers (i.e., typically the principal AF in childhood) showed an increase in their wish to be close to God compared with participants in an attachment-neutral control condition (Birgegard & Granqvist, 2004). We suggest that the effects of loss and separation are due to two factors: (1) Loss of a loved one activates the attachment system, thus giving rise to religious attachment behaviors such as prayer; and (2) bereaved/separated persons may find in God a surrogate AF to replace the absent AF.

God as a Secure Base

Another defining characteristic of an attachment is that it provides a sense of felt security and a secure base for exploration of the environment. As noted, religious literature is replete with references to God's being "by my side" and "watching over me." Perhaps the best-known example is the 23rd Psalm: "Yea, though I walk through the valley of the shadow of death, I will fear no evil: for thou art with me; thy rod and thy staff they comfort me."²²

It is easy to imagine how an AF who is simultaneously omnipresent, omniscient, and omnipotent can provide the most secure of secure bases. This is precisely what led Kaufman (1981) to his previously quoted conclusion that God represents an “absolutely adequate attachment-figure.” It also led Johnson (1945, p. 191), a psychologist of religion, to conclude: “The emotional quality of faith is indicated in a basic confidence and security that gives one assurance. In this sense faith is the opposite of fear, anxiety, and uncertainty.” This description of faith bears a striking resemblance to Bowlby’s (1973, p. 202) own later descriptions of the secure base and its psychological effects: “When an individual is confident that an AF will be available to him whenever he desires it, that person will be much less prone to either intense or chronic fear than will an individual who for any reason has no such confidence.”

Researchers have paid less attention to the question of how religious beliefs affect behavior and cognition in the absence of stressors. Thus, there is considerably less direct evidence for a secure-base function of religion than for a safe-haven function. Nevertheless, there is both direct and indirect support for such a function. Some of the research that is supportive of indirect effects is reviewed when we examine psychological outcomes associated with “attachment to God.” Regarding direct effects, Granqvist, Mikulincer, and colleagues (2012) found in their experiments with theistic Jews in Israel that subliminal priming with the word *God* heightened participants’ cognitive access to secure-base-related concepts (e.g., “loving,” “accepting”) in a lexical decision task and that priming with a religious symbol (a Torah scroll) caused neutral material (Chinese ideographs) to be better liked.

Responses to Separation and Loss

We have noted in a previous section that certain aspects of religiousness often become more salient in response to bereavement and (threatened or actual) separations from loved ones. However, the fourth and fifth defining aspects of attachment, as outlined by Ainsworth (1985), concern responses to separation from, or loss of, the AF per se: The threat of separation causes anxiety in the attached person, and loss of the AF causes grief.

Determining whether God meets these criteria is difficult; God does not die, sail off to fight wars, or file for divorce. The potential for true separation

from God is usually seen by believers to come only in the hereafter, at which time one either spends eternity with God or is separated from God. It is noteworthy, however, that in most Christian belief systems, separation from God is the essence of hell.

Also, there are instances in religious life when believers are unable to experience a previously felt communion with God, which may also occur in situations in which the urge to feel such a communion is experienced as acute. In religious and mystical literature, such states are often referred to as a “wilderness experience” or a “dark night of the soul” (St. John of the Cross, 1990). Perhaps the best-known example is when Christ himself, nailed on the cross, cried out: “My God, my God, why hast thou forsaken me?” (Matthew 27:46). In an experimental paraphrase of this situation, Birgegard and Granqvist (2004) subliminally exposed theistic (mostly Christian) believers to either a separation prime targeting their God relationship (“God has abandoned me”) or attachment-neutral control primes (“People are walking,” “God has many names”), and examined whether the wish to be close to God would increase as expected from pre- to postexposure as a result of the separation-from-God priming. In other words, this was an attempt to create a conceptually analogous situation for adult believers to the separation situation in which infants studied in the Ainsworth Strange Situation find themselves (Ainsworth, Blehar, Waters, & Wall, 1978). Although modest support was obtained for the prediction, the effects were strongly moderated by individual differences, analogous to those observed in the Strange Situation (which we discuss in detail later in this chapter).

Perceiving God as Stronger and Wiser

To highlight the inherently asymmetrical nature of attachment, Bowlby (1969/1982) used the term *attachment relationship* to denote the relationship that a weaker, less competent individual has with another individual perceived as stronger and wiser—prototypically, the mammalian offspring with its adult caregiver(s). Concerning believers’ perceived relation with God, believers undoubtedly do perceive God as very much stronger and wiser than themselves. In fact, God is supposedly omnipotent and omniscient—attributes that are difficult for any earthly caregiver to compete with, as sensitive as he or she may be.

Maturational Aspects in the Development of Attachment and Religion

So far, we have mostly considered adult expressions of religious experience in relation to attachment processes. The story of attachment starts in early childhood, however, as does the story of how a perceived relationship with God develops. We argue here that the relationship with God develops in temporal conjunction with the maturation of attachment, and especially with the cognitive developments thought to be intertwined with this maturation (Bowlby, 1973). Furthermore, we demonstrate that situational experiences associated with heightened attachment activation are already associated in childhood with increased significance of the individual's relationship with God (for reviews, see Granqvist, 2014b; Richert & Granqvist, 2013).

As noted, the biological function of the attachment system is to maintain proximity between an infant and a protective AF. With increasing cognitive abilities, older children are often satisfied by visual or verbal contact, or eventually by mere knowledge of an AF's whereabouts (Bretherton, 1987). This observation led Sroufe and Waters (1977) to suggest that "felt security" is the set-goal of the attachment system. Likewise, the consideration of cognitive abilities was an important part of the "move to the level of representation" (Main, Kaplan, & Cassidy, 1985) that was undertaken in attachment research 30 years ago. This move also opened the door, we argue, to the possibility of representing noncorporeal figures (e.g., gods, imaginary figures) as AFs, although physical contact with such a figure is not possible.

Far from being able to grasp symbolic thought or master mentalizing abilities, the human infant's behavioral repertoire initially consists of a series of fixed action patterns (cf. reflexive behaviors) that are necessary to obtain the biological set-goals of nourishment and proximity to a protective caregiver. However, in preschool, attachment to primary caregivers increasingly moves toward goal-corrected partnerships. This is presumably because of an emerging capacity for symbolic thought and mentalizing abilities (Bowlby, 1969/1982), which enable the child to represent the AF symbolically and to imagine the intentions and goals underlying the AF's behaviors. As a consequence, children become increasingly able to tolerate longer separations as they get older.

It is easy to see how symbolic thought and mentalizing abilities may similarly pave the way for an emerging understanding of God. As children experience themselves thinking and planning, and imagine the intentions of their social interaction partners, they may also apply their increasingly sophisticated mentalizing abilities to abstract, symbolic others. Naturally, related cognitive inclinations, such as a propensity for anthropomorphic thinking, naive physics, naive biology, and agency attributions, contribute further to making God an intuitively sensible ontology to the young child's mind (e.g., Barrett, 2004). As a case in point, young children (even from atheistic contexts) intuitively invent creationist ideas to explain origins but are hard pressed to entertain evolutionary explanations (Evans, 2001). Of course, the child's cognitive elaborations with God-related ideas are particularly likely to become consolidated and endure when adults provide consonant information (Evans, 2001; Granqvist, 2014b).

Although children's God concepts can be viewed as abstractions, they tend to be comparatively concrete and anthropomorphic by adult standards. A preschooler may, for example, explain the rain as a result of God's need to pee. For another example, God is typically described and drawn as a person (Heller, 1986). Common themes observed by Heller in his extensive study of children's images of God included many characteristics reminiscent of a secure attachment figure, such as nurturance, intimacy, and omnipresence. Interestingly, two other themes observed by Heller seem to parallel insecure attachment patterns, *inconsistent God* and *God, the distant thing in the sky*.

Once the requisite cognitive development has occurred, if a child's attachment system is highly activated (e.g., during a separation) the child may draw on God as an abstract yet anthropomorphized attachment surrogate. In a related discussion, Rizzuto (1979) suggested that at roughly age 5–6 years, children develop a "living" God representation, with God being an alternative, affectively charged safe haven rather than a purely cognitive representation in the child's mind.

In middle childhood, as children enter school and move even farther from their parents' immediate care, their God concepts become somewhat less anthropomorphic, although, at the same time, God is typically viewed as personally closer than in early childhood (Eshleman, Dickie, Merasco, Shepard, & Johnson, 1999; Tamminen, 1994). From early childhood on, empirical data indicate that God is indeed perceived as an available safe

haven in times of stress. For example, Tamminen found that a high proportion of Finnish 7- to 12-year-olds reported that they felt close to God, particularly during emergencies and periods of loneliness. In addition, Eshleman and colleagues (1999) found that American preschoolers and elementary schoolchildren placed a God symbol closer to a fictional child when the fictional child was in attachment-activating situations (e.g., sick and in the hospital) than when the fictional child was in situations that contained less clear-cut attachment activators (e.g., the child had stolen an apple).

These findings have now been conceptually replicated in at least three studies, conducted in Sweden, the United States, and Italy, with children from 5 to 8 years of age (Cassibba, Granqvist, & Costantini, 2013; Dickie, Charland, & Poll, 2005; Granqvist, Ljungdahl, & Dickie, 2007). The results of these studies were based on a clearer distinction between attachment-activating and non-attachment-activating situations. Even then, children placed the God symbol closer to the fictional child in the attachment-activating situations. Interestingly, so did children raised by nonreligious parents (Granqvist, Ljungdahl, et al., 2007).

Adolescence and early adulthood have long been known to be periods of major religious transformations (e.g., Granqvist, 2012; James, 1902). These are the life periods most intimately associated with sudden religious conversions and other significant changes in one's relationship with God. Argyle and Beit-Hallahmi (1975, p. 59) referred to adolescence as "the age of religious awakening," although it is notably also the age of apostasy (Roof & McKinney, 1987). It is well known that cult recruiters make teenagers and young adults primary targets of their proselytizing and recruitment activities. Because adolescence is a unique and complex developmental period, it is not surprising that a wide range of explanations has been offered for the prevalence of conversion at this time. These include postulated links to puberty and sexual instincts (e.g., Thouless, 1923); the increased need for meaning, purpose, and sense of identity (Starbuck, 1899); and self-realization (Hood et al., 1996). From an attachment perspective, it is notable that adolescence represents a period of transition between principal AFs—usually from parents to peers (Zeifman & Hazan, 1997). According to Weiss (1982, p. 178), relinquishing one's parents as AFs has a number of predictable consequences, including vulnerability to emotional loneliness, which he defines as "the absence from one's in-

ternal world of an attachment figure." At such a time, adolescents may turn to God (or perhaps a charismatic religious leader) as a substitute AF (for a review, see Granqvist, 2012). As noted, sudden religious conversions and other major religious changes are also typically precipitated by significant emotional turmoil, which is likely to keep the attachment system hyperactivated in this sensitive period of attachment transition.

Compared to the preceding age periods, middle adulthood is typically less associated with attachment transitions and religious drama, and more associated with religious and other forms of "habit . . . the enormous fly-wheel of society, its most precious conservative agent" (James, 1890/1950, p. 121). However, there are notable exceptions, the most pronounced being marital separations and divorce. In old age, a person's relationship with God often regains importance, particularly when the person loses close friends or a spouse to death. As noted, such attachment transitions have been found to be associated with increased emphasis on one's relationship with God (e.g., Brown et al., 2004; Cicirelli, 2004; Granqvist & Hagekull, 2000; Kirkpatrick, 2005).

Religion and Individual Differences in Attachment

An important characteristic of attachment theory is its integration of a normative model featuring a control system dynamic on the one hand, and a model of individual differences in the functioning of that system on the other. To be complete, a theory of religion-as-attachment must do the same. In the preceding sections, we have sketched a normative model within which many aspects of religious belief and behavior, and particularly perceived relationships with God, function psychologically as attachment processes. We turn in this section to the topic of relations between religion and individual differences in attachment. As it turns out, just as individual differences in attachment security modulate the behavioral and linguistic output of the attachment system in general, so do they modulate the effects of attachment activation in the context of believers' perceived God relations.

From the outset, Kirkpatrick (1994; Kirkpatrick & Shaver, 1990) noted that two somewhat opposing hypotheses could be derived from attachment theory concerning relations between religion and attachment security or insecurity, re-

ferred to as the *compensation* and *correspondence* hypotheses. These hypotheses may be seen as delineating two distinct developmental pathways to religion: one (compensation) following experiences with insensitive caregivers, and the other (correspondence) via experiences with sensitive, typically religious caregivers (Granqvist, Ivarsson, Broberg, & Hagekull, 2007; Kirkpatrick, 2005). It is in this developmental-pathway sense that the two hypotheses are conceptualized in the following sections. We describe findings from studies employing both self-reports (e.g., of romantic attachment) and more indirect, implicit assessments of attachment, such as the Adult Attachment Interview (AAI; Main, Goldwyn, & Hesse, 2003).³ Moreover, we argue that essentially the same conclusions can be drawn from studies that have used different kinds of methods.

The Compensation Pathway

According to Bowlby's control system model of attachment, the attachment system continually monitors internal states and external circumstances in relation to the question, "Is the attachment figure sufficiently near, attentive, responsive, approving, etc.?" (Hazan & Shaver, 1994, p. 3). The set point of the system is variable, depending on expectancies (i.e., components of internal working models, or IWMs) concerning the AF and perceived cues of environmental dangers. A negative answer to the question, according to the theory, activates a suite of potential attachment behaviors designed to restore an adequate degree of proximity. Under certain conditions, however, the individual may anticipate (based on prior experience and/or current circumstances) that efforts to achieve adequate proximity and comfort from the primary AF are unlikely to be successful. If so, a search for an alternative and more adequate AF may be initiated, which in some cases will lead to God. In the sections dealing with normative aspects of attachment and religion, we have noted a number of such situations. In this section, we are concerned with whether individual differences in attachment history and attachment security are associated with the use of God and religion in times of distress.

Both Ainsworth (1985) and Bowlby (1969/1982) expected a history of unsatisfactory attachments to predispose a person to search for substitute AFs. Ainsworth argued that children who fail to establish secure attachments to parents are likely to seek surrogates, including teachers,

older siblings, other relatives, or any stronger and wiser other who reliably proves to be accessible and responsive. Subsequent students of attachment largely neglected to pursue further the use of attachment surrogates in their research. However, it should be recalled that insecure (i.e., avoidant and resistant/ambivalent) attachment is believed to reflect a developmentally secondary (or conditional) attachment strategy stemming from defensive processes (e.g., exclusion of attachment-related information and diversion of attention) in the face of a failed primary strategy of obtaining sufficiently sensitive care from the AF (Main, 1991). The use of surrogate attachments may provide a unique opportunity to observe the presumed remnants of such a primary (or secure) attachment strategy. Although Ainsworth did not include God in her list of potential surrogates, it seems reasonable to assume that God may fill this role for many people with insecure attachment histories. In a word, God may provide a kind of attachment relationship one never had with one's parents or other primary AFs. We hypothesize that regulation of distress is at the core of this surrogate use of God and religion. Besides conditional strategies, people who have experienced abuse, frightening, or other aberrant forms of caregiving behavior from AFs (i.e., those with disorganized attachment) are predisposed to enter dissociative states of consciousness, which may also be expressed in the religious and spiritual realm, and consequently be analyzed as a form of compensation.

Compensation and Theistic Religion

Some of the findings reported and arguments advanced in the normative attachment-and-religion sections of this chapter have been found to hold in particular for individuals who were likely to have experienced parental insensitivity while growing up, whether their estimated attachment-related experiences were based on self-reports (e.g., Granqvist, 1998, 2002; Granqvist & Hagekull, 1999, 2003; Halama, Gasparikova, & Sabo, 2013; Kirkpatrick & Shaver, 1990; Pirutinsky, 2009; Schnitker, Porter, Emmons, & Barrett, 2012) or assessed with the AAI (Granqvist, Ivarsson, et al., 2007). For example, sudden religious conversions, the most pronounced examples of religious drama, are associated with estimates of parental insensitivity. This connection was reported in the first study of attachment and religion (Kirkpatrick & Shaver, 1990). Since then, these findings have been strongly supported by a meta-analysis of all stud-

ies conducted before 2004, including almost 1,500 participants (Granqvist & Kirkpatrick, 2004), and later by additional studies (e.g., Halama et al., 2013; Schnitker et al., 2012).

In addition, confirmative evidence has accrued in relation to the “probable experience of parenting scales” used to score the AAI. For example, in an AAI study, participants whose parents were estimated by an independent coder to have been relatively less loving/sensitive self-reported more sudden and intense increases in religiousness (Granqvist, Ivarsson, et al., 2007). Notably, although all studies cited earlier were conducted on largely Christian samples, a later study of converts to Orthodox Judaism provided much needed cross-religion evidence for the association between attachment insecurity and sudden conversion (Pirutinsky, 2009).

In the meta-analysis (Granqvist & Kirkpatrick, 2004), sudden converts outscored both nonconverts and gradual converts on attachment insecurity with parents. Also, as would be expected given the distress-regulating aspect of sudden conversions, we found in the meta-analysis that sudden converts scored higher on a scale created to tap distress-regulating aspects of believers’ perceived relations with God—focusing explicitly on attachment aspects of the relationship (e.g., God being viewed as a safe haven and secure base).

Moreover, several studies have shown that the increases in religiousness reported by individuals whose parents were judged to be low in sensitivity were typically precipitated by significant emotional turmoil (“themes of compensation”) that was typically relationship-related (e.g., Granqvist & Hagekull, 1999; Granqvist, Ivarsson, et al., 2007; Halama et al., 2013). These studies assessed religious changes retrospectively, but Granqvist and Hagekull (2003) showed that the association could also be obtained prospectively; that is, reports of parental insensitivity prospectively predicted increased religiousness—particularly an increased importance of the perceived relationship with God, following the breakup of a romantic relationship.

Similarly, insecure romantic attachment has reliably predicted essentially the same kinds of religious changes. For example, Kirkpatrick (1997) found that over a 4-year period, women with insecure (particularly anxious) attachments established a new relationship with God and reported religious experiences, such as being “born again” and speaking in tongues, to a larger extent than did securely attached women. Findings of pro-

spectively predicted increases in the religiousness of adults reporting insecure romantic attachment were replicated in a second study by Kirkpatrick (1998), this time over a 5-month period, and in both males and females. Unlike the 1997 study, which used Hazan and Shaver’s (1987) three-category measure of attachment orientations, this study utilized Bartholomew and Horowitz’s (1991) four-category model, based on two dimensions: positive versus negative model of self, and positive versus negative model of other. Again, increases in the image of a loving God and in a perceived personal relationship with God were predicted by not only ambivalent/preoccupied romantic attachment but also by fearful-avoidant attachment, both of which are characterized by a negative model of self. Although the magnitude of the effects was modest in these two studies, when the contextual condition of romantic relationship breakup—possibly indicating an increased need to regulate distress via attachment—was considered in yet another sample, insecure romantic attachment prospectively predicted increases in aspects of religiousness somewhat more strongly (Granqvist & Hagekull, 2003).

One interpretation of the findings from these studies is that for people who view themselves as unworthy of love and care, turning to God may be possible because of God’s unique characteristics as compared with other relationship partners. First, turning to God is comparatively risk free because a noncorporeal figure’s responsiveness can always be imagined and need never be experienced as disconfirmed. Also, in most religious belief systems, God’s love is either unconditional—so one need not be “worthy” of love to receive it—or available through particular courses of action (e.g., good deeds, prayer) that allow an otherwise “unworthy” person to “earn” God’s love and forgiveness.

Although these studies might seem to suggest that individuals with insecure attachment patterns become increasingly religious over time, it should be recalled that this is expected primarily in the context of a need to regulate distress. Accordingly, religiousness may also decrease for such individuals (Granqvist, 2002). As expected, this happens under conditions in which the need to regulate distress through attachment surrogates is comparatively low, such as after establishing a new intimate human relationship (Granqvist & Hagekull, 2003).

In summary, the developmental pathway to religion in the case of parental insensitivity and insecure attachment is one marked by attach-

ment system (hyper)activation, under conditions where a perceived relationship with God helps to regulate a believer's distress when no other adequate AFs are available. This conclusion corresponds well with the general speculations about the use of attachment surrogates offered by Bowlby (1969/1982) and Ainsworth (1985). As we have noted elsewhere (Granqvist, 2003; Granqvist & Hagekull, 1999; Kirkpatrick, 2005), this religious profile bears a striking resemblance to William James's (1902) more than century-old characterization of the "religion of the sick-souled."

However, whereas the AAI judges' estimates of parental insensitivity during interviewees' childhoods did predict the interviewees' history of using religion to regulate distress, classifications of the interviewees' *current* attachment organization were generally unrelated to such compensatory use of religion (Granqvist, Ivarsson, et al., 2007). Similarly, self-reported romantic attachment (particularly a negative self-model or a high degree of attachment anxiety) has been linked to increasing religiousness over time (longitudinal compensation), whereas self-reported secure attachment has been linked to higher religiousness at a given time (contemporaneous correspondence; see Kirkpatrick, 2005). An intriguing possibility is that this discrepancy results from the possibility that some individuals who suffered attachment-related difficulties (e.g., rejection, role reversal) in the past may have "earned" a certain degree of attachment security from their surrogate relationship with God. This interpretation is admittedly speculative, but if supported, it would indicate that religion as compensation may sometimes be psychologically reparative and conducive of growth, not just defensively reactive.

Compensation and Altered Spiritual States (Mystical Experiences and New Age Spirituality)

Religion is doctrinal and communal, but all world religions also have an undercurrent of personal spiritual experiences that are not necessarily interpreted doctrinally by the persons having the experiences (e.g., Hood et al., 2009). Experiences known as "mystical" are probably the best example. Mystical experiences represent markedly altered states of consciousness, more specifically, a dissolution of one's usual, integrated sense of self (Stace, 1960). From his extensive studies of religious mystics, Stace noted that mystical experiences usually take the form of a pure, content-free

consciousness, where perceptual objects "disappear," resulting in an experience of "nothingness" (i.e., introvertive states), or a sense of all objects being unified into a perception of totality or oneness with all things (i.e., extrovertive states). The unity experience of extrovertive states may or may not be described as "God"; other examples are "Nature" and "Cosmos."

In much of the contemporary, pluralistic Western world, religious doctrines and communities have lost their privileged position as sources of legitimacy for peoples' spiritual experiences. Religions now coexist with one another and lead a largely marginalized life on the side of the many "nonreligious" movements in the mainstream, which are often individually rather than communally oriented, but some of which still have their say on experiences understood as spiritual. In this "spiritual revolution," the spirit has been taken out of religion/God and moved into the self (Heelas, Woodhead, Seel, & Szerszynski, 2005). The New Age movement is probably the best example. The term *New Age* refers not to a formalized movement but to a wide range of beliefs and activities that typically combine esotericism/occultism, astrology, parapsychology, alternative medicine, outgrowths of humanist psychology, and Eastern thinking in a Western context, and in which the individual is free to pick any ingredient suitable to the self from the diverse spiritual smorgasbord that characterizes the New Age (Farias & Granqvist, 2007). Notably, altered states of consciousness, such as out-of-body experiences, trance states (e.g., in conjunction with "drum trips"), and responses to hypnotic suggestions (e.g., past-life regression), are both prevalent and subjected to affirmative metaphysical interpretations within the New Age movement (Farias & Granqvist, 2007).

Thus, both mysticism and New Age spirituality should be associated with altered states of consciousness. As noted earlier, disorganized (D) attachment (as well as its adult counterpart, unresolved loss/abuse) is believed to be an important developmental precursor to the proclivity to enter altered states (e.g., Main & Morgan, 1996). Indeed, D behaviors such as freezing and stilling have been suggested to represent (proto-)dissociative states, already evident in infancy, and provoked by the approach-avoidance conflict thought to characterize D attachment (Hesse & Main, 2006; Main & Morgan, 1996). In other words, when the infant's attachment system is activated, instead of approaching the AF—who is simultaneously the source of threat *and* of potential comfort—the

infant “spaces out” or dissociates. If this becomes a habitual mode of responding when faced with stress, D attachment should make the individual prone to later experiences of dissociative mental states (e.g., experiences of depersonalization, out-of-body experiences). Confirmatory evidence for this idea comes from studies linking infant D status to later dissociative states throughout childhood and adolescence, and unresolved loss/abuse to a more general propensity to experience altered states (“absorption”; for a review, see Granqvist, Reijman, & Cardeña, 2011).

Putting these pieces together, one of us (Granqvist, Ivarsson, et al., 2007) has proposed a mediational model in which D attachment (including unresolved loss/abuse) is hypothesized to predict altered spiritual states, via dissociation (e.g., absorption) as a mediating variable. This mediational model has now been supported in a prospective follow-up of the Swedish AAI study referenced earlier (Granqvist, Ivarsson, et al., 2007), both with mystical experiences (Granqvist, Hagekull, & Ivarsson, 2012) and New Age spirituality (Granqvist, Fransson, & Hagekull, 2009) as outcomes, and as predicted by unresolved loss/abuse. Moreover, support for this model has recently been independently replicated and extended in a study using unresolved loss as predictor, “supernatural beliefs” (i.e., paranormal beliefs plus mystical experiences) as outcome, and psychopathology-related forms of dissociation as mediator (Thomson & Jaque, 2014). Supporting the discriminant validity of the mediational model, more conventional forms of religiousness, such as theistic beliefs and strength of religious commitment, were unrelated both to unresolved loss/abuse and absorption in the former study (Granqvist, Hagekull, et al., 2012). The findings from these studies are particularly noteworthy when considering that AAI classifications are often unrelated to self-reports of external phenomena (see Hesse, Chapter 26, this volume).

Given that New Age spirituality typically does not revolve around God as an AF, it is reasonable to question whether the attachment model in general and the compensation hypothesis in particular are at all conceptually applicable (see Kirkpatrick, 2005). We speculate that the adoption of New Age practices and beliefs may be driven by motivation similar to that underlying religion as compensation, but that the generalization of IWMs of others (e.g., as frightening) restrict New Agers’ use of God as an attachment surrogate. Note also that although the idea of a single, the-

istic God is usually absent from New Age beliefs, the world of New Agers is often inhabited by imagined angels and spirits, as well as human spiritual advisors and gurus who may fill some attachment-surrogate functions. Of course, the appeal of the New Age for disorganized individuals may also be due, in part, to its provision of metaphysical affirmations of these individuals’ psychological states and experiences (e.g., of telepathy, contact with the dead, possession by abusive perpetrators). Prior to the individuals’ introduction to the New Age, such states and experiences may well have been regarded, by self and others alike, as worrisome signs of poor reality contact.

Finally, we note that this mediational model might seem to “pathologize” New Age spirituality and mystical experiences. This is because virtually all *other* theorizing and research efforts on D attachment portray it as a risk factor in development. However, appearances should always be treated with caution. We have in fact argued that there is a major gap in the literature on potential non-pathological sequelae of D attachment, and that altered spiritual states represent a rare example that helps to fill that gap (Granqvist, Ivarsson, et al., 2012); mystical experiences, in particular, are not linked to psychopathology, although they are often preceded by stress and turmoil (e.g., Hood et al., 2009). Unusual forms of creativity might represent another example.

The Correspondence Pathway

According to Bowlby’s model, continuity of attachment patterns across time and transmission of attachment patterns across generations are traced to IWMs (Bowlby, 1973; see also Bretherton & Munholland, Chapter 4, this volume; Main et al., 1985). As a consequence of repeated experiences in interactions with their AFs, children develop beliefs and expectations (IWMs) about the availability and responsiveness of caregivers, and these models guide future behavioral, emotional, and cognitive responses in other social interactions. Moreover, the models of interaction partners are linked to models of the self—beliefs about the degree to which one sees oneself as worthy of love, care, and protection.

Although the level at which IWMs operate is a matter of debate, it seems likely that people maintain both (1) mental models of AFs in general and (2) mental models specific to particular relationships. Bretherton and Munholland (Chapter 4, this volume) suggest that such models are

hierarchically arranged: The top level comprises a highly general model of self and others; a second level comprises models of parent–child relationships as distinct from peer relationships; and so on. We suggest that for many individuals, IWMs of God (or perceived relationships with God) hold an important place somewhere in this hierarchy.

Whether or not various levels of attachment-relevant mental representations are arranged in this precise hierarchical structure, consideration of the interrelatedness of IWMs leads to a straightforward set of predictions, which we refer to as *IWM correspondence*: Individual differences in religious beliefs and experience should correspond with individual differences in IWMs of self and other. Individuals who possess positive or “secure” generalized IWMs of themselves and their AFs may be expected to represent God and other deities in similar terms. Likewise, an “avoidant” attachment may be expected to manifest itself in the religious realm as agnosticism or atheism, or in a representation of God as remote and inaccessible. In addition, an “anxious” or “ambivalent” attachment may find expression in a deeply emotional, all-consuming, and “clingy” relationship to God. Finally, a disorganized (or fearful) attachment may relate to a representation of God as frightening and ominous.

Besides IWM correspondence, the developmental attachment literature has suggested that caregiver sensitivity and offspring attachment security facilitate the offspring’s internalization of parental standards in general (e.g., Ainsworth, Bell, & Stayton, 1974; Kochanska, Aksan, Knaack, & Rhines, 2004; Richters & Waters, 1991). This conclusion converges with the literature on imitation (or social learning), in which a model’s nurturance has been shown to facilitate children’s imitation of the model’s behaviors (e.g., Hetherington & Frankie, 1967), as well as with previous findings in the psychology of religion, which have repeatedly shown warm, high-quality caregiving to be linked to high parent–offspring similarity in religiousness (see Hood et al., 2009). Thus, a socially based aspect of religion (and religious membership) can be added to the IWM aspect of the correspondence hypothesis (Granqvist, 2002; Granqvist & Hagekull, 1999); that is, the religious beliefs and behaviors of people who are securely attached can be expected in part to reflect their sensitive AF’s (say, a loving parent’s) religious standards. In contrast, insecure offspring can be expected to be less likely to adopt their relatively insensitive or unresponsive AF’s religious standards. This aspect of the correspondence

hypothesis is referred to as *social correspondence* (Granqvist, 2002, 2010). Through this addition, securely attached individuals are expected to become actively religious insofar as their caregivers were (i.e., social correspondence). If so, their perceived relations with God are expected to exhibit attributes of security (i.e., IWM correspondence).⁴

A Review of Social Correspondence Findings

In line with the idea of social correspondence, individuals reporting experiences of being sensitively cared for by parents have been shown to score higher in religiousness than those reporting experiences of being less sensitively cared for, but only insofar as their parents also displayed high levels of religiosity (Granqvist, 1998, 2002; Granqvist & Hagekull, 1999; Kirkpatrick & Shaver, 1990). In addition, such people score higher on a scale created to assess religiosity as socially rooted in the parental relationship (Granqvist, 2002; Granqvist & Hagekull, 1999). Moreover, both sets of findings were supported in the Swedish AAI study, when coded estimates of parental sensitivity rather than direct self-reports were used (Granqvist, Ivarsson, et al., 2007). Similarly, in the case of romantic attachment, secure attachment is associated with scores on the scale measuring religiosity as socially based in the parental relationship (Granqvist, 2002).

Notably, the idea of social correspondence has now been supported in not only Christian populations but also a Jewish Israeli sample (Pirutinsky, 2009), and not only in samples drawn from the normal population but also from a maltreatment sample (Reinert & Edwards, 2009). Social correspondence has also been supported in prospective studies. In a study of adolescents about to undergo a Young Life Evangelical summer camp (Schnitker et al., 2012), secure attachment with parents prospectively predicted an at-camp reaffirmation of the faith one had been brought up with (cf. Halama et al., 2013; Wright, 2008).

We note that parental religiousness has often been portrayed in the psychology of religion as the single strongest predictor of offspring religiousness, especially by scholars who approach the topic from a social learning perspective (e.g., Batson, Schoenrade, & Ventis, 1993; Spilka, Hood, Hunsberger, & Gorsuch, 2003). However, the “effect” of parental religiousness is importantly moderated by the estimated quality of the offspring–parent attachment relationship. In fact, whereas parent–offspring correlations for retrospectively defined

secure dyads have been large ($r \approx .50$), they have usually been nonsignificant and close to zero for insecure dyads (e.g., Granqvist, 1998; Kirkpatrick & Shaver, 1990). An implication of these findings for religious parents who wish their children to embrace their own religion is that religious preaching/teaching is not enough; in fact, it may fall on entirely deaf ears unless combined with placing a high priority on sensitive caregiving that meets the children's needs for protection and security. It is even possible that sensitive caregiving—in the absence of explicit religious training—suffices as long as a child has an opportunity to observe a caregiver engage in religious speech and behavior.

A Review of IWM Correspondence Findings

Evidence for IWM correspondence between the interpersonal attachment and religious domains has also accrued in relation to attachment history as estimated through the AAI. The AAI study described earlier revealed that coded estimates of probable experiences with loving/sensitive parents were associated with participants' reports of a loving, as opposed to a distant, God image (Granqvist, Ivarsson, et al., 2007). Conversely, inferred experiences with rejecting and role-reversing parents were associated positively with a distant God image and negatively with a loving image of God.

Similar findings have been reported in an Italian AAI study (Cassibba, Granqvist, Costantini, & Gatto, 2008) that contained two subsamples: a highly religious group (Catholic nuns, priests, and seminarians) and a comparison group of lay Catholic believers, matched for sex. The highly religious group was coded significantly higher on not only loving experiences with mothers but also a continuous dimension of current security/coherence of discourse, and this group contained a higher proportion of secure-autonomous classifications than the worldwide nonclinical meta-analytic distribution (Bakermans-Kranenburg & Van IJzendoorn, 2009). Finally—regardless of subsample—secure-autonomous participants reported a more loving God image than insecure-nonautonomous participants.

Although religious transformations are less frequent for individuals who have experienced sensitive caregiving, they sometimes do occur. When they do, the life context and the constituents of the change are very different from those reported in the sections on the compensation pathway. For example, prospectively predicted increases in religiousness occurred *not* following romantic relationship dissolution, but rather after

the establishment of a new intimate relationship, for participants who reported sensitive parenting (Granqvist & Hagekull, 2003). Also, religious changes tend to be gradual rather than sudden and to occur at a comparatively young age for these individuals (Granqvist & Hagekull, 1999; Granqvist, Ivarsson, et al., 2007; Halama et al., 2013; Schnitker et al., 2012).

Regarding romantic attachment, IWM correspondence has typically been supported in contemporaneous relations between religious variables and romantic attachment security. For example, Kirkpatrick and Shaver (1992) found that people with a secure romantic attachment displayed a higher personal belief in and relationship with God, as well as perceptions of God as loving, whereas people reporting avoidant romantic attachment were agnostic or atheist to a larger extent. These findings have since been conceptually replicated in a number of studies (e.g., Byrd & Boe, 2000; Granqvist & Hagekull, 2000, 2003; Kirkpatrick, 1998; TenElshof & Furrow, 2000). For example, Byrd and Boe (2000) found that participants reporting secure romantic attachments engaged more in prayer that served to maintain closeness to God. Moreover, even in prospective analyses, IWM correspondence between romantic attachment security and religious change has been supported in expected contexts—for example, following the formation of a romantic relationship in between assessments of religiosity (Granqvist & Hagekull, 2003).

Besides the correlational studies just reviewed, four sets of attachment and religion experiments (or quasi-experiments) involving subtle attempts to activate attachment have been performed (Birgegard & Granqvist, 2004; Cassibba et al., 2013; Granqvist, Ljungdahl, et al., 2007; Granqvist, Mikulincer, et al., 2012). The normative/main effects of attachment activation observed in these studies have already been described. However, in all four sets of studies, the main effects were qualified, or moderated, by perceived attachment history or current attachment security in a manner that supports the notion of IWM correspondence.

As we have seen, individuals who have experienced insensitive care are more likely to regulate intense distress through their perceived relationship with God than are those who have experienced sensitive care (i.e., a compensation effect). However, across the three experiments conducted by Birgegard and Granqvist (2004), an increase in the use of God to regulate distress was observed following subliminal separation primes among

adult believers who had reported sensitive experiences with parents, thus supporting IWM correspondence instead. Because indirect assessments of religiosity (i.e., regression residuals from pre- to postpriming) were used in the context of *subliminal* priming, participants were unaware of attachment activation. Birgegard and Granqvist speculated that these conditions might have undermined the possibility of a compensatory use of religion in individuals who had experienced parental insensitivity, resulting in their withdrawal from God or (put differently) their defensive shift of attention away from attachment (e.g., Main et al., 1985). Conversely, presumably via automatic activation of IWMs, individuals with more sensitive experiences with caregivers could draw upon God in this situation, or turn their attention to attachment.⁵

In line with these speculations, the heightened psychological accessibility of God concepts following subliminal threat exposures (i.e., God as an implicit safe haven), observed by Granqvist, Mikulincer, and colleagues (2012), was particularly notable in participants with a relatively secure (nonavoidant) romantic attachment orientation. This experiment therefore conceptually replicated and extended those of Birgegard and Granqvist (2004). Similarly, concerning implicit access to God as a secure base, participants with a relatively secure romantic attachment style had particularly heightened cognitive access to secure base-related concepts following subliminal priming with the word *God* (Study 3) and implicitly reacted with more positive affect following subliminal exposure to a religion-related picture (Study 4) (Granqvist, Mikulincer et al., 2012). Hence, not only was attention to God more heightened for individuals reporting relatively secure romantic attachment than for those reporting insecure attachment when faced with unconscious threat, but the former individuals were also more likely to implicitly associate God with secure-base-related constructs and to benefit more implicitly from being unconsciously exposed to God-related material.

In addition, in the Swedish “felt board” study of 5- to 7-year-old children who were asked to place a God symbol at a chosen distance from a fictional child who was in attachment-activating or attachment-neutral situations (Granqvist, Ljungdahl, et al., 2007), secure children placed the God symbol closer to the fictional child when the fictional child was in attachment-activating situations. However, the pattern was reversed when the fictional child was in attachment-neutral situations (i.e., insecure children placed God closer).

Overall, the discrepancy in God symbol proximity between the two types of situations was much larger in secure than in insecure children. Our interpretation of this interaction is that secure children’s attention shifted to God following attachment activation, whereas insecure children’s attention to God did not shift as a function of attachment activation. Importantly, this study used the adapted Separation Anxiety Test (SAT; Kaplan, 1987), an indirect (semiprojective) method, to measure security, and the God symbol placement procedure was similarly semiprojective (i.e., the fictional child, not the study participant, was in different situations that were more or less likely to activate a child’s attachment system). As in the adult experiments using subliminal priming techniques, this semiprojective procedure may have undermined a compensatory use of religion in insecure children, and instead yielded automatic activation of IWMs, thus supporting the correspondence hypothesis.

Cassibba and colleagues (2013) extended these findings in an Italian sample, showing that just as attachment security tends to be transmitted across generations from mother to child (Van IJzendoorn, 1995), *maternal* security on the AAI strongly predicted a higher degree of proximity in *their children’s* God symbol placements relative to the fictional child. These findings are theoretically important in illustrating, perhaps for the first time, that mothers’ IWMs generalize to the next generation’s perceptions of the availability of another AF besides the mother.

In summary, substantial empirical support has been obtained for the idea that the developmental pathway to religion for individuals with secure attachments runs through extensive experience with sensitive, often religious caregivers and leads to the development of a security-enhancing representation of God. Moreover, in such cases, God, like other good AFs (Mikulincer & Shaver, 2004), is implicitly seen as available in times of need, although secure individuals are unlikely to need to use the perceived relationship with God specifically to regulate distress.

Attachment to God and Psychological Outcomes

To the extent that having a safe haven and secure base prevents or reduces fear and anxiety, as argued by Bowlby (1969/1982) and others, a

representation of God as a safe haven and secure base should confer certain psychological benefits. The connections between religion and mental health/well-being, which are both very complex, multifaceted constructs, are immensely complex: It seems clear that religious belief and commitment can have highly positive, highly negative, or neutral effects on mental health as variously defined (see Paloutzian & Kirkpatrick, 1995, for examples). In other words, the connection between religion and mental health is heavily influenced by moderators. A thorough review of this largely atheoretical and fragmented literature is beyond the scope of this chapter, but in this section, we argue that attachment–theoretical considerations may provide insight into why certain moderators underlie the links observed between religion and mental health. In order to facilitate a more systematic understanding of these links, we suggest three sets of moderators (for a more detailed discussion, see Granqvist, 2014a).

First, *contextual factors* associated with heightened attachment activation (e.g., stress, unavailability of one’s secular AFs, low social welfare) increase the strength of the links observed between religion and mental health. For example, the positive effects of religious variables, such as those of “positive” religious coping (e.g., designed to increase the experience of spiritual support; Pargament, 1997) and “intrinsic” religiousness (i.e., religion as an end to itself, a master motive in life), on mental health outcomes are typically moderated by levels of stress, such that religion confers its most beneficial effects in times of real trouble. A meta-analysis of studies of religion and depression offers more specific evidence: Aspects of religion were negatively linked to depression, especially under conditions of high stress, whereas the main effect of religion on depression was relatively modest (Smith, McCullough, & Poll, 2003). Conversion research provides further evidence. Not only are intense/sudden conversion experiences likely to occur during times of stress, but such experiences are associated with marked attenuation of distress and at least short-term increases in well-being (Hood et al., 2009; Pargament, 1997).

Besides stress, research suggests that religion may be especially helpful in contexts in which other AFs are unavailable or insufficient as security providers. For example, in an early study by Kirkpatrick and Shaver (1992), the “effects” of attachment to God on psychological outcomes were moderated by perceived attachment history with

the mother. Respondents who remembered their mothers as relatively insensitive but perceived themselves as having a secure attachment to God (i.e., viewing God as responsive, loving, and caring) appeared to benefit the most from their perceived relationship with God.

The broader societal and cultural context should also be borne in mind. In particular, demographic data indicate that the one specific parameter that explains most (roughly 50%) of the statistical international variance in population estimates of religiosity (including seeking comfort, or a safe haven, in religion) is governmental welfare spending (i.e., proportion of gross national product [GNP] spent on schools, health care, health insurances, etc.). The conclusion from this literature is very clear: People are much less religious in welfare states. Parts of Europe (especially Scandinavia) are the very best cases in point, and this strong association seems to withstand control for every conceivable covariate (Gill & Lunds-gaarde, 2004; Scheve & Stasavage, 2006). In these countries, state agencies and other functions of the welfare system appear to have replaced many of the functions historically served by religion. From an attachment–theoretical viewpoint, it may be that the successful implementation of welfare politics normally helps to keep people relatively safe and secure from alarm; they need not be shaken to their bones by misfortune because there is usually a safety net on which to fall back. As a corollary, religion may be especially likely to be conducive to mental health in societies marked by lower social welfare, that is, in contexts in which religion is typically both “needed” and culturally normative.

Second, *aspects of mental health* that are most notably affected by having a safe haven to turn to and a secure base to depart from are particularly reliably linked to religion. The psychological desideratum of a safe haven is the sense of having someone perceived as a protective, stronger, and wiser other to turn to when alarmed and distressed, which should be accompanied by attenuated worry and fear. The psychological desideratum of a secure base is that it promotes a sense of personal competence and control, which enables calm and confident exploration. Not coincidentally, in their review of research on associations between aspects of mental health and religious orientations, Batson and colleagues (1993) concluded that the most consistent positive links were obtained between freedom from worry and fear, and personal competence and control on the one hand, and intrinsic religiousness on the other.

As noted, another attachment-related aspect of mental health that religion appears to promote is the attenuation of grief (e.g., Brown et al., 2004; Cicirelli, 2004). Relatedly, it is also possible that religion may aid in reparation of maladaptive IWMs, for example, following loss of and/or experiences of having been insensitively cared for by other AFs. The possibility of the latter “earned security” form of reparation was discussed earlier in the section on compensation. Concerning loss, Bowlby (1980) noted that to proceed favorably in terms of promoting adaptation to a life without the loved one physically available, the mourning process requires that bereaved individuals ultimately accommodate information regarding the permanence of the loved one’s death into their representational world, or else they are at risk of remaining unresolved/disorganized with respect to the loss (e.g., may display continued searching behaviors; Main et al., 2003). Available evidence indicates that the proportion of unresolved loss is somewhat lower in religious samples (3–17%; Cassibba et al., 2008, 2013; Granqvist, Ivarsson, et al., 2007) than in the nonclinical meta-analytic sample (16%; Bakermans-Kranenburg & Van IJzendoorn, 2009). Religion may promote mental resolution of loss by offering the bereaved both (1) the prospect of reunion with the deceased in the hereafter (Cassibba et al., 2008) and (2) the perfect surrogate AF (i.e., God) for dealing with the grief.

Finally, *aspects of religion* that are most consistently linked to mental health are partially those that express attachment components, including belief in a personal, loving God with whom one experiences a close and secure relationship. In fact, based on comprehensive research reviews, leading scholars on the religion–mental health connection have even suggested that “belief in/attachment to God” is the very source of religion/spirituality that makes people engage in other, more specific health-enhancing religious behaviors (e.g., rituals, commitment, coping) (Koenig et al., 2012, p. 587). Similarly, Pargament (2002) has concluded that mental health and well-being are predicted, positively and uniquely, by a secure relationship with God and perceived closeness to God (cf. secure attachment to God), whereas a tenuous (cf. insecure) relationship with God has an unfavorable effect on mental health and well-being.

Unfortunately, however, the empirical evidence for the vital role of attachment to God is far from conclusive. Interpretation of the data collected so far is limited by several methodological problems (Granqvist, 2014a). As one example, the causal direction of cross-sectional correlations

between religion and various outcomes remains open to question. For another example, the (self-report) mode of measuring attachment to God and well-being in the studies conducted to date (e.g., Beck & McDonald, 2004; Kirkpatrick & Shaver, 1992; Rowatt & Kirkpatrick, 2002; Sim & Loh, 2003; Zahl & Gibson, 2012) leaves us unable to exclude the possibility that (any combination of) self-deception, impression management, shared method variance, semantic overlap, and so on, may be at least partly responsible for the associations obtained. Therefore, it is imperative to use less explicit methods for evaluating individual differences in believers’ perceived relationship with God. Based on a longitudinal follow-up of our AAI study sample (Granqvist, Ivarsson, et al., 2007), we currently address this issue by using an interview about believers’ representations of God in relation to the self (Granqvist & Main, 2003), which was adapted from the AAI protocol. One aim in developing this interview is to be able to undermine some of the potential validity threats to the self-reports of attachment to God. This method may ultimately prove to be useful also for shedding light on the attachment foundation of the religion–mental health connection, and particularly on the important question of whether earned security is sometimes derived from one’s attachment to God.

Current State of Theory and Research on the Attachment–Religion Connection

Since the previous edition of this volume in 2008, religion-as-attachment research has continued to mature. In fact, this field has been singled out in an authoritative handbook as the last decade’s most promising “midlevel” theoretical contribution to the psychology of religion as a whole (Paloutzian & Park, 2013). This continuing maturation is remarkable considering that the religion-as-attachment model has been around for approximately a quarter of a century. We believe that there are two broad sets of reasons for the progress that has been made, one relating to increasing methodological rigor, and the other to conceptual expansions (Granqvist, 2010).

Regarding increasing methodological rigor, past attachment–religion research was predominantly correlational, whereas experimental and quasi-experimental designs have been increasingly added to the database in more recent years (e.g.,

Cassibba et al., 2013; Granqvist, Mikulincer, et al., 2012). Also, whereas past studies predominantly used samples of convenience, which were often drawn from student populations, recent studies have increasingly used more careful sample recruitment strategies and well-defined study populations (e.g., Cassibba et al., 2008; Reinert & Edwards, 2009; Schnitker et al., 2012). In addition, although past research was almost exclusively based on Christian samples in the Western world, recent studies have also used non-Christian samples from other parts of the world (e.g., Granqvist, Mikulincer, et al., 2012; Pirutinsky, 2009). Finally, whereas most past studies used explicit self-report assessments of both religion and attachment constructs, indirect, implicit assessments have been increasingly added to the research in recent years (e.g., Cassibba et al., 2008, 2013; Granqvist et al., 2009; Granqvist, Mikulincer, et al., 2012; see also Zahl & Gibson, 2012). Consequently, we are now better able to make causal inferences, to understand what populations—drawn from which religions—our inferences apply to, and to rule out self-report biases as an alternative explanation of some of the key findings.

Regarding conceptual expansions, several are noteworthy. First, as a complement to the many single-generation studies conducted, Cassibba and colleagues (2013) conducted a two-generation study focusing on intergenerational links between mothers' states of mind regarding attachment and their children's sense of God's closeness. As noted, this study is noteworthy in documenting that a mother's attachment organization is linked not only to her child's attachment to the mother herself (reviewed by Van IJzendoorn, 1995) but also to the child's sense of the availability of another AF besides the mother (i.e., God). Future research might show that similar generalizing effects extend to other attachment-related targets as well. Second, whereas the safe-haven function of religion has been supported and is particularly strongly emphasized in prior religion-as-attachment research, two recent experiments have provided equally compelling support for the secure-base function of religion (Granqvist, Mikulincer, et al., 2012). Third, most prior research focused on links between organized attachment patterns and theistic forms of religion, but recent research has also focused on other aspects of spirituality, such as in religious syncretism (Granqvist, Broberg, & Hagekull, 2014), in the context of Buddhism (Granqvist, Mikulincer, & Shaver, 2010), and in links between unresolved loss/abuse and altered spiritual states (Granqvist et al., 2009; Granqvist, Hagekull, et al., 2012;

Thomson & Jaque, 2014). Finally, although the attachment–religion connection was placed in the context of a broader evolutionary psychology perspective on religion several years ago (e.g., Kirkpatrick, 2005), more specific conceptual connections have recently been suggested between attachment and central parameters of cognitive science in explaining an individual's development of religious beliefs and representations (Granqvist, 2014b; Richert & Granqvist, 2013). In this context, special attention has been given to cultural and environmental factors (e.g., religious models) that presumably serve to calibrate human psychological mechanisms, such as the attachment system, to make religious “output” highly likely to occur and also to remain stable and important in people's lives (Granqvist, 2014b).

Much of the progress made in religion-as-attachment research in recent years builds coherently on the heuristic potential of attachment theory and on associated research in other areas of mainstream psychology. However, the database on the attachment–religion connection is still evolving relatively slowly, at least as far as high-quality empirical contributions are concerned, and as compared to some other branches of psychological science. Thus, there is ample room for continued progress. We believe that the most important factor holding back the speed of progress is that the psychology of religion is not institutionally anchored in the psychological mainstream. Although the psychology of religion is quickly becoming less marginalized (e.g., Paloutzian & Park, 2013), it is still in many ways a fringe field, garnering almost no academic positions and funding opportunities compared to other psychological subfields. This state of affairs reflects psychology's undisputed bias against religion, including the psychological study of it (e.g., American Psychological Association Council of Representatives, 2007). This bias is likely to make most psychologists deaf and blind to the fascinating and socially relevant aspects of religion. We hope that this chapter removes some of the barriers to accepting the psychology of religion into mainstream psychology.

Conclusions and Future Directions

In this chapter, we have marshaled evidence from various sources pertinent to the hypothesis that many aspects of religious belief and experience, particularly those related to perceived relationships with God or other supernatural figures, re-

flect (at least in part) the operation of attachment processes. From a normative perspective, although God is a noncorporeal figure, God evinces all of the defining characteristics of an AF to whom people turn for a safe haven and secure base. We have also attempted to demonstrate that the attachment components of believers' perceived relations with God are far from surface aspects of religion but are instead central components of it. Moreover, we have argued that people's perceived relationships with God develop in tandem with the maturation of the attachment system and associated aspects of cognitive development (e.g., IWMs). From an individual-differences perspective, we have described two attachment-related pathways relevant to the development of religion. One of these runs through experiences with insensitive caregivers and the resulting attachment insecurity, in which case a relationship with God is sometimes a surrogate attachment that is useful in regulating distress (the compensation pathway). The other path runs through experiences with sensitive, often religious caregivers and attachment security, in which case religion is socially rooted in the parental relationship and reflects a generalization of IWMs of the self as worthy of care, and of others (including God) as willing and able to provide it (the correspondence pathway). We have also addressed attachment-related individual differences, in particular disorganized attachment and unresolved loss/abuse, associated with spiritually relevant altered states, as present in mystical experiences and New Age spirituality. We have discussed ways in which attachment-related individual differences are linked to implicit versus more explicit uses of religion. Finally, we have discussed evidence suggesting that the representation of attachment to a God perceived as a reliable safe haven and secure base may confer the kinds of psychological benefits associated with secure interpersonal attachments, especially in times of personal trouble, when other AFs are insufficient or unavailable.

As we have seen, for some individuals, religious beliefs seem to reflect responses to insecure interpersonal attachments; for others, religious beliefs are established early in life, during childhoods characterized by secure attachment, in which cases they remain fairly constant across the lifespan. This distinction raises a host of interesting empirical questions. For example, do the religious beliefs emerging from these alternative processes differ qualitatively with respect to their effects on psychological outcomes? The prospective longitudinal findings from Brown and colleagues (2004), along with other lines of evidence, suggest that

individuals who either are currently insecure or have suffered attachment-related difficulties in the past are particularly well served by religion. However, additional prospective longitudinal research is needed before a firm conclusion can be drawn. Such research should also aim to clarify whether—and if so, when and how—religion may be both a salutary factor and a risk factor for psychological outcomes in the context of insecure attachment and past attachment difficulties.

A related set of questions concerns the interaction of correspondence and compensation processes within individuals across time. For example, in cases in which religious change is motivated by insecure interpersonal attachment, does one's orientation toward interpersonal attachments change concomitantly? We have noted the possibility of "earned security" effects from religion for some individuals, but much remains to be done methodologically to secure such an interpretation, to predict for whom and under what conditions earned security might develop, and to pinpoint more precisely the psychological processes involved. Increased knowledge in this area might provide a useful basis for the development of therapeutic strategies for dealing with relationship-related difficulties, particularly in religious populations.

An additional aspect of correspondence and compensation processes that warrants future research is the distinction between implicit- and explicit-level uses of religion. Our expectation, based on the conclusions drawn from the studies reviewed here, is that when activation of the attachment system causes high levels of subjective distress (e.g., in the context of overwhelming anxiety and personal crises), individuals with insecure attachment experiences with insensitive caregivers will be more inclined to regulate distress specifically by turning to God. This is because the insecure "conditional" strategies (i.e., minimization/avoidance and maximization/preoccupation; Main, 1991) are likely to prove insufficient during intense stress. If the insecure individual cannot bear the high levels of suffering experienced sufficiently well by employing his or her usual strategy for managing stress, God may be sought in a final attempt to find a security-providing AF. This could be conceived of as a way of retrying the failed "primary" attachment strategy of seeking closeness and security (Main, 1991), albeit in relation to a different and less psychologically threatening target than one's usual AFs.

In contrast, when attachment activation is unconscious or subtle, and God is the only AF available in the situation, automatic activation of

IWMs and associated neural networks may lead individuals with secure attachment experiences with sensitive caregivers to experience God as psychologically accessible, due to a generalized coherent/singular representation (Bowlby, 1973; Main, 1991) of God. Thus, the IWM aspect of correspondence may apply particularly at an implicit level. Notably, insecure individuals with insensitive caregivers would instead shy away in such situations, due to a generalized incoherent/multiple representation (Main, 1991).

Regarding limitations in the foci of attachment and religion studies to date, two are particularly important. First, there are still no long-term longitudinal studies that have followed participants from early childhood, when their first attachments developed, to later in development, when their God relationship and other attachment relationships unfold. Second, few attachment–religion studies have been conducted outside the Western world, and, to the best of our knowledge, none outside the major monotheistic traditions other than the New Age beliefs discussed previously.

Concerning general theoretical issues, we have found in discussions with colleagues that a common misconception of the religion-as-attachment model is that it would be built on, or even require, an adaptationist understanding of religion (i.e., an assumption that religion itself promoted inclusive fitness in our environments of evolutionary adaptation, or EEAs). In contrast, our view has consistently been that religion is more likely to be an evolutionary by-product than a direct adaptation (or set of adaptations); that is, whereas the attachment system has a clear and very important biological function within its usual sphere of operation (promoting inclusive fitness through caregivers' protection and support of offspring), it is unlikely that a relationship with (an imagined) God increased inclusive fitness by systematically protecting individuals who had such a relationship from danger in our EEAs. Although some theorists would suggest that the God relationship promoted inclusive fitness in some other ways, such as through sexual selection or group selection mechanisms, we believe that there are a number of good arguments against an adaptationist view of religion (for extensive discussion, see Kirkpatrick, 1999, 2005, 2006). Nevertheless, once a mechanism has established itself within the gene pool of a species, it may well continue to operate within individuals and in contexts that are not associated with its original biological function. Therefore, the question of religion's biological functional-

ity is more or less orthogonal to the question of whether the relationship between a believer and God involves the attachment system and is a kind of attachment relationship.

Another general issue is the conceptual limit of attachment theory in the psychology of religion. We have deliberately restricted most of our discussion to aspects of religion that we believe to be psychologically grounded in the attachment system *per se*. Many other applications of attachment constructs to religion are tempting: "attachment" to human religious leaders (pastors, cult leaders, shamans); "attachment" to religious groups (congregations, cults, denominations); and the concept of "nonattachment" in Buddhism—to name just a few. Although these and other religious phenomena may seem analogous to attachment in certain ways, we suspect that many reflect the operation of psychological processes and systems other than attachment (Kirkpatrick, 1999, 2005, 2006). In short, we make no claim that attachment theory constitutes a comprehensive psychology of religion. What we do claim, however, is that attachment is a central component underlying individuals' beliefs about, ways of relating to, and representations of God, particularly, but by no means exclusively, in Christianity.

Notwithstanding many unanswered questions, we submit that no model of adult interpersonal relationships in general, or attachment relationships in particular, will be complete without explicit acknowledgment of the role of God and other imaginary figures in people's relationship networks. Incorporating religious beliefs into research on adult relationships may be useful in addressing vexing questions in the attachment literature concerning issues such as the content, structure, and generality of IWMs, and the dynamic processes underlying change in attachment patterns and IWMs over time. Thus, application of attachment theory to religion has not only held promise for the psychology of religion, but it may also have much to offer the study of attachment processes and individual differences across the lifespan.

Notes

1. God is obviously different from human AFs by being unobservable. Therefore, it is not possible to have a physical, face-to-face relationship with God. Notably, attachments typically develop based on a joint interaction history between the attached person and the AF. Without getting into the realm of metaphysics-

ics, we cannot determine that a believer's perceived relationship with God is based on such an interaction history (i.e., an expression of theism), but neither can we determine that it is not (i.e., an expression of atheism). However, our primary concern is whether, despite this difference from other attachments, a believer's perceived relationship with God can function psychologically like an attachment relationship. For the sake of readability and simplicity, throughout this chapter we speak of God "as" an attachment figure and of a believer's relationship with God "as" an attachment relationship, recognizing that some readers might prefer to characterize these phenomena as merely "attachment-like" or as "symbolic attachments."

2. All Biblical quotes are from the King James Version.
3. All attachment data reported in this chapter that required coding were coded by evaluators who were unaware of participants' religiousness and spirituality.
4. Although IWM correspondence and social correspondence are independent in principle, they are not so in practice. For example, insofar as a caregiver has an overtly expressed God image, a secure offspring is expected to adopt his or her caregiver's God image to a larger extent than an insecure offspring, even if the image is of, for example, a distant God (social correspondence). On the other hand, the secure offspring is anticipated to have a less distant God image, due to the operation of a generalized, positive set of IWMs (IWM correspondence). In practice, this is not a serious problem because a reliably sensitive caregiver's God image is unlikely to be distant. Hence social and IWM correspondence will usually operate in concert rather than in opposition.
5. In the social cognition literature, these distinctions are paralleled by distinctions between *contrast* (cf. compensation) and *assimilation* (cf. correspondence) effects (e.g., Wheeler & Petty, 2001). Contrast effects tend to occur when conditions or response modes require explicit processing (e.g., guided imagery, self-reports), whereas assimilation effects tend to occur when only implicit processes are operating (e.g., subliminal priming, lexical decision tasks).

Chapter 40

Divorce through the Lens of Attachment Theory

Brooke C. Feeney
Joan K. Monin

The only thing more unthinkable than leaving was staying; the only thing more impossible than staying was leaving.

—ELIZABETH GILBERT, *Eat, Pray, Love*

Divorce is a significant life event because it involves the termination of one of the strongest affectional bonds formed by adults. In this chapter, we consider divorce and its aftermath from an attachment-theoretical perspective. We consider the process of divorce, the effects of divorce on the couple members' postdivorce adjustment, and the effects of divorce on children. In doing so, we review the literature and consider how individual differences in attachment orientation may affect the process and outcome of divorce. We conclude by discussing important next steps for research.

The Relevance of Attachment Theory to the Study of Divorce

First, it is important to emphasize that one of the most common attachment bonds formed in adulthood is the one formed with a romantic/marriage partner. According to attachment theory, neither love nor grief nor other forms of strong emotion are felt for just any person; instead, they are felt for particular individuals with whom one has estab-

lished an attachment bond (Bowlby, 1969/1982, 1979). *Attachment bonds* are strong, persistent ties that cause each member of a dyad to maintain proximity to the other and to engage in proximity-seeking behavior when greater protection or support is needed. The biological function of attachment bonds is protection, and the capacity to make and maintain bonds appropriate to each phase of life is as important for species survival as are nutrition and reproduction (Bowlby 1969/1982, 1979). Once formed, an attachment bond tends to endure, and its disruption is strongly resisted. To the extent that dissolving a marriage requires the dissolution or reorganization of an attachment bond, divorce is a very significant life transition.

Although attachment theory does not specifically delineate the factors that contribute to divorce, it provides an important foundation for understanding the mechanisms underlying this prevalent form of social disruption in adulthood. The theory stipulates two important criteria for healthy human functioning: First, every individual (throughout the lifespan) requires the presence and availability of a trustworthy figure who is willing and able to provide a *safe haven* (where

a person can retreat for comfort and support in times of need) and a *secure base* (from which to engage in exploration of the world and one's own capacities). Second, everyone must be able both to recognize when another person is a trustworthy attachment figure and to collaborate with him or her to maintain a mutually rewarding relationship (Bowlby, 1979). The absence of one or both of these important features of a marriage—for one or both partners—sets the stage for dysfunctional relations and eventual separation and divorce.

What Happens When a Spouse Fails to Function as a Trustworthy Attachment Figure?

Human beings of all ages are happiest and able to deploy their talents to best advantage when they are confident that, standing behind them, there are one or more trusted persons who will come to their aid should difficulties arise.

—JOHN BOWLBY (1979, p. 103)

This proposition from attachment theory is important to the stability and dissolution of marriages because “trusted persons” in adulthood often include a person's spouse. Attachment theory specifies the characteristics of a trustworthy figure—one who enhances a person's safety and security by providing (1) a safe haven to which he or she can retreat in times of need and (2) a secure base from which to explore (to learn, discover, work, play, engage in challenging activities, develop relationships with peers, and grow as an individual). Attachment figures who foster security recognize and respect their partner's needs/desire for a safe haven and secure base, and they act accordingly. Such attachment figures understand, accept, and respect both attachment behavior (proximity seeking in times of need) and exploratory behavior, and recognize that one of the most common causes of negative emotion is frustration of one's desires for love and care. Emotions such as anxiety and anger often stem from uncertainty about whether attachment figures will be available and responsive to one's needs (Bowlby, 1979).

Of course, spousal provision of a safe haven and a secure base can vary considerably, and a person's ability to fulfill the role of reliable caregiver to a romantic/marital partner is often influenced by one's previous attachment history. As Bowlby (1979) said, “Each of us is apt to do unto others as we have been done by” (p. 141). Attachment theory and research suggests that when spouses provide favorable conditions for each other (as

just described), each is likely to feel secure and self-reliant, trusting, cooperative, and helpful in dealing with the other, and with their children. When favorable conditions are not provided, spouses are likely to be insecure in their relationship and plagued by feelings of anxiety, hurt, anger, mistrust, resistance to cooperation, and frustrated personal growth (Bowlby, 1979, 1988).

Spouses may encourage each other's attachment anxiety (worry about rejection or abandonment) or avoidance (discomfort with intimacy) by being unresponsive to signals of need for care, behaving in a rejecting/disparaging manner, threatening the partner or family as a means of controlling the partner, and not being consistently available (Bowlby, 1969/1982, 1979, 1988). Such experiences may cause the partner to live in constant anxiety, have a low threshold for activation of attachment behavior, and be overly solicitous/dependent. Alternatively, the partner may react to inadequate spousal care by inhibiting attachment feelings/behavior, being distrustful of the spouse, and insisting on extreme self-reliance.

According to attachment theory, all kinds of poor care are likely simultaneously to arouse anger toward one's attachment figure and to inhibit its expression (Bowlby, 1969/1982, 1979, 1988). The result is often underlying resentment that contributes to dysfunctional relations because everyone, even people who have learned to be what Bowlby (1969/1982) called “compulsively self-reliant,” needs love, care, and support. Moreover, when a person's attachment needs go unmet, he or she is more vulnerable to stress and less capable of dealing with it. In fact, unmet attachment needs may be expressed in aberrant forms of care-eliciting behavior (substance use, sexual infidelity) that are likely to take a great toll on marriage and family relations (Bowlby, 1979).

What Causes a Person to be Unable to Recognize a Trustworthy Attachment Figure and Collaborate in a Mutually Rewarding Relationship?

There is a strong causal relationship between an individual's experiences with his parents and his later capacity to make affectional bonds.

—JOHN BOWLBY (1979, p. 135)

According to attachment theory, a healthy person is able to trust and rely on others, and to know who can be relied upon (Bowlby, 1969/1982,

1988). A healthy adult is also capable of exchanging roles when the situation calls for it, at one time providing a secure base and safe haven from which a partner can operate, and at other times being able to rely on the partner to provide a secure base and safe haven in return. Each partner must have the capacity to adopt either role as circumstances require. Each must be able to express a desire for help/support in a direct and effective way, and each, in turn, must be able to give to the other—and to their children (Bowlby, 1979, 1988).

The theory also stipulates that impairment of the ability to collaborate in a mutually rewarding relationship can take many forms. For example, a person who has difficulty trusting his or her spouse may either be unable to express a desire for support when needed or do so in a demanding, aggressive way. Both kinds of behavior reflect lack of confidence that support will be forthcoming and dissatisfaction with what is given when provided. Marriage partners with these impairments may exhibit anxious clinging and make excessive demands or be aloof, unavailable emotionally, and defiantly independent (Bowlby, 1979, 1988). They may exhibit either an inability to give spontaneously to others or a compulsively overinvolved caregiving style in order to meet attachment needs. According to attachment theory, these impairments may stem from inadequate care from previous attachment figures, most often one's parents.

A major claim of the theory is that mental and behavioral patterns learned in prior attachment relationships tend to persist because people construct representational models of self and attachment figures during childhood and adolescence, and new partners get assimilated to these models, often despite extensive evidence that the model is no longer appropriate. These biased perceptions result in misconceptions of others, false expectations about the way people behave, and inappropriate actions intended to forestall expected negative experiences. For example, Bowlby (1979, p. 142) said,

A man who during childhood was frequently threatened with abandonment can easily attribute such intentions to his wife. He will then misinterpret things she says or does in terms of such intent, and then take whatever action he thinks would best meet the situation he believes to exist. Misunderstanding and conflict must follow. In all this he is as unaware he is being biased by his past experience as he is that his present beliefs and expectations are mistaken.

Bowlby (1979) further stated that inappropriate but persistent representational models often

coexist with more appropriate ones: "A husband may oscillate between believing his wife to be loyal to him and suspecting her of plans to desert" (p. 142). Bowlby contended that the stronger the emotions aroused in a relationship, the more likely are the earlier, less conscious models to become dominant and guide perception and behavior. Thus, in order to collaborate in a mutually rewarding relationship with a spouse, an adult must consider how his or her prior experiences may influence needs, worries, expectations, and relational behavior. A major premise of attachment theory is that representational models, and patterns of behavior based on them, can be so entrenched that they continue unchecked, even when they are dysfunctional.

For example, people who have learned a pattern of fault finding, punishment, revenge, guilt induction, or evasion tend to carry those patterns into their marriages, where they are likely to contribute to a destructive downward spiral that is difficult to break. Breaking such a negative interaction cycle may require (1) discovering the specific situations (current or past) that may underlie the negative interaction patterns and recognizing that negative interaction patterns are either responses to those situations or side effects of trying not to respond to them; (2) identifying the representational models of self and attachment figures that govern one's perceptions, predictions, and actions, often without conscious awareness or clarity; and (3) reevaluating relationships, modifying representational models in light of more recent experiences, and making deliberate changes in ways of treating others (Bowlby, 1979). Such changes are typically slow and patchy; they require a great deal of motivation and effort, and insecurity often hinders this process (Bowlby, 1979). This may explain why many marriages end despite couples having sought marital counseling.

Relevant Empirical Work

Empirical work specifically linking attachment history and attachment orientation to the prediction of divorce is scarce. However, attachment theory offers a useful framework for explaining and integrating the processes that have been shown to predict marital dissolution. Personal characteristics and marital interaction patterns that predict divorce are indicative of either having a spouse who is not a trustworthy attachment figure and/or being unable to recognize, benefit from, and maintain a mutually rewarding relationship with a trustworthy figure.

As we explained earlier, attachment theory stipulates that every individual builds experience-based representational models of self and others that affect how he or she perceives events, forecasts the future, constructs plans, and selects strategies for interacting with others (Bowlby, 1969/1982, 1973, 1980). These models are thought to underlie individual differences in attachment orientation that have proven strongly predictive of relationship dynamics, including conflict behaviors (Brassard, Lussier, & Shaver, 2009; Saavedra, Chapman, & Rogge, 2010; Simpson, Rholes, & Phillips, 1996), caregiving behaviors (Feeney & Collins, 2001; Feeney & Thrush, 2010; Kuncz & Shaver, 1994), motivations (Feeney, Collins, Van Vleet, & Tomlinson, 2013), biased information processing (Collins & Feeney, 2004; Ein-Dor, Mikulincer, & Shaver, 2011; Feeney & Cassidy, 2003), coping strategies (Mikulincer & Florian, 1998; Schmidt, Blank, Bellizzi, & Park, 2012), physiological responses to stress (Jaremka et al., 2013; Pietromonaco & Powers, 2015; Roisman, 2007), emotion regulation/expression (Monin, Feeney, & Schulz, 2012; Simpson, Collins, Tran, & Haydon, 2007), trust (Mikulincer, 1998), defensiveness (Fraley, Garner, & Shaver, 2000; Kohn, Rholes, & Schmeichel, 2012; Mikulincer & Orbach, 1995), and forgiveness (Liao & Wei, 2015; Mikulincer, Shaver, & Slav, 2006). Specifically within the context of marriage, attachment insecurity has been linked with relationship dissatisfaction, poor communication, poor emotion regulation, poor problem solving, and poor support behavior (Davila, Karney, & Bradbury, 1999; J. A. Feeney, Noller, & Callan, 1994; Kohn, Rholes, & Schmeichel, 2012).

In happy, well-functioning relationships, the attachment system works, so that both partners feel secure and protected, each is able to depend on the other, and each is unafraid of the other's dependence or both partners' interdependence (Fisher & Crandell, 1997). In a securely attached couple this reciprocity is achieved, but in insecure couples, there is rigidity (Reibstein, 1998). In insecure couples, protecting oneself is the primary objective, and it often overrides one's ability to respond empathically to one's partner. Insecure couples include ones in which (1) both partners defensively avoid dependency, each fleeing or withdrawing in times of distress; (2) one partner feels deprived of responsive support, while the other feels overwhelmed by what seem to be the other's insatiable needs; and (3) one partner always occupies the dependent role, while the other is defensively accusatory and dismissive, which

may appear as one partner continuously giving and sacrificing, while the receiving partner is continuously dissatisfied, controlling, unappreciative, and demanding (Fisher & Crandell, 1997). In all such cases, the attachment relationship, which ideally is supportive and rewarding, has become painful, conflictual, and unsatisfying, and the defensive processes that ensue—the very ones delineated so well and extensively by Gottman and colleagues (Gottman, 1994; Gottman & Levenson, 1992, 2000)—are likely to result in marital dissolution.

Attachment theory and research provide additional insight into the mechanisms underlying stability or instability of marriages. In a 4-year longitudinal study of newlyweds, Davila and Bradbury (2001) found that, compared with spouses in happy marriages and divorced spouses, spouses in stable but unhappy marriages showed the highest levels of attachment insecurity both initially and over time. It seems that insecurity causes spouses to be dissatisfied with their marriages yet simultaneously keeps them tied to the marriage. Although dissatisfaction is a proximal predictor of divorce (Karney & Bradbury, 1995), many couples do remain together despite dissatisfaction. Anxious/preoccupied individuals, who are chronically concerned about abandonment and love-worthiness, may attempt to maintain their relationships at any cost (Kirkpatrick & Davis, 1994), whereas avoidant individuals may view divorce as a suitable way to avoid intimacy. Consistent with this idea, research has shown that avoidant attachment is a risk factor for multiple marriages (Ceglian & Gardner, 1999).

Effects of Divorce on Couple Members

Attachment theory describes the propensity of human beings to form strong emotional bonds with particular others and explains the many forms of emotional distress and personality disturbance (including anxiety, anger, depression, and emotional detachment) to which unwilling separation and loss can give rise (Bowlby, 1973, 1979). Because attachment is an instinctive process that is elicited particularly during times of threat and stress, the loss of an attachment figure may intensify feelings of distress and have an adverse effect on a person's health and well-being if the attachment bond is not broken for both couple members.

Psychological and Physical Health

Studies of divorce have focused primarily on adjustment to divorce and the effects of divorce on physical and psychological well-being. Most such studies have examined the link between marital status and various indicators of individual well-being, and have found consistently that separated and divorced individuals have higher rates of physical and mental health disturbance than married individuals, and often higher rates even than widowed individuals (Blumenthal, 1967; Mirowsky & Ross, 2003). Specifically, separated and divorced individuals experience increased rates of acute (infectious diseases, respiratory illnesses) and chronic (diabetes, heart disease) physical illnesses, physical limitations, psychopathology, depression, suicide, homicide, violence, substance abuse (alcoholism), accidents and injuries, and disease-caused mortality (Aseltine & Kessler, 1993; Bloom, Asher, & White, 1978; Booth & Amato, 1991; Burman & Margolin, 1992; Chatav & Whisman, 2007; Hu & Goldman, 1990; Kiecolt-Glaser et al., 1987; Lorenz, Wickrama, Conger, & Elder, 2006; Overbeek et al., 2006; Perrig-Chiello, Hutchison, & Morselli, 2014; Sbarra, 2015; Sbarra, Hasselmo, & Nojopranoto, 2012; Stack & Scourfield, 2015; Williams & Umberson, 2004). Divorced individuals also report lower levels of happiness, life satisfaction, self-esteem, self-confidence, and competence (Amato, 2000; Glenn & Weaver, 1988; Gustavson, Røysamb, von Soest, Helland, & Mathiesen, 2012; Kurdek, 1991; Lucas, 2005; Spanier & Casto, 1979).

It is important to note that although divorced individuals are worse off than married people in general, if divorced people are compared with people in the most unhappy marriages, the divorced have higher morale, fewer physical problems, fewer depressive symptoms, and greater life satisfaction, self-esteem, and overall health (Hawkins & Booth, 2005; Overbeek et al., 2006). Thus, the more unhappiness and distress experienced in a marriage, the greater the relief and potential benefit that may follow divorce (see also Gustavson, Nilsen, Orstavik, & Røysamb, 2014; Gustavson et al., 2012; Spanier & Thompson, 1984). Also consistent with the idea that divorce is not uniformly harmful, research has shown that following a period of both emotional and physical upheaval, most adults cope successfully with divorce (Amato, 2000; Aseltine & Kessler, 1993; Booth & Amato, 1991; Hetherington & Kelly, 2002; Perrig-Chiello et al., 2014; Sbarra & Emery, 2005), and some re-

port opportunities for growth, increased independence, and increased life satisfaction (Huddleston & Hawkings, 1991; Maatta, 2011; Marks, 1996; Symoens, Colman, & Bracke, 2014).

Nonetheless, a great deal of research indicates that divorce is generally very taxing and distressing. Although some studies have suggested that marital dissolution affects men more than women (Hu & Goldman, 1990; Symoens, Van de Velde, Colman, & Bracke, 2014), and others have suggested the reverse (Aseltine & Kessler, 1993; Gottman & Levenson, 1992; Kiecolt-Glaser et al., 1987), the effects of separation and divorce on psychological and physical health have been extensively documented for both sexes. It appears, however, that the processes responsible for the link between divorce and particular health outcomes may be different for women and men. For example, the health effects of marital loss have been attributed to the economic hardships and material conditions suffered by women when marriages dissolve (Lillard & Waite, 1995) and to the loss of social networks and social control that encourages healthy living for men (Gove & Shin, 1989; Umberson, 1987; see Dupre & Meadows, 2007, for a review). Also, Gottman (1994) found that the health of women is directly affected by marital distress, whereas for men it is mediated through loneliness.

It is important to note, however, that most of the studies in this area provide little information about why or how marital status is related to health or well-being (Mirowsky & Ross, 2003). Most researchers explain their results in terms of the protective effects of marriage, which include a healthier lifestyle, higher socioeconomic status, more financial resources, and a stable social network. Other explanations include (1) a social selectivity or preexisting pathology model, according to which people who divorce are less physically or psychologically fit for marriage, and (2) a crisis model, according to which divorce is a traumatic event that induces psychological distress and health problems that lessen as a person adjusts to a changed social situation (Bloom et al., 1978; Kitson, 1982; Lucas, 2005; Solomon & Jackson, 2014). The crisis model identifies divorce-related stressors likely to affect health and well-being, such as the emotional strain of marital breakdown, continuing conflict with the ex-spouse, fewer material and economic resources, more risky behaviors (drinking, driving recklessly), less stringent health monitoring, loss of supportive social networks, loss of social status, social isolation, hardships of single

parenthood, time constraints, role strain, and the need to rebuild one's life. Attachment theory provides an integrative account of both perspectives by postulating that although separation anxiety and distress are normative responses to loss, some people are predisposed by previous experiences to react more strongly to losses (Kitson, 1982; Simos, 1979; Weiss, 1975).

Individual Differences in Adjustment

Because attachment theory predicts differential experiences of relationships, appraisals of threats, emotion regulation, and coping strategies, depending on attachment styles (Mikulincer & Florian, 1998; Shaver & Mikulincer, 2007; Mikulincer & Shaver, Chapter 24, this volume), there are likely to be systematic individual differences in adjustment to divorce. In fact, individual differences should be especially evident in the context of divorce because divorce raises a core attachment issue (loss of an attachment figure), and the stresses/challenges associated with divorce are likely to heighten activation of the attachment system. According to attachment theory, stressful life events such as divorce should be particularly taxing for individuals with troubled attachment histories (insecure attachment orientations) (Bowlby, 1979). Insecure individuals are particularly likely to break down after loss or separation because the separation confirms their worst fears and expectations. The divorce is likely to reactivate earlier unresolved separations from attachment figures, and because insecure individuals lack the inner resources and coping strategies needed for adjusting to divorce, they are likely to have difficulty dealing with the loss (Mikulincer & Florian, 1996).

When discussing bereavement in adult life, Bowlby (1979) noted that adults generally respond to separation and loss in a series of stages, including numbness, yearning and searching, disorganization and despair, then reorganization. He also identified characteristics of loss situations that interfere with healthy adjustment. These include (1) having been in a relationship that provided considerable self-esteem and role identity, which are less sustainable without the lost partner; (2) having no close relationship with another person to whom the individual can transfer some of the feelings that were bound up with the lost spouse; and (3) a marriage that was conflicted or ambivalent. Bowlby emphasized that in order for mourning to result in a favorable outcome, the bereaved person must be able to express his or her feelings

(yearning, anger, sadness, fear of loneliness) and may need the support of another trusted person.

Attachment theory makes predictions regarding individual differences in adjustment to divorce. The divorce-related distress experienced by secure individuals is likely to be buffered by social and personal resources that facilitate coping (e.g., the ability to seek and elicit support from others; Vareschi & Bursik, 2005). In contrast, insecure individuals view stressors as more threatening. Those high in attachment anxiety view themselves as less capable of coping and report greater distress (Davis, Shaver, & Vernon, 2003); those high in avoidant tendencies use distancing to cope, do not turn to others for support, and report greater hostility (Mikulincer & Florian, 1998; Ognibene & Collins, 1998).

A few studies have specifically examined divorcing adults' adjustment as a function of attachment orientation. Birnbaum, Orr, Mikulincer, and Florian (1997) found that dispositional attachment anxiety and avoidance are associated with greater divorce-related distress and poorer coping (see also Cohen & Finzi-Dottan, 2012). Lee, Sbarra, Mason, and Law (2011) found that separated adults high in attachment anxiety showed higher levels of hyperactivating coping strategies and the highest levels of blood pressure during a divorce-specific task. Fraley and Bonanno (2004) studied a group of bereaved (not divorced) adults and found differences between two kinds of avoidance: Whereas some avoidant individuals (those who are also high in anxiety, called *fearful avoidants*) have difficulty adapting to the loss of a loved one, those who are *dismissing avoidants* seem resilient in adapting to loss, perhaps because they were not as invested in their relationship before the loss. In extremely threatening situations in which it is impossible to maintain a defensively dismissive stance, both anxious and avoidant attachment are associated with symptoms (Mikulincer, Horesh, Eilati, & Kotler, 1999; Mikulincer & Shaver, 2007). Corroborating these findings, Yamoz-Yaben (2010) found poor adjustment to divorce particularly among preoccupied and fearful (high anxiety) individuals. In another study, among avoidant individuals, those who were able to self-regulate (as indexed by heart rate variability during a divorce-related mental activation task) showed improvements in their self-concept over 3 months, whereas those who were less able to self-regulate showed either no improvement or worsening of their self-concept over the subsequent 3 months (Sbarra & Borelli, 2013), which suggests

that some people (perhaps dismissing avoidants) are better able to deactivate attachment-related thoughts and feelings than others. It will be important to conduct more in-depth studies of the links between attachment security and adjustment to divorce, as well as the mechanisms underlying these links, one of which may be the ability to self-regulate.

Continuing Attachment and Postdivorce Contact between Ex-Spouses

Although there are many problems and stressors with which divorced individuals must cope (economic problems, legal issues, property settlements, social network changes, concerns regarding children and coparenting, formation of new relationships; see Bohannon, 1970; Spanier & Casto, 1979), the loss of the marital relationship itself, combined with continuing contact and involvement with the ex-spouse, has been viewed as the most stressful part of the divorce experience (Bohannon, 1970; Hetherington, Cox, & Cox, 1982; Weiss, 1975, 1976). Separation from a spouse elicits conflicting emotions in both partners, including anger, contempt, regret, resentment, longing, affection, wish for reconciliation, guilt, anxiety, panic, sadness, and loneliness—regardless of what led to the divorce (Weiss, 1976). This mixture of positive and negative emotions can be confusing and is attributed to the persistence of the attachment bond when intimate relationships are disrupted (Berman, 1988a, 1988b; Weiss, 1975).

Studies have shown that many men and women going through divorce continue to have feelings of attachment toward their ex-spouses (Berman, 1988b; Brown, Felton, Whiteman, & Manela, 1980; Kitson, 1982; Spanier & Casto, 1979; Weiss, 1975). Although feelings of attachment are greatest when the divorce is recent and the spouse was the one who initiated it, attachment does not seem to be influenced by the length of marriage, suggesting that attachment bonds may be established fairly quickly but are broken slowly (Brown et al., 1980; Brown & Reimer, 1984; Kitson, 1982) and that the loss of an attachment bond is as difficult for those married a few years as for those married many years (Weiss, 1975). Once partners have significantly bonded, attachment often persists and resists dissolution—even in the face of anger, hurt, and knowledge that the relationship should be terminated (Aydintug,

1995; Davis et al., 2003; Mazor, Batiste-Harel, & Gampel, 1998).

These continued feelings of attachment for an ex-spouse have been considered to be a primary cause of the emotional and adjustment problems that follow separation (Berman, 1988a, 1988b; Brown et al., 1980; Kitson, 1982; Weiss, 1976). Although not consistently shown (Masheter, 1991; Spanier & Casto, 1979), continuing attachment to an ex-spouse has been linked with a variety of symptoms, including depression, anxiety, distress, loneliness, anger, lowered self-efficacy, lack of social self-confidence, less autonomy, less life satisfaction, and poor self-rated adjustment (Brown & Reimer, 1984; Emery, 1994; Madden-Derdich & Arditti, 1999; Masheter, 1997).

Continuing attachment to an ex-spouse may be accounted for by the biological predisposition to use attachment figures as a safe haven and a secure base. Losing an attachment figure eliminates these protective functions and creates both separation anxiety and attachment system activation. The many challenges associated with divorce are stressors that are likely to intensify activation of the attachment system and create a desire for proximity to one's attachment figure (which may have been the spouse prior to the divorce). The process of detachment and reorganization (Bowlby, 1980) is likely to be more difficult than either spouse anticipates because attachment bonds are likely to be partly unconscious and sometimes masked by feelings of dissatisfaction with the spouse (Weiss, 1975, 1976). This idea is consistent with research indicating that partners are often unaware of their emotional investment in their relationship until the relationship ends (Berscheid, 1983). This may explain why 42% of couples headed for divorce separate and then reconcile at least once before ending the relationship (Kitson & Raschke, 1981), why some ex-spouses end up having sex when they were intending only to transfer their children from one parent to the other (Davis et al., 2003), and why only a few years after their divorce, a majority of remarried men say they regret having divorced their former wives (Reibstein & Bamber, 1997).

Because of the difficulty of detaching, Reibstein (1998) notes that divorced individuals often experience a deep vulnerability to their former spouse, which they feel they must guard against with defensive strategies to prevent the pain of reevoked attachment feelings. Regardless of who initiated the divorce, both couple members are likely to be vulnerable, and the process of detachment is likely to be slow and painful for both. In

fact, Bowlby (1973) noted that before detachment occurs, the attachment bond may be reactivated if the attachment figure reappears and invites renewed attachment. Attachment feelings and behaviors can be easily reactivated by drawing the former spouse back into old behavior patterns (Reibstein, 1998). Mikulincer and Florian (1996) proposed that adaptation to loss of an attachment figure involves a dialectical interplay of two opposing forces: the desire to maintain proximity to the lost person and the simultaneous desire to detach from the person to form new relationships.

Despite a large empirical literature on other aspects of the divorce experience, little is known about postdivorce relationships between ex-spouses. This is surprising given that postdivorce relations are likely to have important effects on the entire family system (Cole & Cole, 1999). It was once assumed that all postdivorce relations reflect separation distress and should be avoided (Kressel, Lopez-Morillas, Weinglass, & Deutsch, 1978). Clinical and empirical reports have shown that continued relations with a former spouse are often problematic (Aydintug, 1995; Kitson & Morgan, 1990) and that postdivorce harmony is rare, particularly when children are involved (Ambert, 1988; Buunk & Mutsaers, 1999). For example, research has shown that one-half of divorced women and one-third of divorced men continue to be intensely angry at their former spouses, even 10 years after the breakup (Wallerstein & Blakeslee, 1989). Moreover, a study of remarried individuals found little continued friendship between former spouses (Buunk & Mutsaers, 1999). Few relationships offer as many opportunities for anger, blame, hatred, retaliation, desires for revenge, and violence as the ones between former spouses (Guisinger, Cowan, Schuldberg, 1989), particularly given that ex-spouses know each other's vulnerabilities. Remarriages may also contribute to poor postdivorce relations because a close relationship with a former spouse may be threatening to a new spouse and create conflict in the new marriage (Buunk & Mutsaers, 1999).

Attachment theory provides a basis for explaining some of the negative ways in which former spouses behave toward each other. Bowlby (1969/1982) knew that behavior of an aggressive sort (protest, anger) often plays a role in maintaining affectional bonds. Anger can be functional when separation is perceived to be temporary because it may hasten reunion and make it less likely that another separation will occur. This may explain why high levels of disagreement and con-

flict typically occur during the first year of marital separation (Toews, McKenry, & Catlett, 2003), why many women continue to suffer physical and verbal abuse after separation and divorce, typically by men who do not want the relationship to end (Arendell, 1995; Jasinski & Williams, 1998), and why many relationships without a history of violence often become violent at the time of separation (Ellis & DeKeseredy, 1989; Toews, McKenry, & Catlett, 2003).

Although research has indicated the downside of continuing attachment to one's ex-spouse, it is important to note that a majority of divorced individuals report at least occasional contact with their ex-spouses, and that continuing attachment (presumably relatively secure attachment) might be associated with healthy development as well (Masheter, 1991). For example, research on children's continued contact with both parents has acknowledged the benefits of postdivorce relationships between ex-spouses (Ahrns & Rodgers, 1987; Ahrns & Wallisch, 1986; Dozier, Sollie, Stack, & Smith, 1993). Cooperative postdivorce parenting can reduce role strain for custodial parents and the sense of estrangement and loss for noncustodial parents (Hetherington & Camara, 1984; Masheter, 1991). In fact, it has been argued that for couples who share custody of children, detachment can be only limited (Reibstein, 1998) and some degree of attachment, if transferred effectively into constructive behavior, might be beneficial (Furstenberg & Cherlin, 1991; Madden-Derdich & Arditti, 1999; Masheter, 1991).

Reibstein (1998) argued that, given the strength of the attachment bond, divorced couples need protection from each other during and after divorce in the form of limited and rule-bound contact (agreed-upon rules of engagement and civility to set limits on dysfunctional behavior). Just as children need clarity, predictability, and consistency in the divorce context, so do the divorcing adults. The challenge for divorced couples is to redefine their relationship in a way that is mutually supportive, while minimizing behaviors that adversely affect adjustment (Madden-Derdich & Arditti, 1999). Because the relationship between former spouses often determines the emotional climate in which families function after a divorce (Ahrns & Rodgers, 1987; Hetherington et al., 1982), this redefinition process has significant implications for the functioning of the family in its new form.

Thus, both theoretical and empirical work on the redefinition process is needed. In some ways

this process may be like the reorganization of attachment representations following bereavement. At first, Bowlby (1969/1982) viewed this as a case of “detachment,” but in his later years (Bowlby, 1988), he viewed it as a matter of reorganization of attachment representations (Fraley & Shaver, 2008). Perhaps as postdivorce attachments can be reorganized so that some of the earlier positive feelings and a new commitment to cooperative interdependence (in parenting) can be beneficial, whereas the disappointment/animosity engendered by the failed marital relationship can fade into the background of memory. This redefinition process may involve a process of transition from an attachment bond to an affiliative bond, which, according to attachment theory, relies on a separate behavioral system. This redefinition process also involves the coordination and maintenance of joint caregiving responsibilities toward the children, while recognizing that other aspects of the prior marital relationship (attachment, sexuality, and caregiving toward the spouse) no longer apply. Positive relations between ex-spouses serve the interests of both spouses’ caregiving systems, enhancing the children’s well-being and the divorced parents’ reproductive fitness.

Divorcing parents with secure attachment orientations are at an advantage because qualities associated with secure attachment (good communication skills, constructive coping strategies, ability to regulate emotions, and the ability to solve conflicts cooperatively) should enable them to share parenting while keeping their children’s best interests in mind (Cohen & Finzi-Dottan, 2005; Roberson, Sabo, & Wickel, 2011; Shimkowski & Schrodt, 2012). Interventions may assist in this redefinition process. For example, Vareschi and Bursik (2005) found that parenting workshops increase positive and decrease negative parental interactions for insecure participants, suggesting that interventions can provide insecure individuals with previously unused or unfamiliar tools/strategies for diffusing conflict and facilitating cohesion in shared parenting (for an intervention to increase attachment security, see Bowers, Ogolsky, Hughes, & Kanter, 2014; Yamoz, Plazaola, & Etxeberria, 2008).

Effects of Divorce on Children

Not only does divorce present attachment-related challenges for children, but the divorce-related

stressors experienced by parents frequently interfere with their ability to respond sensitively, responsively, and consistently to their children’s needs for safety and security (Page & Bretherton, 2001). Next we describe theory and research regarding the effects of divorce on children’s attachment security, psychological and physical health, and future relationship functioning.

Attachment Security

Again, a major proposition of attachment theory is that, based on experiences with caregivers, people build representational models of themselves and others, and these models are the essence of attachment security and insecurity (Bowlby, 1969/1982, 1973, 1980). To the extent that divorce reduces a child’s confidence in who and where his or her attachment figures are; in his or her perceived acceptability in the eyes of attachment figures; and in the availability, accessibility, and sensitive responsiveness of attachment figures (all core aspects of working models), divorce is likely to affect children’s attachment security. The mere fact that parents are living apart may undermine a child’s feelings of security because parental accessibility becomes more tenuous (Maccoby, Buchanan, Mnookin, & Dornbusch, 1993; Page & Bretherton, 2001). In fact, Bowlby (1980) noted that some children who have experienced loss of or separation from one parent may fear the loss of or separation from the other.

Infants and Children

Few studies have investigated the effects of divorce on infants’ and young children’s attachment patterns, and the few that exist have yielded mixed results. Nair and Murray (2005) found that 3- to 6-year-old children from divorced families had lower security scores on the Attachment Q-Set. Clarke-Stewart, Vandell, McCartney, Owen, and Booth (2000) also found that children from divorced families were less secure, as measured by the Strange Situation at 15 months, the Attachment Q-Set at 24 months, and a modified Strange Situation at 36 months. Similarly, Solomon, George, and Wallerstein (1995; cited in Nair & Murray, 2005) found that infants from divorced families were more likely than infants from intact families to be classified as insecure in the Strange Situation. However, Kier and Lewis (1997) found no differences between infants from divorced versus

intact families using the Strange Situation. Also, Vaughan, Gove, and Egeland (1980) found only a trend for infants from nonintact families to be more anxiously attached to their mothers than children from intact families.

Investigators have identified several factors that moderate the association between divorce and attachment security in young children and are likely to explain the inconsistent links. First, as predicted by attachment theory, quality of parenting moderates the link. For example, mothers from intact families are more likely than divorced mothers to use positive/authoritative parenting styles (involving sensitivity and responsiveness), which directly affects attachment security (Hetherington et al., 1982; Nair & Murray, 2005). One study indicated that maternal emotional availability (the ability to read and respond appropriately to a child's emotional cues) contributed to the child's secure attachment above and beyond age of onset of overnight stays and interparental conflict (Altenhofen, Sutherland, & Biringen, 2010).

Second, father visitation patterns influence mother–infant attachment. For example, repeated overnight separation from a primary caregiver, usually the mother, is associated with disruption in mother–infant attachment when the conditions of visitation are poor (e.g., when parents do not provide adequate psychological support to the child) (Hodges, Landis, Day, & Oderberg, 1991; Solomon & George, 1999). However, mothers who function as a secure base for their children promote attachment security despite separations due to overnight visits with fathers. Furthermore, mothers who provide psychological protection to their children in the context of father visitation (by being sensitively responsive to the child during the visitation) also promote secure attachment to the father (Solomon & George, 1999). Interestingly, attachment transmission from fathers to children occurs only when fathers function as the primary caregivers (when divorced fathers have full custody; Bernier & Miljkovitch, 2009).

Third, maternal education and family income reduce the effects of divorce on attachment security (Clarke-Stewart et al., 2000) and psychological well-being (Mandemakers & Kalmijn, 2014), perhaps because better education and finances facilitate the kind of parenting that fosters attachment security. Finally, a child's cognitive ability (associated with age) has been identified as a protective factor. Kier and Lewis (1997) tested two contradicting predictions about the effects of parental separation on infants' attachment to

mother: Whereas the "early adversity" hypothesis predicts that infants will be adversely affected by negative life events and therefore develop an anxious attachment to mother, the "protective" hypothesis predicts that infants are resistant to stressors because of their limited cognitive ability. Results supported the protective hypothesis, suggesting that cognitive ability associated with age and incomplete attachment formation to the father protected young children against the ill effects of divorce.

Overall, research supports a context-sensitive view in which separation effects are moderated by the conditions of separation and reunion (Solomon & George, 1999). Observations of young children undergoing separations under varying circumstances (Heinicke & Westheimer, 1965; Robertson & Robertson, 1971) show, consistent with attachment theory, that a familiar and sensitive caretaking environment during separation can mitigate or even prevent infant distress and detachment (Solomon & George, 1999). According to this view, separation is a risk factor for attachment insecurity that may be potentiated by adverse conditions or prevented by conditions known to promote security.

Adolescents and Young Adults

A larger number of studies have investigated the impact of divorce on children's attachment later in life. With some exceptions (e.g., Bernstein, Keltner, & Laurent, 2012; Washington & Hans, 2013), the consensus is that adolescents and young adults from divorced families are more likely to be insecurely attached than those from intact families, with most evidence pointing toward a greater likelihood of becoming fearful or preoccupied (more anxious) as an adult (Brennan & Shaver, 1998; Kilman, Carranza, & Vendemia, 2006; Ozen, 2003). For example, Beckwith, Cohen, and Hamilton (1999) found that adverse life events through age 12, particularly parental divorce, reduced the likelihood of secure attachment and increased the likelihood of preoccupied representations at 18 years of age. Similarly, other longitudinal investigations have shown that divorce is predictive of an insecure attachment status at 18 years (Crowell, Treboux, & Brockmeyer, 2009; Lewis, Feiring, & Rosenthal, 2000), and that stressful life events, which included divorce in some cases, were significantly related to the likelihood of an infant classified as secure in the Strange Situation

becoming insecure by early adulthood (Waters, Merrick, Treboux, Crowell, & Albersheim, 2000; see also Ruschena, Prior, Sanson, & Smart, 2005). Riggs and Jacobvitz (2002) also found that adults classified as preoccupied and unresolved on the Adult Attachment Interview (AAI) were more likely than others to report a history of divorce or parental separation during childhood. And Mickelson, Kessler, and Shaver (1997) found parental divorce or separation to be negatively associated with secure attachment and positively related to anxious attachment in a nationally representative sample (see also McCabe, 1997; Shaver & Mikulincer, 2004; Summers, Forehand, Armistead, & Tannenbaum, 1998). Thus, it appears that parental separation or divorce is linked with attachment anxiety, which underlies both fearful and preoccupied attachment orientations.

The studies that do not support this conclusion found no relation between parental divorce and offsprings' later attachment style (Brennan & Shaver, 1993; J. A. Feeney & Noller, 1990; Hazan & Shaver, 1987; Hazelton, Lancee, & O'Neil, 1998). Fraley and Heffernan's (2013) research, using two Internet surveys of adults between ages 18 and 65, suggests that parental divorce has selective rather than broad implications for insecure attachment. This study showed that parental divorce was more strongly related to insecure relationships with parents in adulthood than insecure relationships with romantic partners or friends. Also, insecurity was more pronounced when parental divorce took place in early childhood, suggesting that there may be sensitive periods in attachment development.

Although the majority of empirical evidence suggests that divorce has a negative impact on adolescents' and young adults' attachment security, many factors have been shown to moderate this association. First, Brennan and Shaver (1993) found that parents' postdivorce marital status was related to their offsprings' attachment style. It seems that having either a mother or both parents remarry is associated with the best attachment outcome for young adults. Second, researchers have shown that individuals who come from divorced families do not differ from those who come from unhappy/intact families in their attachment security, indicating that the quality of the parents' relationship is important (Sprecher, Cate, & Levin, 1998). Third, perceptions of the reasons for divorce are important (Walker & Ehrenberg, 1998). For example, young people who felt that they were not involved in their parents' decision to divorce scored higher

on measures of attachment security, whereas those who felt they were involved were more likely to be preoccupied or fearful. Fourth, among adult children of divorce, exposure to parental alienation strategies (one parent speaking negatively about the other parent) is related to young adults' insecure attachment (Baker & Ben-Ami, 2011a). Fifth, gender of the child has sometimes been a moderator, such that women from divorced families are less likely to be securely attached and are more sensitive to the divorce experience than men from divorced families (Barber, 1998; Crowell et al., 2009; Evans & Bloom, 1996).

Finally, the quality of parent-child relationships is a key mediator between parental divorce and children's later adjustment (Amato, 2000; Amato & Sobolewski, 2001). Because divorce entails significant changes in family structure, it has the potential to influence the sensitive responsiveness and accessibility (both physical and psychological) of attachment figures, and thus affect the safe haven and secure base functions that parents normally provide. Parents may fail to provide these functions following divorce by inverting the parent-child relationship such that the child becomes a major attachment figure for the parent, or by becoming psychologically and/or physically unavailable to the child (Bowlby, 1969/1982, 1979). Not surprisingly, the influence of divorce on parent-child relationships has been an important topic in the literature (Bretherton & Page, 2004; Bulduc, Caron, & Logue, 2007; Cohen & Finzi-Dottan, 2005; Fabricius & Leucken, 2007; Hetherington, 1999; Hetherington, Cox, & Cox, 1978). Recent longitudinal studies have shown that divorce negatively impacts the mother-child relationship due to marital conflict and a collapse in parenting (Wallerstein, Lewis, & Packer Rosenthal, 2013; Yu, Pettit, Lansford, Dodge, & Bates, 2010), and that maternal sensitivity is lower in mother-child dyads in divorced families compared to intact married families (Sutherland, Altenhofen, & Biringen, 2012). Also, studies indicate that attachment to the father is particularly affected by divorce (Hannum & Dvorak, 2004; Tayler, Parker, & Roy, 1995), and that boys are more distressed than girls by separation from their fathers because of their strong identification with the same-sex parent (Hetherington et al., 1978). However, girls are most likely to feel a burden or responsibility for the father's well-being when the parents engage in conflict (Bretherton & Page, 2004; Bretherton, Ridgeway, & Cassidy, 1990; Page & Bretherton, 2001).

Psychological and Physical Health

Children of divorce may experience the effects of separation and loss to an even greater extent than the divorcing adults because children typically have no control over the decision, and it often seems to them to occur suddenly and without warning. For children, the disruption of important attachment bonds occurs not only with regard to one or both parents, but often also with regard to friends and extended family members. The cumulative toll of these separations and losses, coupled with other divorce-related stressors (economic hardship, moving, changing schools, and parental remarriage), may complicate the child's psychological development and influence adjustment (Amato, 2000).

Thus, an enormous amount of research has focused on the effects of divorce on children's psychological health. There are some studies showing that divorce may have a positive effect on children's adjustment (Bernstein et al., 2012; Crosnoe & Elder, 2004; Hagerty, Williams, & Oe, 2002), and that children may benefit if stress decreases or resources increase following divorce (Amato, 1993). However, the majority of studies indicate that children from divorced families score lower on a wide range of outcome measures associated with well-being, including academic achievement, psychological adjustment, self-esteem, conduct, and social competence, and that they are at increased risk for developmental delays, psychopathology, anxiety, depression, phobia, and problematic behavior such as aggression (Amato, 2000, 2010; Bray & Hetherington, 1993; Brennan & Shaver, 1998; Chase-Lansdale, Cherlin, & Kiernan, 1995; Clarke-Stewart et al., 2000; Kilman et al., 2006; Sirvanli-Ozen, 2005; Strohschein, 2012; Uphold-Carrier & Utz, 2012; Wallerstein & Blakeslee, 1989). Longitudinal studies suggest that the effects for some children may be quite large and enduring (Gilman, Kawachi, Fitzmaurice, & Buka, 2003; Laumann-Billings & Emery, 2000; Wallerstein & Lewis, 2004).

Researchers have also found that physical health problems are associated with exposure to distressing parental divorce processes (Bloch, Peleg, Koren, Aner, & Klein, 2007; Fabricius & Luecken, 2007; Luecken & Fabricius, 2003; Mechanic & Hansell, 1989). For example, Troxel and Matthews (2004) highlighted five studies that demonstrated a link between parental divorce and increased physical health problems (Dawson, 1991; DeGoede & Spruijt, 1996; Guidubaldi & Clemen-

shaw, 1985; Maier & Lachman, 2000). Overall, research indicates that parental divorce in childhood is associated with increased risk for unintentional injuries, illness, hospitalization, somatic symptoms, premature mortality, and suicide (Aro & Palosaari, 1992; De Jong, 1992; D'Onofrio et al., 2006; Schwartz et al., 1995; Tucker et al., 1997). Parental divorce has also been linked with health-related behaviors, including irregular eating and sleeping patterns (Sirvanli-Ozen, 2005) and risky health behaviors such as substance abuse (Amato & Keith, 1991; Bray & Hetherington, 1993), alcohol use (Hope, Power, & Rodgers, 1998; Sartor, Lynskey, Heath, Jacob, & True, 2007), smoking (Isohanni, Moilanen, & Rantakallio, 1991), marijuana use (Hoffman, 1995), early sexual activity (Amato & Keith, 1991; Barber, 1998), and teen pregnancy (Aseltine & Doucet, 2003).

Of course, important moderating variables have been identified and are consistent with attachment theory's predictions that disruptions in important attachment bonds adversely affect individual functioning (Rogers, 2004). First, the increased risk for children from divorced homes stems from discordant, conflictual relationships that precede or follow the losses associated with divorce (Cherlin et al., 1991; Rutter, 1994), and not from the divorce itself. In fact, children experience better outcomes when parents in high-conflict marriages divorce rather than remain together (Amato & Booth, 2000; Amato & Keith, 1991; Booth & Amato, 2002; Emery, 1982; Hetherington, 1999). The quality of marital and familial relations is more predictive than marital status of health outcomes, including physical symptoms (Mechanic & Hansell, 1989; Sweeting & West, 1995), cancer (Duszynski, Shaffer, & Thomas, 1981; Shaffer, Duszynski, & Thomas, 1982), and mortality (Lundberg, 1993). Thus, the overall toxicity of the home environment is a central factor in explaining the link between divorce and adverse outcomes. Corroborating this, research examining biomarkers shows that divorce has significant and sustained effects on children's hypothalamic-pituitary-adrenal (HPA) axis only in the context of traumatic separation (stress at home and disrupted parental bonding; Bloch et al., 2007). Similarly, in undergraduates whose parents divorced before age 16, Fabricius and Luecken (2007) found that exposure to parental conflict was related to poorer physical health status and more distress, and other research has shown that regardless of family type, children whose parents had a hostile interparental relationship had poorer emotional well-being than

children whose parents had a nonhostile relationship (Baxter, Weston, & Qu, 2011).

Second, high levels of warmth, affection and availability in the custodial mother-child relationship are negatively associated with post-divorce adjustment problems (Bretherton et al., 2013; Brown, Wolchik, Tein, & Sandler, 2007; Simons, Lin, Gordon, Conger, & Lorenz, 1999; Wolchik, Wilcox, Tein, & Sandler, 2000). Negative aspects of the mother-child relationship that contribute to adjustment problems include maternal depressive mood, which has been directly related to child/adolescent functioning (Forehand, McCombs, & Brody, 1987), and fear of abandonment, which mediates the link between mother-child relationship quality and internalizing-externalizing problems (Wolchik, Tein, Sandler, & Doyle, 2002). In fact, recent preventive interventions with the goal of enhancing relations between mothers and children going through divorce show positive effects on children's postdivorce adjustment (Velez, Wolchik, Tein, & Sandler, 2011; Wolchik et al., 2013). This makes theoretical sense given that a hallmark of secure attachment is open and relaxed communication between parent and child (Bowlby, 1969/1982).

Third, a strong social support network moderates the effects of divorce on children's well-being. Divorce mediation for the parents and extended family support (Emery, 1999) protect against maladjustment, particularly if the parent is psychologically unable to provide quality parenting following a divorce. For adolescents, peer support also moderates the effect of low parental support after divorce on internalizing symptoms (Rodgers & Rose, 2002). However, in a 3-year longitudinal investigation of divorcing families, MacCoby and colleagues (1993) found that the factors most powerfully associated with good adolescent adjustment were having a close relationship with a residential parent who monitored the child and remained involved in decisions concerning his or her life, and not feeling caught in the middle of parental conflict. Noncustodial parent involvement (Furstenberg, Morgan, & Allison, 1987; Sirvanli-Ozen, 2005), strong father-child or noncustodial parent-child relations (Fabricius & Luecken, 2007; Sandler, Wheeler, & Braver, 2013), and attachment to the family home (Stirtzinger & Cholvat, 1991) have also been identified as potentially protective factors. These network supports may reduce negative feelings about parental divorce, which has been linked with hostility, somatic complaints, and illness reports, indicating that it

is the negativity of experiences associated with divorce (and not the divorce itself) that increases vulnerability (Leucken & Fabricius, 2003).

Consistent with this research and with attachment theoretical predictions, Troxel and Matthews (2004) proposed that many health effects of divorce are mediated through disrupted parenting, specifically diminished warmth/sensitivity and reduced physical and psychological availability (see also Ross & Wynne, 2010). Inadequate parenting or physical absence of the parent, in turn, is hypothesized to cause children's emotional insecurity regarding their parents' love and ability to care for them (Davies & Cummings, 1994; Wolchik et al., 2002). Emotional insecurity is hypothesized to disrupt emotion regulation processes and render children susceptible to stress-related health problems. Consistent with this idea, maltreatment (most often in the form of denying emotional responsiveness) has been reported by adults whose parents divorced when they were 15 years of age or younger, and was positively associated with reports of physical and sexual abuse, and negatively associated with attachment security, self-sufficiency, and self-esteem (Baker & Ben-Ami, 2011b). Researchers have identified biopsychosocial pathways from the parental marital system to childhood health that require future study (Krantz & McCeney, 2002; Troxel & Matthews, 2004).

There is a large literature on custody issues and a fierce, two-sided debate about whether it is detrimental or beneficial for young children to have a consistent home for sleeping versus ensuring adequate sleeping time at both parent's houses—with each side interpreting attachment theory differently. One side emphasizes that secure attachment is fostered by stability with one parent and emphasizes the risk engendered by frequent/lengthy absences from a primary caregiver in disrupting attachment organization with that parent (Main, Hesse, & Hesse, 2011; McIntosh, Smyth, & Kelaher, 2013; Sroufe & McIntosh, 2011), whereas the other side argues for ensuring that children develop secure attachment with both parents and posit that the necessary mechanism for doing so is spending equal time with both parents (Kelly & Lamb, 2000; Lamb & Kelly, 2001). Existing empirical work on this issue is mixed and suggests that outcomes may depend on factors such as age of the child, parental conflict, strained relationships with parents, and whether parents have new partners (McIntosh et al., 2013; Tornello et al., 2013; Vanassche, Sodermans, Matthijs, & Swicegood, 2013). It remains for future research to establish

the ideal means by which emotional security and optimal outcomes are attained for children of differing ages with regard to living arrangements with divorced parents.

Future Romantic Relations

Attachment theory stipulates that working models of attachment and forecasts derived from them, once developed, guide behavior, feelings, and the processing of information in future relationships (Bowlby, 1980). Because the construction of these working models is thought to be influenced by experiences of separation and loss, attachment theory predicts that (particularly unresolved) experiences of separation/loss should be linked to the quality of one's future romantic relationships.

Although some investigators have found that young adults from divorced versus intact families do not differ on measures of intimacy (Nelson, Hughes, Handal, Katz, & Searight, 1993; Sinclair & Nelson, 1998), dating behavior (Greenberg & Nay, 1982), or quality of attachment to adult intimates (Olivas & Stoltenberg, 1997; Tayler et al., 1995), a majority of studies do find differences in later romantic relationship functioning between those who grew up in intact versus postdivorce families (see Amato, 1999). First, young adults from divorced families are likely to hold less positive attitudes toward marriage/relationships (Sirvanli-Ozen, 2005), show less trust (Southworth & Schwartz, 1987; Sprague & Kinney, 1997), have problems with dependency and control (Bolgar, Zweig-Frank, & Paris, 1995), be less optimistic (Sprecher et al., 1998), and believe that disagreement is destructive (Sinclair & Nelson, 1998; but see Coleman & Ganong, 1984, for an exception). Second, parental divorce increases the risk of marital instability and dissolution in offspring (Amato & DeBoer, 2001; Glenn & Kramer, 1987; Wolfinger, 2000) and of conflict in romantic relationships (Chen et al., 2006). Both divorce and marital conflict in the family of origin contribute to couple instability in offspring (Hetherington, 2003). Third, a history of parental conflict and divorce predicts lower intimacy in romantic relationships (Ensign, Scherman, & Clark, 1998; Sprecher et al., 1998), avoidance of short-term relationships (Knox, Zusan, & DeCuzzi, 2004), and perpetration of teen dating violence (Banyard, Cross, & Modecki, 2006). Corroborating these findings, Cui and Fincham (2010) showed that parental divorce and marital conflict were independently associated

with young adult children's romantic relationships, but through different mechanisms: Parental divorce was associated with young adults' low level of relationship quality through a negative attitude toward marriage (positive attitude toward divorce) and lack of commitment to their own current relationships, whereas parental marital conflict was associated with young adults' low level of relationship quality through their conflict behavior with their partner (see also Cui, Fincham, & Durtschi, 2011). In addition, adults who experienced multiple parental divorces are more likely (than adults with a single parental divorce) to claim that they are hard on their romantic partners (South, 2013), and one study suggests that parental remarriage quality has more influence on adults' current relational outcomes than the quality of their parents' first marriage (Yu & Adler-Baeder, 2007).

It is important to consider, however, that not all children from divorced families have the same risks for troubled romantic relationships in adulthood, and not every child from a divorced family experiences later relationships in the same way. Closeness to parents and positive appraisals of parental divorce have been identified as protective factors (Coleman & Ganong, 1984; Haaz, Kneavel, & Browning, 2014; Shulman, Scharf, Lumer, & Maurer, 2001), whereas parental conflict associated with divorce has a particularly negative effect on children's later relationships. The significant differences between those from intact and postdivorce families are often due to dysfunctional family dynamics and not to the divorce per se (Sprecher et al., 1998). In support of this conclusion, Hayashi and Strickland (1998) found that college students who experienced protracted interparental conflict, parental rejection, or overprotective parents were more likely to report jealousy and fears of abandonment in their love relationships, regardless of whether their parents divorced. Also, in a study of couples assessed 3 months prior to their weddings and 6 years later, those who were classified as secure (compared to those classified as insecure) were less likely to divorce in the early years of marriage (Crowell et al., 2009), indicating that attachment security is a protective factor.

Although several explanations have been offered for the intergenerational transmission of relationship instability (Amato & DeBoer, 2001; Glenn & Kramer, 1987; Hetherington & Kelly, 2002; McGue & Lykken, 1992), attachment theory offers a particularly comprehensive explanation for why some children from divorced families

grow up to have more problems with relationships than do children from intact families (Brennan & Shaver, 1993). Because the process of divorce is taxing on the separating parents (who are the primary, and perhaps the only, attachment figures for their children), it is likely to have a large influence on their caregiving capacity. The separation anxiety and attachment system activation that is often experienced by separating adults is likely to interfere with their caregiving system. In fact, in the absence of personal and social resources for coping, simultaneous activation of the attachment and caregiving systems is likely to result in caregiving that is more self-focused than other-focused (Kunce & Shaver, 1994). These caregiving dynamics, coupled with parental modeling of poor marital communication, are likely to play an important role in shaping the child's attachment orientation and experiences in romantic relationships (Brennan & Shaver, 1993).

The State of the Research since the Previous Edition of the *Handbook*

Additional research has been conducted on adults' adjustment to divorce and potential mechanisms that may account for positive or negative adjustment, and a few additional studies have focused specifically on attachment differences in adjustment. There is still a scarcity of research overall that considers the process of divorce from an attachment perspective, particularly research regarding postdivorce relations between ex-spouses.

Recent research continues to suggest that parental divorce can increase risk for negative mental and physical health outcomes in children, but this is often through parental conflict or traumatic separation. Research has continued to examine moderators of the association between divorce and well-being, identifying factors that are protective. New studies have examined mechanisms through which young children's attachment is influenced by divorce, and researchers are more often considering fathers in attachment transmission. Studies continue to show that parental divorce is associated with adult children's insecure attachment; however, new research suggests that divorce may have relationship-specific rather than broad implications for young adults' attachment. Recent longitudinal studies corroborate past research showing that divorce can negatively affect

parent-child relationships due to a breakdown in parenting, and studies continue to show effects of parental divorce on adult children's romantic relationships and attitudes toward marriage. Recent preventive interventions for families going through divorce show positive effects. A debate regarding custody issues and optimal distribution of time with divorced parents for young children will require additional empirical work.

Conclusions

Our purpose in this chapter has been to explore the relevance of attachment theory for understanding the divorce process. Although divorce has received a great deal of attention, the research on divorce lacks theoretical motivation and integration, and many aspects of divorce have not been thoroughly investigated. More work is needed to (1) specify the combinations of intrapersonal and interpersonal processes (both distal and proximal) that lead to divorce; (2) establish the mechanisms responsible for the links between divorce and health for both adults and children; (3) determine the benefits and costs of various forms of postdivorce contact between ex-spouses, particularly where children are involved; and (4) specify the connections between parental divorce and future romantic relationship functioning, particularly with regard to the intergenerational transmission of the tendency to divorce. Attachment theory provides an integrative framework for such a research program because it suggests that divorce is a *process* of disrupted attachment that has far-reaching roots in previous relationships and profound implications for future relationships.

In taking an attachment-theoretical approach to divorce, it will be necessary to elaborate and test more detailed hypotheses concerning the normative processes involved in detaching from or reorganizing attachment bonds. Although Bowlby discussed separation and loss extensively, most of his insights came from observations of children who were separated from their attachment figures, and there was much less attention given to separation in adult relationships, except in the case of bereavement. Because divorce often requires a continuing and evolving relationship with a living person, the issue of negotiated reorganization becomes important (e.g., the possibility of transforming a primary attachment with sexual components into an affiliative relationship).

Surprisingly little research or theorizing has focused on individual differences in attachment orientations that affect the divorce process. Clinicians have provided some theoretical elaboration regarding the ways that attachment patterns may affect the divorce process (Cohen, Finzi, & Aviyonah, 1999; Finzi, Cohen, & Ram, 2000; Johnson, 2003; Todorski, 1995). They propose that individuals with different attachment orientations deal differently with divorce, experience separation differently, have different coping capacities/strategies, and interact differently with ex-spouses as coparents, and they offer guidelines for clinical intervention. These ideas require empirical testing. Given the significance of divorce for adult and children, theory-guided investigations of divorce processes are important for revealing approaches that separating couples can take to ensure the health and well-being of all family members.

Chapter 41

Attachment and School Readiness

Amanda P. Williford
Lauren M. Carter
Robert C. Pianta

Research in the fields of education and psychology demonstrate the critical importance of a child possessing a diverse toolbox of school readiness skills upon kindergarten entry (e.g., Duncan et al., 2007). This toolbox includes skills related to academics, such as preliteracy and premathematics skills, as well as those related to socioemotional competence, including cooperation, frustration tolerance, and social problem-solving skills (Bierman et al., 2008; Snow, 2006; Webster-Stratton, Reid, & Stoolmiller, 2008). School readiness skills have been examined in both the education and developmental literatures, and are most often defined as the skills that a child acquires through his or her experiences in the home and early childhood education environments prior to entering formal schooling—usually kindergarten. The interactions that occur between a young child and the important adults in his or life are considered to be one of the key ongoing experiences from which children develop school readiness skills (e.g., Ainsworth, Blehar, Waters, & Wall, 1978; Mashburn et al., 2008). Early research in this topic area focused on the role that parents play in a child’s cognitive, social, and emotional development during the first several years of life, but more recent research has examined the interactions and relationships between a young child and his or her teacher as a significant contributor to the development of school readiness skills.

Attachment theory provides a useful framework to further our understanding and thinking

about the predictors of a child’s academic, socioemotional, and behavioral development within the early education setting. This chapter synthesizes the research literature linking the quality of children’s interactions with their parents and their teachers to the development of school readiness skills. We begin by examining research on the links between child–parent attachment and school readiness skills. However, the links between child–parent attachment and children’s development are described in more detail in other chapters in this handbook. Thus, although we provide a brief review of the literature linking child–adult attachment to the development of children’s readiness skills, our focus is on the quality of teacher–child interactions and relationships as contributors to the development of children’s school readiness skills. We end the chapter by providing implications for both practice and future research.

Conceptual Frameworks and Definitions

In the next section, we provide an overview of several key conceptual frameworks and definitions that have informed how researchers and practitioners understand the field of teacher–child relationships and how it relates to the development of school readiness skills. The following are included: school readiness, attachment theory, developmen-

tal systems theory, and the concept that relationships comprise daily interactions. Each of these frameworks is directly applicable to understanding the implications that attachment theory has for teacher–child relationships and the promotion of school readiness skills.

School Readiness

Our focus in this chapter is the links between a child's attachment to adults (particularly teachers) and the development of school readiness skills. The term *school readiness* has become increasingly popular as more attention has turned to early childhood education and preparing children for kindergarten entry. School readiness has been defined as a set of skills that children possess when they enter school that prepares them for later school success. These skills can be classified into several key domains: language and literacy development; cognition and general knowledge; approaches to learning; physical health (including well-being and motor development); and social and emotional development (Bierman et al., 2008; U.S. Department of Health and Human Services, 2010; Snow, 2006; Webster-Stratton et al., 2008). We specifically stress the importance of both academic (e.g., language, literacy, mathematics) and traditionally socioemotional (e.g., emotional competence, self-regulation, executive functioning) school readiness skills for a child to be successful in kindergarten and later schooling.

Current conceptualizations of school readiness strongly emphasize the role of context, seeing a child's skills as situated within and dependent on the environment (Downer, Driscoll, & Pianta, 2006; Ramey & Ramey, 1998). This conceptualization of school readiness highlights how a child's learning and development are shaped by interactions with others. As the majority of young children now spend a significant portion of their time within a child care/preschool setting outside the home before entering into formal schooling (American Community Survey, 2005–2007), it is important to describe how the quality of the teacher–child relationship in addition to the parent–child relationship contributes to early success in school.

Attachment Theory

Attachment theory is built on the belief that the quality of a child's relationships with one or more caregivers serves a critical role in the child's de-

velopment (e.g., Ainsworth et al., 1978; Sroufe, 1983). In a secure attachment relationship, the adult serves as (1) a secure base from which the child can explore new environments and (2) a safe haven for a child to return to when he or she needs to feel safe, comforted, or delighted in (Ainsworth et al., 1978). Broad constructs from attachment theory have informed the conceptualization of high-quality teacher–child relationships (Pianta, Hamre, & Stuhlman, 2003). For example, the *quality of emotional support* can be defined as the warmth, sensitivity, and support for individuality that a teacher provides to children in his or her classroom; this parallels the attachment concept of a secure base. Additionally, when children enter preschool at the age of 3 or 4 years, they carry with them the ongoing influence of the bond developed with one or both parents. The level of security achieved through the child–parent bond is theorized to influence directly the child's ability to successfully interact in and navigate this new environment.

To further extend attachment theory, one may view the daily relational interactions between a teacher and child as contributing to the creation of the child's internal working model, or schema, of the relationship that creates expectations and may guide subsequent perceptions by both the teacher and the child (Pianta, 1999). The quality of information conveyed (e.g., tone of voice, posture and proximity, timing) is just as important as the content of what is said or done within the dyad. When the quality of teacher–child interactions is high, it promotes a child's feeling of attachment and security toward the teacher. This, in turn, allows a child to engage more fully in learning activities, which supports his or her school adjustment. When teachers are able to establish an emotional connection and match levels of support to a child's abilities, they are more effective in addressing a child's problems and concerns. This responsiveness is thought to optimize the child's ability to use the classroom environment to its maximum potential in order to learn, develop, and grow.

Developmental Systems Theory

An additional theory that influences the way we think about the connections between child–adult attachments and the development of children's school readiness skills is developmental systems theory (DST). This ecologically oriented theory portrays a child as embedded within layers of sys-

tems that are both organized and dynamic (Bronfenbrenner & Morris, 1998; Good & Weinstein, 1986; Pianta, 1999). Systems may be either proximal, such as the child's family or classroom, or distal, such as the government or a parent's place of employment. DST informs how we view a child's relationships with both teacher(s) and parent(s). This theory emphasizes that a child (and subsequently, his or her relationships) exists within a multilevel system, where each level (community, classroom, family, and individual) has a dynamic bidirectional influence on relational processes (Bronfenbrenner & Morris, 1998; Sameroff, 1995). Thus, a shift in any of these levels has the potential to influence the child in either a direct or indirect manner (depending on the level of proximity of the change). For example, if, at a distal level, a child's caregiver's employer requires him or her to begin to work more hours, this will affect, among other things, the caregiver's level of stress and the amount of time available to devote to the child, which may lead to consequences for the child. At a more proximal level, a change in classroom dynamics (e.g., a new teacher or new peers) may influence the child's immediate environment and the ways in which he or she interacts in the classroom.

Relationships Comprised of Interactions

The development of school readiness skills, including academic and socioemotional skills, has been repeatedly linked to the quality of relationships that children form with their teachers (e.g., Hamre & Pianta, 2001; Mashburn et al., 2008; Pianta et al., 2003). High-quality teacher-child relationships often include high levels of warmth, sensitivity, and emotional connection, and low levels of dependency, negativity, and conflict (Pianta, 1999; Spilt, Koomen, Thijs, & Van der Leij, 2012). The quality of the teacher-child relationship is built, in part, through the daily interactions that occur between the child and teacher; these reciprocal exchanges continuously provide information to each participant and help to establish and maintain the quality of the relationship. For example, a teacher may notice that a child and a peer are struggling to work together in a learning center. The teacher acknowledges this challenge (e.g., "You two are working hard to figure this out") and provides a scaffold (e.g., "I'm here if you need me to help"). This provides the support the child needs to resolve a conflict with a peer. Additionally, this interaction provides evidence to the

child that the teacher is an adult who notices his or her struggles and is available for help, if necessary.

The quality of teacher-child relationships can be measured at the global level, with a measure such as the Student-Teacher Relationship Scale (STRS; Pianta & Hamre, 2001), or at the discrete level, with an individualized child-teacher observational measure, such as the Individualized Classroom Assessment Scoring System (inCLASS; Downer, Booren, Lima, Luckner, & Pianta, 2010). Patterns of interactions are created that are based on the daily teacher-child interactions, which form the basis of the teacher-child relationship. The temporal interactions and subsequent relationships are the primary mechanisms through which children develop and learn.

This framework dovetails with attachment theory, in that the manner in which a child engages in daily interactions with a primary attachment figure, such as a parent, may form an internal model of relationships. These mental representations formed with early caregivers subsequently guide the interpretation and behavior of other relational patterns (e.g., with teachers; Buyse, Verschueren, Verachtert, & Van Damme, 2009; Rydell, Bohlin, Thorell, 2005; Zajac & Kobak, 2006). For example, the quality of the child's interactions with his or her caregiver may influence the quality of his or her interactions with a teacher or at least the expectations the child has for adults and their ability to provide emotional support. In a similar vein, interactions with a sensitive and warm teacher may help shape (or reshape) a child's interactional models that influence how he or she responds to future teachers during progression through school (Sabol & Pianta, 2012).

Empirical Support

In the next section, we describe seminal and recent research that supports the links among child-parent attachment, child-teacher attachment, and a child's school readiness skills (see Figure 41.1).

Children's School Readiness and Child-Parent Attachment

The quality of a child's attachment to a parent has been repeatedly associated with the development of school readiness skills across a wide

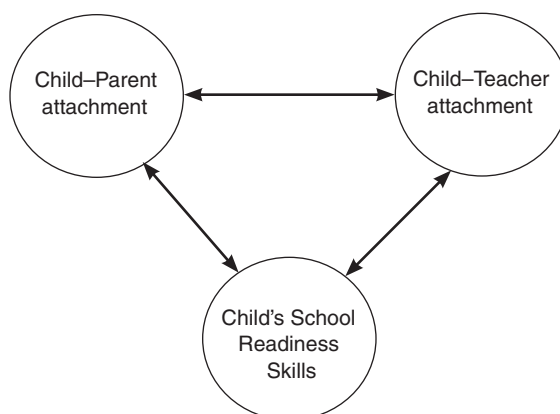

FIGURE 41.1. Empirical connections between child–parent attachment, child–teacher attachment, and a child’s school readiness skills.

range of early learning domains (e.g., Bus, Belsky, Van IJzendoorn, & Crnic, 1997; Cassidy, Jones, & Shaver, 2013; Sroufe, 1983). With regard to academic skills, preschool children who display a secure parent attachment develop better reading and prereading skills compared to children who display an insecure attachment (Bus et al., 1997; Bus & Van IJzendoorn, 1997). Granot and Mayseless (2001) confirmed this link between attachment and preliteracy skills and extended it to premathematics skills. In their study, children with an insecure attachment tended to display lower verbal and math skills, lower reading comprehension skills, and lower overall academic achievement compared to children evidencing a secure parent attachment. Thus, children who do not experience a secure child–parent attachment are more likely to enter kindergarten displaying lower academic skills compared to securely attached peers. Furthermore, children with a secure child–mother attachment at 24 or 36 months of age demonstrated higher cognitive abilities in later years of childhood (West, Matthews, & Kerns, 2013). For some children, particularly children experiencing multiple risk factors such as poverty or a poor school environment (Akiba, LeTendre, & Scribner, 2007; Burchinal et al., 2011), this initial achievement gap initiates a trajectory of lower school achievement that tends to widen over time and consequently leads to future academic difficulties (Martocchio, Brophy-Herb, & Onaga, 2014).

Although academic skills are an important component of school readiness, findings from Rimm-Kaufman, Pianta, and Cox (2000) suggest

that socioemotional skills, such as a child’s behavioral or emotional control, problem solving, or working memory, are even more important to teachers at kindergarten entry. Sroufe (1983) conducted one of the first studies to establish the association between child–parent attachment quality and socioemotional school readiness skills. In this seminal study, child–parent attachment was evaluated at 12 months and again at 18 months of age. Several years later, children with an insecure attachment to their mother were rated by their preschool teachers and were found to demonstrate lower curiosity, empathy, compliance, and social competence. Additionally, children who were insecurely attached had lower self-esteem and displayed greater dependence on their teacher (Sroufe, 1983). Granot and Mayseless (2001) confirmed and extended the link between insecure attachment and lower levels of socioemotional skills in a more recent study. In this study, over 100 fourth- and fifth-grade students were assessed to determine their level of maternal attachment security. Based on teacher report and sociometric data, secure children experienced better school adjustment and had a higher social status with peers. This is important in the classroom context because children with higher socioemotional skills may be more likely to take a risk in learning or to access available experiences more fully at school.

Children’s attention skills, often considered an aspect of executive functioning, are another kind of key school readiness skill because they heavily influence a child’s ability to focus on and process information being presented within the classroom. Research demonstrates that young chil-

dren who evidence insecure attachments to their mother have shorter attention spans and tend to perform worse on cognitive functioning tasks than do those with secure attachments (e.g., Frankel & Bates, 1990; Main, 1983; Moss & St-Laurent, 2001). This may keep these children from fully accessing instruction in the classroom setting.

The quality of a child's attachment to a caregiver has also been linked repeatedly to child behavioral outcomes; children who do not display secure child-parent attachments are at higher risk for displaying externalizing and antisocial behavior (e.g., Fearon & Belsky, 2011; Kobak, Cassidy, Lyons-Ruth, & Ziv, 2006). Disruptive behavior in early childhood predicts multiple maladaptive outcomes, including the development of negative relationships with adults (Howes, 2000; Ladd & Burgess, 2001), unsuccessful kindergarten entry (Rimm-Kaufman et al., 2000), school failure, and long-term social adjustment problems (Conyers, Reynolds, & Ou, 2003). Kochanska and Kim (2012) provide support for the theory that the quality of child-parent attachment early in life moderates the impact of future socialization strategies, such as parenting practices, on children's outcomes. They found that only within the context of a prior insecure child-parent attachment relationship was there evidence of a causal pathway between child anger proneness, power assertive parenting practices in preschool, and children's later antisocial behavior problems. For children who experienced a secure child-parent attachment, anger proneness was not related to power assertive parenting practices, and power assertive parenting practices were not related to children's later antisocial behaviors.

As outlined earlier, educational and psychological research provide strong evidence that the quality of a child's attachment to a primary caregiver (with most research examining the relationship between child and mother) is linked to school readiness skills across a wide range of academic and socioemotional early learning domains. This provides a framework within which to understand the relationships that develop between the child and additional important adults; our focus in this chapter is on preschool/child care teachers. When a child enters school, he or she spends on average 30 hours per week with this adult (Blau & Currie, 2006). Thus, it is important to understand how the attachment quality that a child has developed with his or her parent(s) extends into the school environment and the attachment the child develops with his or her teacher.

Connections between Child-Parent and Child-Teacher Attachment Quality

A child engages across multiple ecological systems, including those that are more proximal (e.g., home and school), as well as those that are more distal (e.g., community and government) (Bronfenbrenner & Morris, 1998). Evidence suggests that the attachment quality a child develops with an adult who plays a significant role in that child's experiences within one of these ecological systems, such as the home, may transfer to another system, such as the school, leading to an association between a child's attachment to a caregiver and the quality of attachment to a teacher. There are multiple reasons this may occur. The child elicits interactions from others across settings, which influence attachment (e.g., characteristics of the child or his or her behavior may lead adults to interact with him or her in similar ways; Belsky, 2005). In addition, the child forms an attachment with an adult in one setting, which is theorized to inform the creation of an internal working schema of how relationships with adults are expected to be. Thus, the child's attachment experience with his or her parent can be expected to apply to a subsequent relationship the child forms with a teacher. It is important to note that in early childhood, a teacher's role with a child often has many parallels with a parent's role; for example, a teacher may help a child develop important adaptive and self-care skills, such as solving problems independently or managing basic hygiene skills. Teachers also provide support and give evaluative feedback as children navigate the classroom environment (Hamre & Pianta, 2001; Myers & Pianta, 2008; O'Connor & McCartney, 2007). Hence, we would expect that the quality of a child's relationship with his or her early childhood teacher would prove important for the quality of later relationships. This is demonstrated in research indicating that a child's level of closeness with a teacher (as reported by the teacher) is stable across different teachers in the early school years (O'Connor & McCartney, 2007).

Booth, Kelly, Spieker, and Zuckerman (2003) studied the association between child-mother and child-teacher attachment quality in 24-month-old children. They found a significant correlation ($r = .31, p < .05$) between the observer-reported secure-base composite score of the mother-child and teacher-child attachment using the Attachment Q-Set (AQS) instrument. Booth and

colleagues noted an additional reason this may occur—selection bias (i.e., sensitive mothers choose sensitive caregivers). This link between the quality of the child–parent and child–teacher attachment continues into the preschool years, although at a modest level (Ahnert, Pinquart, & Lamb, 2006; Sroufe, 1983). Ahnert and colleagues (2006) conducted a meta-analysis that examined the extent to which observed security with teachers matches the observed security with parents. Findings suggested that, overall, children’s security with parents was significantly, albeit modestly, correlated with children’s security with teachers ($r = .14, p < .001$).

These findings support the idea that children’s early attachments to their parents guide the formation of internal models of relationships, which may influence the manner in which a child interprets the behavior of subsequent relational partners (Buyse, Verschueren, Verachtert, & Van Damme, 2009; Rydell et al., 2005). By integrating the theories of attachment and developmental systems, theorists postulate that teacher/caregiver characteristics, such as sensitivity, may change the internal working models that the child previously developed through their attachment experiences with their parents. This would subsequently revise the child’s previous mental representation of adult relationships (for better or worse), which may then shift subsequent relationships with new important adults.

Children’s School Readiness and Child–Teacher Attachment

A positive relationship with a teacher, particularly in early childhood, increases the likelihood that a child will have higher academic performance, lower levels of externalizing behaviors, and better social skills (Crosnoe, Johnson, & Elder, 2004; Ladd & Burgess, 2001; Mashburn et al., 2008; Pianta & Stuhlman, 2004; Shields et al., 2001). The attachment framework can easily be applied to the teacher–child relationship. In the school context, the quality of this relationship may serve as a secure base from which the child explores the classroom environment, learns new skills, and to which he or she returns to for help, comfort, and support.

Howes and Ritchie (1999) described four primary types of child–teacher attachment that mirror child–parent attachment styles—secure, near secure, avoidant, and resistant. Additionally, a child–teacher attachment may not fit into any of the categories and is therefore labeled as inse-

cure/unclassifiable or may demonstrate an avoidant/resistant pattern. Below are brief descriptions of each type (for a more detailed description, see Howes & Ritchie, 1999):

- *Secure*: A secure child–teacher attachment relationship looks similar to a secure parent–child relationship. A child views the teacher as a secure base, accepting comfort and going to the teacher for help and with new discoveries.
- *Near-secure*: In a near secure child–teacher attachment pattern, the child responds somewhat positively to the teacher, if the *teacher* initiates contact, but does not tend to initiate contact independently. The child has a tendency to avoid interactions with the teacher and is more interested in classroom materials/activities.
- *Avoidant*: An avoidant style characterizes a child who is more interested in the classroom materials, does not approach the teacher for help, and ignores the teacher if he or she approaches.
- *Resistant*: In a resistant child–teacher attachment, the child tends to be upset and irritable, and cries frequently. The child often resists classroom rules and routines, and may engage in physical or verbal aggression with the teacher (i.e., kicking, crying for attention, being angry).

Howes and Ritchie (1999) validated these categories with a sample of 3,062 preschool children and their primary teacher; the sample was drawn from five studies of children enrolled in center-based child care and intervention programs. The majority of child–teacher attachments (35.4%) fit into the near-secure classification. The remaining children fit into categories labeled secure (29%), avoidant (20%), insecure/unclassifiable (10%), resistant (4%), and avoidant/resistant (0.4%). Children with a secure attachment to their teacher engaged in more complex play with peers compared to children categorized into one of the other attachment classifications; in contrast, those with an unclassifiable, resistant, or avoidant classification had a higher level of conflict with peers.

More recently, Commodari (2013) conducted a study of 152 Italian children between the ages 4 and 5. Results from this study suggest that the quality of a child’s attachment to a preschool teacher is significantly correlated with multiple school readiness skills, including linguistic developmental level (linguistic and phonological skills), psychomotor skills, attention and metacog-

nitive skills, and specific cognitive abilities (those involved in the prerequisites of mathematics, reading, and writing). These results may have important implications for how schools provide intervention services for children who are behind in school readiness skills. Commodari suggests that the early identification of children who demonstrate insecure teacher attachment and subsequent intervention to improve school adjustment may be critical pieces of a strategy to prevent future academic difficulties.

Williford, Maier, Downer, Pianta, and Howes (2013) conducted another study that examined teacher–child interactions at both the classroom level and the individual-child level. Results suggest that the quality of teacher–child interactions at the classroom level were predictive of gains across all school readiness skills, including language, literacy, and self-regulation. The effect of an individual child's level of engagement in the classroom was moderated by the quality of the teacher–child interactions at the classroom level; that is, in classrooms with high-quality teacher–child interactions, the gap in the development of school readiness skills between children with typical engagement and those with high levels of engagement was reduced (Williford, Maier, et al., 2013).

As discussed in the previous sections, existing empirical evidence provides support for connections among child–parent attachment, child–teacher attachment, and a child's readiness skills. However, much of the research linking the quality of the relationship between a child and teacher to a child's school readiness skills does not take into account a child's prior attachment experiences with his or her parent. Therefore, we currently cannot answer the question of whether the quality of children's early relationships with their parents moderates the associations between the child–teacher relationship and children's development of school readiness skills. However, there is evidence that the links between the quality of the teacher–child relationship and children's school readiness development is stronger for certain children. Children's positive relationships with teachers have been found to protect against poor academic and social outcomes for children classified as being at risk due a range of factors, including an unsupportive home environment, minority ethnicity, authoritarian parenting practices, or low academic achievement (Baker, 2006; Burchinal, Peisner-Feinberg, Pianta, & Howes, 2002; Ladd & Burgess, 2001). The evidence connecting the

quality of teacher–child relationships and social interactions with children's school readiness skills is summarized below.

Children who struggle academically often have reduced levels of behavioral and socioemotional outcomes, and for these children, a strong teacher–child relationship is particularly important (Eisenhower, Baker, & Blacher, 2007). Children who display lower academic skills also tend to experience less close and more conflictual relationships with teachers. However, research evidence suggests that when these children develop a warm and responsive relationship with their teacher, they tend to demonstrate more adaptive behavioral outcomes and lower levels of delinquency and socioemotional problems (Al-Yagon & Milulincer, 2004; Murray & Greenberg, 2001).

The quality of the teacher–child relationship has been found to link directly to children's socioemotional outcomes (behavior, social skills, self-regulation, executive functioning), as well as to moderate the relation between children's disruptive behavior and their later school outcomes. For children who display externalizing or disruptive behavior (i.e., aggression, hyperactivity, impulsivity), the teacher–child relationship tends to be negative and conflictual (Doumen et al., 2008; Howes, 2000; Ladd & Burgess, 2001; Spilt & Koomen, 2009). The reciprocal (and often negative) interactions that occur as a result of this may get worse over time and lead to poorer attachment quality with the current, as well as with future teachers. For example, there is growing empirical evidence suggesting that the quality of the teacher–child relationship longitudinally predicts children's behavior (e.g., Baker, Grant, & Morlock, 2008; Hamre & Pianta, 2001; Meehan, Hughes, & Cavell, 2003; Pianta & Stuhlman, 2004). Researchers found that after controlling for children's initial problem behaviors, teacher–child relationship quality significantly predicted children's later socioemotional adjustment, especially when there were concurrent ratings of relational quality (Pianta, Nimetz, & Bennett, 1997; Pianta & Stuhlman, 2004). In contrast, when teacher–child relations are negative and conflictual, children are at risk for increased problem behaviors, decreased academic and social skills, and increased school disengagement (e.g., Birch & Ladd, 1998; Graziano, Reavis, Keane, & Calkins, 2007; Henricsson & Rydell, 2004; Mantzicopoulos, 2005; Stipek & Miles, 2008).

However, a close and supportive teacher–child relationship has been found to be protective

for children who display early disruptive behaviors. When children who display impulsivity and aggression are paired with teachers who are able to establish a positive emotional bond with them and meet their behavioral and regulatory needs in the classroom with low frustration and negativity, these children are more likely to evidence declines in aggression and exhibit greater socioemotional development, including acceptance by peers (e.g., Baker et al., 2008; Decker, Dona, & Christenson, 2007; Meehan et al., 2003).

Self-regulation is a school readiness skill within the socioemotional domain that can be defined as a child's ability to focus attention, manage emotions appropriately, and cope with environmental demands and stimuli (Baumeister & Vohs, 2004; Blair & Razza, 2007; Calkins & Williford, 2009; Rimm-Kaufman, Curby, Grimm, Nathanson, & Brock, 2009). During the early childhood period, children develop substantially in this skill domain and are increasingly expected to demonstrate self-regulation in order to be successful in the classroom environment (Williford, Whittaker, Vitiello, & Downer, 2013). Williford, Whittaker, and colleagues (2013) found that children's positive engagement with their teacher was related to the development of behavioral compliance and executive functioning skills during the preschool year. Results from this study also indicate that children who engage in a positive manner with their teacher or peers are more likely to show gains in their active task engagement and decreases in their emotion dysregulation during preschool.

Improving the Teacher–Child Relationship to Support Children's School Readiness

The empirical evidence that supports the importance of a child's attachment to an early childhood teacher for his or her early learning has multiple implications for how we can support teachers in their efforts to develop accepting, sensitive, and responsive relationships with the young children in their classroom that facilitate children's early learning and later success in school. In this section, we describe recent experimental and quasi-experimental research that provides support for the hypothesis that improving the quality of teacher–child interactions and relationships leads to children's improved school readiness skills.

Multiple professional development/early intervention programs have been developed that target the improvement of teachers' skills in initiating and maintaining high-quality affective relationships with children in their classroom. Many of these interventions have been created using attachment theory as a foundation. Until the past decade, few experimental studies examined the extent to which targeted relational professional development systems improve the teacher–child relationship. These studies have assessed the more proximal observed teacher–child interactions as a proxy for measuring the more global construct of teacher–child relationship quality (e.g., Arnett Caregiver Interaction Scale [CIS; Arnett, 1989], inCLASS [Downer et al., 2010]), whereas other research has used teacher report of the teacher–child relationship quality, such as the STRS [Pianta & Hamre, 2001]). In aggregate, this research provides good evidence that improving teacher interaction behaviors through a relational lens can improve children's outcomes (e.g., Murray & Malmgren, 2005; Webster-Stratton, Reid, & Hammond, 2004).

Research suggests that targeting the teacher–child relationship holds particular promise as a strategy to prevent negative outcomes for children at higher risk. Early intervention may deflect children from poor school adjustment, particularly children who are socially and academically at risk. This section describes interventions/professional developments that focus on improving the teacher–child relationships or teacher–child interactions as a mechanism for improving children's academic and/or socioemotional outcomes.

Incredible Years Training Programs—Teacher Classroom Management Program

The Incredible Years intervention (Webster-Stratton, Reid, & Hammond, 2001) is an evidence-based, multicomponent intervention that targets children ages 4–8 years old. The components of this program include a parent-training program, a child-training program, a teacher-training program, and a socioemotional curriculum (“Dinosaur School”), which can be used as a package or independently. For the purposes of this chapter, we describe the teacher-training program designed to improve teachers' classroom management skills by using five techniques: building positive relationships, using encouragement and praise, providing behavioral incentives, preventing negative behav-

iors, and addressing inappropriate behaviors. The teacher-training program is extensive and can take as long as 36 hours total (Webster-Stratton et al., 2004). In this training, teachers learn classroom management strategies as a group, then discuss videos of teacher-child interactions (Webster-Stratton et al., 2001).

The first element of the teacher program focuses on the importance of the teacher-child relationship (Webster-Stratton et al., 2004). The beginning sessions help teachers understand that high-quality relationships lead to increased motivation and cooperation on the part of children, as well as greater engagement in learning activities in the classroom. Additionally, emphasis is placed on the importance of becoming familiar with students by asking about their interests outside of school. Teachers are also encouraged to spend individual time with children. Other strategies include sending home "happy grams," having children celebrate each other's accomplishments, and encouraging a safe climate. Teachers are encouraged to model their own thoughts and to share feelings with the use of positive self-talk. In addition, teachers use behavior-based techniques (e.g., labeled praise, selective attention) to increase children's positive behaviors.

The effectiveness of the Incredible Years curriculum and training to improve both teacher practice and children's outcomes, particularly behavioral outcomes, can be found in multiple studies (e.g., Webster-Stratton et al., 2001, 2004). Webster-Stratton and colleagues (2001) demonstrated the effectiveness of both the parent and teacher training components in a randomized controlled trial (RCT). Results suggest that the program improved teachers' management techniques, children's social competence, and children's observed school behavior, while reducing conduct problems. A follow-up RCT conducted by Webster-Stratton and colleagues (2004) provided evidence for the importance of including individual child therapy in the model. More recently, the Incredible Years teacher-training program and the Dinosaur School curriculum were implemented, and together, they improved school readiness skills (including socioemotional skills) and child behavior (reduced conduct problems) (Reinke, Stormont, Webster-Stratton, Newcomer, & Herman, 2012; Webster-Stratton, Reid, & Stoolmiller, 2008). These results suggest that the suite of Incredible Years programs can reduce negative child behavior and improve children's school readiness skills, specifically their socioemotional skills.

Chicago School Readiness Program

In 2008 and 2009, Raver and colleagues adapted the Incredible Years teacher-training program for use within an early childhood, multicomponent teacher consultation model. Results indicate that this adaptation may improve teacher practices and children's socioemotional and behavioral school readiness skills. The Chicago School Readiness Program (CSRP) is an example of an evidence-based, multicomponent treatment that delivers a combination of programs largely through mental health consultation in the schools (Raver et al., 2009). The project targeted children attending Head Start (a federally funded preschool program for children living in poverty; National Head Start Association, 1974). The primary purpose of the CSRP was to improve emotional and behavioral outcomes of young children living in poverty and at increased risk for negative school-based outcomes. The intervention contains four distinct phases: (1) teacher training, (2) coaching focused on strategy implementation, (3) mental health consultation for teacher stress reduction, and (4) mental health consultation for challenging children.

The first part of the intervention occurs at the beginning of the year and consists of 30 hours of teacher training over 5 weeks (based on the Incredible Years program [Webster-Stratton et al., 2004]), targeting teacher management strategies. Then, teachers work with trained mental health consultants to implement the learned strategies using a collaborative consultation process. After winter break, the third part of the intervention is implemented, which focuses on teacher stress reduction and strategies for coping with difficult situations. The final component of the intervention, child mental health consultation, occurs during the final 10 weeks, during which consultants provide direct services to children with high levels of behavior problems (individual and group therapy).

Results suggest increased positive teacher practices and reduced children's behavior problems (Raver et al., 2008). Teachers in the intervention condition demonstrated increased attachment-related caregiving behaviors (e.g., teacher sensitivity) and were more likely to demonstrate improved behavior management skills relative to controls (Raver et al., 2008). The intervention also improved child behaviors, with significant reductions in behavior problems (Raver et al., 2009). These results demonstrate an improvement in classroom dynamics and child behavioral outcomes. Further-

more, results cannot be attributed to an extra adult in the classroom because control classrooms were staffed with a teacher aide. CSRP has subsequently been replicated in two larger trials (now known as the Foundations of Learning Project [FLP]), and each of these trials also showed improvements in child outcomes, including improved academic and socioemotional school readiness skills (Morris, Millenky, Raver, & Jones, 2013). Collectively, the results from the CSRP suggest that targeting teacher skills with an attachment lens has the potential to improve children's ability to manage their own behavior. Unfortunately, there is a limited ability to disentangle the various components that may have produced change due to the multi-component nature of the intervention.

My Teaching Partner

My Teaching Partner (MTP) is an individualized coaching model focused on improving teacher-child interactions (Pianta, Mashburn, Downer, Hamre, & Justice, 2008). It is based on the hypothesis that the quality of teacher-child interactions directly contributes to children's achievement by increasing engagement, motivation, and on-task behavior (Hamre & Pianta, 2005). The program uses the Classroom Assessment Scoring System (CLASS; Pianta, La Paro, & Hamre, 2008) as a foundation for observing and analyzing video and giving feedback on teacher practice. The CLASS organizes teacher-child interactions into three broad domains—emotional support, classroom organization, and instructional support. MTP coaching provides several key opportunities for teachers. Teachers are given the chance to (1) observe videotaped high-quality teacher-child interactions, (2) identify effective responses to children's cues, and (3) receive ongoing individualized feedback concerning their own teacher-child interactions. The MTP coach and teacher go through five steps together: (1) The teacher videotapes interactions with children in the classroom (e.g., a math lesson, circle time, or small-group instruction); (2) the coach edits the video and prepares written prompts that focus on particular dimensions of the CLASS (e.g., support for child autonomy) to facilitate the teacher's self-analysis skills; (3) the teacher views the video and responds; (4) the teacher and coach conference by phone; and (5) the two collaborate to construct an action plan for the teacher to change his or her interactions. Each MTP coaching cycle takes about 2 weeks to complete and repeats continually throughout the school year (–12

cycles. Teachers and coaches interface through an online portal that includes a video library of over 200 effective teacher-child video clips. The intervention and coaching focuses on helping teachers become better observers of their own practice in order to improve their interactions with children, which subsequently encourage positive child behavior and engagement in the classroom.

The impact of MTP within preschool classrooms has been examined in two large trials. In the first preschool trial, MTP coaching was combined with implementation of a language and literacy and socioemotional curriculum (Pianta et al., 2008). Results demonstrated that teachers in the intervention condition improved their teacher-child interactions as measured with CLASS scores. These effects were more substantial for those whose classroom composition included a higher proportion of at-risk children (Pianta et al., 2008). With regard to children, those whose teachers were engaged in MTP demonstrated improved school readiness skills, including literacy, receptive vocabulary, task orientation, and assertiveness (Hamre et al., 2012; Mashburn, Downer, Hamre, Justice, & Pianta, 2010). Downer and colleagues (2015) conducted a study that suggested that MTP specifically increases a preschool teacher's instructional support. Additionally, children in the intervention condition of this study displayed improved positive engagement with their teachers as measured through classroom observations (Downer et al., 2015). Although there were no main treatment effects on children's readiness indicators during the coaching year, in the postintervention year, children with teachers who had participated in MTP had, on average, higher levels of inhibitory control (Pianta et al., 2015). Together, these results suggest that improving teacher-child interactions at the classroom level by using targeted professional development and consultation have the potential to improve children's academic and socioemotional school readiness skills.

Banking Time

Banking Time is an attachment-based, dyadic intervention intended to improve a teacher's relationship with a specific child with whom he or she has had trouble connecting (Driscoll & Pianta, 2010; Pianta & Hamre, 2001). The difficulty may be due to the child's disruptive behavior or lack of social skills. It may also be due to the teacher, for any number of reasons (e.g., too many children), not engaging individually with a particular child.

The name of the intervention, Banking Time, comes from the idea that when a teacher invests in his or her relationship with a child, the relationship can become a resource in the classroom for both the child and the teacher during times of challenge (e.g., when the teacher is asking the child to complete a task). The hypothesized mechanism for change is strengthening the bond between the child and teacher, which in turn helps the child develop important socioemotional skills (e.g., better communication, more effective help-seeking behavior, and better self-management skills). These skills can be used in the classroom with adults and peers to improve school success in both socioemotional and academic areas.

In each session, a teacher and child engage in brief, 10- to 15-minute, one-on-one interactions in which the teacher conveys messages of support to the child, specifically in the areas of exploration, sensitivity, predictability, and encouragement. These sessions occur when the teacher is available to provide individualized attention and are not contingent on the child's behavior. The child leads each Banking Time session by choosing materials and guiding the interactions and play. The teacher is instructed not to ask questions, give commands, or teach a lesson, but rather to observe and describe the child's actions, label the child's positive and negative emotions, and emphasize positive relational themes. Teachers describe what the child is doing through narration or imitation; this shows that the adult is attending to the child and validates the child's action. Teachers label the child's positive and negative emotions in order to emphasize acceptance. Finally, the teacher chooses a specific theme that conveys a message to the child about the importance of the teacher's relationship with the child. For example, if the child tends not to seek help from the teacher, the theme may be "I'm here for help if you need me." These techniques are intended to enhance the teacher's and child's relationship with one another, which in turn recasts the teacher as a secure base for the child to use in the general classroom setting.

The effectiveness of Banking Time on teacher and child outcomes has been examined in several samples. Two studies show that the implementation of Banking Time increases a teacher's perceptions of closeness with children. In a quasi-experimental study, information about Banking Time was made available to teachers who were participating in a Web-based teacher professional development intervention (Driscoll, Wang, Mashburn, & Pianta, 2011). Teachers could implement

the techniques in order to improve teacher-child relationships if they chose. Results from this study indicated that over the course of the year, teachers who chose to implement these techniques reported closer relationships. It is important to note that this study did not use random assignment of children to the intervention, but the trial does provide preliminary support for the effectiveness of Banking Time. In a second study that was an RCT, researchers found that teachers participating in Banking Time reported increased child-teacher closeness (Driscoll & Pianta, 2010). Furthermore, teacher reports of classroom behavior revealed that children participating in the intervention demonstrated improved behavioral outcomes. These trials suggest that Banking Time is a promising intervention for improving teacher perceptions of their relationships with disruptive preschool children. Importantly, because a warm teacher-child relationship is related to positive child outcomes, changing this relationship may be helpful in improving children's school readiness and decreasing levels of disruptive behavior (Driscoll & Pianta, 2010).

A large, federally funded RCT of Banking Time is currently under way. This study examined whether teachers' implementation of Banking Time with 3- and 4- year-old children at risk for a disruptive behavior disorder can improve children's behavioral and emotional outcomes. This study used classroom observations, direct assessment, and informant report (teachers', parents' and children's) to assess the teacher-child interactions and children's behavioral outcomes. Results indicated that use of Banking Time was effective in decreasing children's behavior problems and improving the observed quality of teacher-child interactions (Williford et al., 2015).

Playing-2-gether

Playing-2-gether is a school or center-based intervention designed for teachers and their preschool children with moderate to high levels of disruptive behavior (e.g., impulsivity, hyperactivity, aggression). The mechanism for changing a child's disruptive behavior that is targeted by the intervention is the interactions between the teacher and child. Playing-2-gether consists of two components: the Relationship-Game and the Rule-Game. For each component, the teacher and child meet for approximately 15 minutes, at least twice weekly for 6 weeks. During the first component, the teacher and child meet for sessions that are

consistent with the guidelines of Banking Time sessions: child-led, teacher as observer, and the teacher conveying understanding and sensitivity toward the child. This first component is heavily rooted in attachment theory. In the second session, the Rule-Game, the teacher leads the activity and uses skills to encourage appropriate behavior, such as clear commands, rules for good behavior, praising the child for following good behavior, and so forth. The second component draws on principles from learning theory and effective behavior management.

Vancraeyveldt and colleagues (2015) conducted a three-wave, randomized study of a sample of 175 teacher–child dyads. All children were identified as having elevated levels of externalizing behavior. Teachers were randomly assigned to the intervention or a business-as-usual condition. After intervention implementation, the teachers and children in the intervention group had made significant gains with regard to the teacher–child relationship and child behavior. Within this group, teachers rated their relationships as having significantly less conflict, and children were identified as having decreased conduct and behavioral problems (e.g., hyperactivity, impulsivity). Interestingly, the positive effects of the two-part intervention all occurred after the first component of the intervention—the attachment-based, relationship-focused component. These positive effects remained but did not strengthen during the second component. Additionally, teachers in the intervention group rated their relationships with children as closer after the first component, but this effect disappeared after the second component. This study supports the effectiveness of engaging in Banking Time sessions with children who display disruptive behavior.

In summary, results from recent experimental research provide evidence that early intervention/professional development programs that focus on improving the quality of teacher–child interactions can help children develop school-readiness skills with most of the interventions targeting children’s behavior. However, with the exception of Banking Time, all of these programs consist of multiple components based on multiple theories of how to affect children’s development and learning. In the next section, we conclude our chapter by describing how future research can extend our understanding of how the quality of children’s attachment to their parents and their teachers contributes to their development of school readiness skills.

Future Research Directions

Recent research has made significant gains in describing the nature of teacher–child relationships and understanding the association between the quality of teacher–child relationships and interactions, and children’s development of school readiness skills. Attachment theory has been used heavily to conceptualize the key characteristics that should comprise high-quality teacher–child relationships and interactions, and to explain why relationships characterized by interactions that are consistent, responsive, and warm allow children to take full advantage of learning opportunities, engage maximally in the classroom, and develop the skills needed to be successful in kindergarten. The review of empirical work in this chapter demonstrates the complexity of examining teacher–child relationships, particularly when researchers expand beyond describing the nature of the child–teacher dyad in order to investigate multiple ecological levels of influence (e.g., the association between parent–child and teacher–child relationships), and how these levels of influence independently and jointly contribute to children’s school readiness skills. Significant gains in research methodology, as well as greater integration across disciplines, pave the way for future research into the complexities of understanding the impact of teacher–child and parent–child relationships on children’s school readiness skills.

Statistical techniques, such as multilevel modeling, allow researchers to expand beyond the child–teacher dyad paradigm and examine the effects of multiple levels within the child’s developmental system. Developing a better understanding of home-, school-, classroom-, and community-level factors associated with close teacher–child relationships will help schools and teachers to create environments and experiences that support children’s success in school across academic, behavioral, emotional, and social domains.

Another area of potential research is a deeper exploration of how the quality of teacher–child attachment may serve as a moderator for children at risk due to an insecure child–parent attachment. Additional studies examining children’s school readiness skills with tighter controls and research designs must be conducted in order to examine the extent to which the quality of the teacher–child relationship during early childhood may moderate the relation between the quality of the parent–child relationship and children’s development of school readiness skills. There are few studies that

have included *both* the quality of parent–child and teacher–child relationships when examining how early child–adult relationships predict children’s school readiness skills.

The majority of the research on teacher–child relationship quality has used teacher report of the teacher–child relationship or naturalistic observations of the quality of a teacher’s interactions across all children in the classroom. New measures that examine the quality of a teacher’s interactions with an individual child may help us understand how a teacher differentiates his or her level of sensitivity and support to individual children in the classroom (Williford et al., 2013). Additionally, current classroom-based measures examine teacher’s interactions as they occur naturally in the classroom during an allocated block of time. Conducting observations in natural settings is important for ecologically valid measurement. However, the lack of standardization across activities limits our ability to understand whether the quality of interactions is due to characteristics of the child, the teacher, or the demands of the activity. The development of a standardized task, similar to laboratory-based research examining the quality of child–mother interactions, may help us understand the factors that influence the quality of teacher–child relationships and has implications for early intervention efforts to improve the affective quality of teacher–child interactions.

With regard to future experimental work, except for studies examining Banking Time, the intervention programs described in this chapter focus on improving the quality of teacher–child interactions as one component of a more comprehensive program. Therefore, we do not know whether the enhanced teacher–child relationship, another aspect of the program, or the combination of components is responsible for improvements in the quality of teachers’ interactions with children or children’s improved outcomes. Research is needed that “unpacks” these comprehensive intervention programs to determine whether particular components are critical for improving the quality of the teacher–child relationship and whether this improvement is responsible for improved child outcomes.

Conclusion

The increase in the number of multidisciplinary studies allows researchers to examine ideas with a new lens. By applying the attachment framework

from the field of child development to the field of early childhood education, we are better able to understand how the teacher serves as a resource for children, helping them to engage maximally with activities in the classroom and acquire skills needed to be successful in school. Empirical evidence supports links between a child’s attachment to a parent, to a teacher, and to the development of essential academic and socioemotional school readiness skills. The creation of interventions based on these findings has already begun; there are several evidence-based interventions that increase the quality of the child–teacher attachment and, consequently, the child’s school readiness skills. Future work devoted to understanding the mechanisms explaining how the teacher–child relationship serves as a protective factor for children at risk may enhance current and future interventions, so that they more effectively and efficiently promote a young child’s school readiness skills.

Acknowledgments

We would like to thank Sarah Brooks for helping us to complete this chapter. This work was supported in part by a grant awarded to Amanda P. Williford by the Institute of Education Sciences, U.S. Department of Education, through Grant No. R324A100215 to the University of Virginia. Chapter 42

Implications of Attachment Theory and Research for Child Care Policies

Michael Rutter
Camilla Azis-Clauson

The version of this chapter (Rutter, 2008) in the second edition of the *Handbook of Attachment* began with a discussion of some of the novel features of Bowlby's (1969/1982) attachment theory that were important for its policy applications. Here, we recapitulate these features only briefly and devote most of the chapter to more recent developments.

One feature of Bowlby's theorizing was that despite his psychoanalytic background, he relied heavily on empirical findings from observational studies of both humans and other animals. First, he insisted on the importance of children's real-life experiences and not just their internal thought processes, which initially led to an extremely hostile response from his psychoanalytic colleagues. Second, Bowlby gave primacy to a biologically based need for social relationships rather than to feeding or to sexual motives. Third, he focused on the importance of love relationships as they develop over time between parent and child rather than on the here-and-now stimulation or reinforcement emphasized by behaviorist theories.

The theory was revolutionary, not only in its overall conceptual approach but also in terms of several key specifics. Most crucially, attachment theory replaced the general undifferentiated notion of "mother love" with a specific, postulated

biological mechanism by which early parent-child relationships shaped psychological development. Specifically, Bowlby proposed that the development of selective attachments served a biological purpose in providing emotional support and protection against stress. In emphasizing these special qualities, he indicated that attachment does *not* constitute the whole of social relationships, although it reflects a psychological need that persists throughout the lifespan. Early child-caregiver selective attachments constitute one basis of all later intense reciprocal relationships, including love relationships and the provision of parenting, not just the receipt of it, although the issue of how to conceptualize and measure attachment security in the postinfancy years remains unresolved.

Early Effects of Attachment Concepts on Child Care Policies

Along with this historical background, before turning to contemporary issues, we should mention the early effects of attachment concepts on child care policies. Actually, the first main impact on child care came from Bowlby's (1951) World Health Organization (WHO) monograph and not

from his exposition of attachment theory some 18 years later (Bowlby, 1969/1982), although the two were always closely linked in his own writings. People were shocked by the findings concerning children in institutions and were persuaded not only by Bowlby's writings but also by the Robertsons' (1971) moving films that the apathy and loss of interest shown by many young children in residential care represented a negative reaction and not contentment.

The link with attachment theory lay in Bowlby's postulate that the damaging feature of institutions was the lack of personalized care and hence the lack of opportunity to develop selective attachments. Over time, this led to a revolution in patterns of hospital care for children (Rutter, 1979) and in the use of residential nurseries as a means of caring for children who experienced a breakdown in parenting (Triseliotis & Russell, 1984). After a period of foot-dragging in medical circles, hospital policies were changed to allow regular daily visiting by parents, then unrestricted visiting, and finally encouragement for parents to stay overnight in hospitals with their young children. Although it would be misleading to claim that all is well in all hospitals, patterns of hospital care in the 21st century could scarcely be more different from those prevailing half a century ago.

The second revolution concerned the virtual abandonment of residential nurseries and orphanages as the primary solution for young children whose parents could no longer care for them (Cliffe & Berridge, 1991). Instead, there was increasing use of long-term as well as short-term foster care. The aim, in line with attachment theory, was to provide personalized care in a family context that offered an opportunity for continuity over time in relationships. Unfortunately, the consequences were not as satisfactory as the aims. Tizard (1977), for example, reported that in the nurseries she studied there was an average of 24 different caregivers for each child by the age of 2 years, and double that number by age 5. The problem has not been ignorance (or ignoring) of attachment theory, so much as a societal unwillingness to make the necessary investment in child care. Yet another problem was the observed high rate of breakdown in foster-family placements (Berridge & Cleaver, 1987; Parker, Ward, Jackson, Aldgate, & Wedge, 1991). Regrettably, there has been very little progress on this problem in recent years. It was also problematic that findings on residential care were incorrectly generalized to day care (see the WHO Expert Committee on Mental Health [1951] warning about the supposedly permanent

deleterious effects of day nurseries and crèches). This important problem has been the source of much subsequent research.

Another revolutionary, but complex, effect of attachment theory on child care policies concerns legal discussions of custody and contact following parental divorce or separation (Bretherton, Walsh, Lependorf, & Georgeson, 1997) and in relation to applications by rearing parents to adopt when the biological parents withdraw permission (Hale & Fortin, 2015). The downside of this influence has been a tendency to focus on whether the children concerned are, or are not, "attached" or "bonded" to the various adults disputing who should care for the children. In part, this focus represents a failure to appreciate that attachment theory emphasizes the security of attachments and not just their presence.

Interconnections between Attachment Theory and Child Care Policy

Following a discussion of these historical issues, the previous version of this chapter went on to include 10 main topics: (1) attachment disorders, (2) neural underpinnings, (3) attachment therapies, (4) measurement issues, (5) continuities and discontinuities over the lifespan, (6) parental sensitivity, (7) group day care, (8) divorce/separation, (9) assisted conception, and (10) the search for biological parents by individuals not reared by them. Readers are referred to that chapter for coverage of these issues up to 2008, when the second edition of the *Handbook* was published.

New Evidence Since the Second Edition of the Handbook

Noteworthy evidence on the various ways in which child care policies have implications for attachment theory has come from several different sources. First, two new long-term follow-up studies of children from Greek orphanages (Vorria, Ntouma, & Rutter, 2014, 2015a, 2015b; Vorria, Ntouma, Vairami, & Rutter, 2015) and Chinese orphanages (Feast, Grant, Rushton, Simmonds, & Sampeys, 2013; Rushton, Grant, Feast, & Simmonds, 2013) that lacked personalized care but did not involve profound, pervasive deprivation, have raised questions about the adverse consequences of early institutional rearing as such. Second, a study in St. Petersburg of attempts to change the qual-

ity of institutional care and to assess the benefits for children provided hope and raised challenges (McCall, 2011). An SRCD Monograph by McCall, Van IJzendoorn, Juffer, Groark, and Goza (2011) brought together findings on children without permanent parents in order to consider research, practice, and policy considerations.

Third, there has been further thinking about attachment disorders, with the introduction into DSM-5 (American Psychiatric Association, 2013) of a new diagnosis of “disinhibited social engagement disorder” (Zeanah & Gleason, 2010), as well as cautions regarding the marked dangers of overdiagnosing attachment disorders (Woolgar & Scott, 2013). Fourth, there has been exploration of a possible dimensional measure of attachment (Zeanah, Smyke, Koga, & Carlson, 2005) and a stranger-at-the-door procedure to assess disinhibited social engagement disorder (Gleason et al., 2014). These have been informative and helpful by extending the observational measurement of attachment features in the years of middle childhood onward, when the Strange Situation procedure (Ainsworth, Blehar, Waters, & Wall, 1978) is no longer appropriate. Fifth, along with various preventive and therapeutic interventions, there have been interesting attempts to determine the extent to which benefits are mediated by attachment features (see Gleason et al., 2014; McGoron et al., 2012). Sixth, there have been important new studies comparing adoption by gay couples, lesbian couples, and heterosexual couples (Farr & Patterson, 2013; Golombok et al., 2014; Mellish, Jennings, Tasker, Lamb, & Golombok, 2013). And finally, there has been a renewed interest in considering the evolutionary implications of the high frequency of insecure attachments and the possibility that, at a population level, there may be advantages in having a diversity of attachment patterns (Ein-Dor, Mikulincer, Doron, & Shaver, 2010). We discuss each of these topics below.

Institutional Rearing or Profound Deprivation as the Main Risk Factor?

It has generally been supposed that institutional rearing in early childhood constitutes a major risk for children’s subsequent psychosocial development, especially the development of secure attachments (McCall, 2011), which has been thought to arise from the many changes in caregivers in institutions versus a few stable and consistent caregiv-

ers in most families. Also, most institutions have a large number of children that each caregiver is expected to care for and a substantial inconsistency resulting from the turnover in the caregivers available to each child. Accordingly, given the structural characteristics of each institution, there are few one-on-one interactions between caregivers and their children. However, two recent studies of adoptees who experienced early institutional rearing have provided findings that challenge this assumption.

First, a recent Chinese study involved females who experienced institutional care up to a mean age of 23 months, with follow-up to a mean age of 48 years (Feast, Grant, Rushton, Simmonds, & Sampeys, 2013; Rushton et al., 2013). The findings indicated that 82% of the women had married, with an average length of partnership being 18 years; 71% had at least one child, and most had confiding friendships. This mostly very good social outcome was comparable to that of both adoptees and the general population in the British samples. In addition, the Chinese adoptees had an outstandingly good educational outcome, with one-third of the sample gaining university degrees—a proportion higher than that of both adopted and nonadopted participants in British general population samples. The orphanages from which these women were adopted had relatively good material conditions, and efforts were made to provide stimulation and to promote psychological development. However, the staff:child ratio varied from between 1:8 and 1:22. Rotation of staff members meant that the children necessarily lacked the one-to-one care and stimulation provided in ordinary parented families. This generally very good outcome is strikingly better than that found among children adopted in the United Kingdom from profoundly depriving institutions (Rutter & Sonuga-Barke, 2010). This was so even when the Romanian adoptees who did not show significant subnutrition were separately considered (Rutter, Kumsta, Schlotz, & Sonuga-Barke, 2012).

The second study is a Greek follow-up by Vorria, Ntouma, and Rutter (2014, 2015a, 2015b; Vorria, Ntouma, Vairami, & Rutter, 2015), which began with infants in the Metera baby center. A comparison was made with a family-reared sample experiencing day care but not institutional care. Most of the children showed attachment disorganization while in the institution, but the rate of disorganization fell markedly after they left. There were no significant differences at follow-up between the adoptees and the family-reared comparison group

in the rate of secure attachment to mother. Also, when the attachment measure and the emotional openness measure were combined, there were no significant differences between the groups in the proportion of children who were both secure and emotionally open (about half in both groups). There was a small and statistically nonsignificant difference in the proportion of adoptees (44%) who were neither secure nor emotionally open as compared with 25% in the comparison group. As with the Chinese study, the Metera study showed that the institution provided generally good overall care, but contemporaneous measurement showed that those in the Metera study lacked personalized caregiving (Vorraia et al., 2003). The Greek study findings were also important in showing that the risks from early institutional rearing only applied when such care lasted beyond the age of 2 years.

The McCall and colleagues (2011) monograph on children without permanent parents noted that the Spanish follow-up undertaken by Palacios and his colleagues involved children from generally well-staffed institutions who attended schools in the community. Unfortunately, no measures of attachment in relationships were obtained.

Too few studies of children prospectively followed from nondepriving institutions have been undertaken to draw firm conclusions. However, the evidence suggests that the risks associated with early institutional care are probably not as great as previously supposed. Although this definitely does not mean that it would be appropriate to consider institutional care as a good option for children from deprived backgrounds, it does mean that strenuous efforts to improve the care within such institutions would be worthwhile. There needs to be continuing concern about the very large number of children admitted to institutions in some countries (e.g., Romania) because their parents are experiencing major poverty. The answer to this problem must lie in improving financial circumstances for the population of Romania as a whole rather than enforcing any compulsory closure of child care institutions without putting any other form of care in their place.

Changing Institutional Practices

In 2008, a St. Petersburg–U.S. orphanage research team published an important, innovative study comparing three orphanages, or baby homes, that looked after children up to the age of 4 years, with

two interventions designed to improve the socioemotional relationships of the children. First, training used a train-the-trainer approach to educate staff in the key aspects of early childhood development and mental health, emphasizing warm, caring, sensitive, responsive, and developmentally appropriate interactions, especially during routine caregiving duties. Second, structural changes consisted mainly of reducing group size from approximately 12 to 6, assigning two primary caregivers to each subgroup so that a primary caregiver was available every day, and terminating periodic transitions of children to new wards and caregivers. The three baby homes were selected because they were among the best in St. Petersburg and their directors were willing to cooperate with the research. It was important that all three directors believed in the interventions that were employed. The director of the no-intervention institution took pride in having a well-run baby home with top-quality nursing, good living conditions, and good nutrition. Her starting point was that change was not needed and might indeed disrupt good functioning.

The St. Petersburg study was outstanding in terms of both the fact that it involved a genuine collaboration between the U.S. investigators and the Russian staff, and the great care taken to engage the staff and make changes that were rewarding for them, as well as for the children.

The first question was whether the intervention could indeed change the functioning of the baby homes. Observational measures, questionnaires, and interviews were employed for this purpose. A longitudinal design was used, thereby making it possible to examine changes within each institution as well as to examine differences among the three institutions. The findings were clear-cut in showing that on a variety of indices, including the Home Observation for Measurement of Environment (HOME) scales, there were major changes in the training-plus-structural-change institution as compared with the training-only and the no-intervention institutions. Moreover, the changes were maintained over time, and the longitudinal sample showed that the changes occurred within individuals and were not simply a function of selective attrition and hiring over the three time points. It is noteworthy that the changes were much greater for the training-plus-structural-change orphanage than for the orphanage that received training but no structural change. Following the interventions, the training-plus-structural-change caregivers in free-play observations displayed more positive socioemotional

engagement, responsiveness, and child-directed behaviors than caregivers in either of the other two institutions.

During the course of the study, there were two unfortunate, sudden, and unexpected changes. The director of the no-intervention home unfortunately died, and the director of the training-only home was ousted for political reasons. Detailed attention was paid to the possibility that this might invalidate the between-group differences but, on the basis of the longitudinal study findings, it was concluded that it was unlikely that any major bias was created.

The second major part of the study was determining whether the changes in the orphanages had beneficial effects on the children. The findings clearly showed that the training-plus-structural-change home evinced major improvements in the children's developmental level, physical growth, and behavior, as measured by both standard instruments and qualitative observations. The effects were much greater in the training-plus-structural-change institution than in either of the other two, but there was some tendency for the training-only institution to do better than the no-intervention institution. The one striking exception was that there was no evidence in either the cross-sectional between-group comparisons or the longitudinal data for any effect on head circumference. In keeping with other research, the preintervention measures of attachment showed that almost all of the children in the institutions showed disorganized attachment. The percentage with disorganized attachment remained at about 85% in both the training-only and the no-intervention institutions but fell to 61.5% in the training-and-structural-change institution. Findings on measures of attachment other than the Strange Situation procedure) yielded broadly comparable between-group differences. Conclusions regarding attachment should be made cautiously because there were few children in the 8- to 18-months age period for which the Strange Situation was most appropriate. Also, there are question marks about the validity of the Strange Situation in institutional circumstances. In addition, there had to be some modifications of that procedure in the study. Nevertheless, there is one negative finding of some importance: training in child development had negligible benefits if it was not accompanied by a reduction in the number of children that each staff member was assigned to care for.

Two intervention studies in Romania are also relevant. First, Sparling, Dragomir, Ramey, and Flo-

rescu (2005) undertook two sequential studies—the first, quasi-experimental, and the second, an RCT. In both cases the intervention, based on the Abecedarian study (Ramey & Campbell, 1992), lasted approximately 1 year. Video recordings of adult-child interactions, together with questionnaires and interviews, provided evidence about the institutional practices, and the outcome was assessed by the Denver Developmental Scales (Frankenburg, van Doorninck, Liddell, & Dick, 1986), which are designed to be used by parents to focus on readily observable attainments, such as lifting the hands, standing while holding on, and making meaningful “da-da” sounds. The experimental groups had a caregiver:child ratio of 1:4; this was enhanced by the use of trained volunteers, without the rotating patterns of staff that existed in the control group. The intervention involved both enriched caregiving and staff training on the use of educational activities, as well as the improved level and stability of staffing. The results indicated that the experimental groups showed greater improvement than the control group on caregiving, and this was accompanied by significant benefits for the children on several dimensions of psychological development. Somewhat similarly, Smyke, Dumitrescu, and Zeanah (2002) considered a Romanian orphanage in which a good caregiver:child ratio was provided, together with training in socio-emotional relationships. This resulted in improved attachment. One of us (M. Rutter) recently visited two orphanages in Romania, where there have been vigorous attempts to improve the quality of care. As yet, there are no systematic quantified findings, but it was obvious that not only had major changes been achieved but there was also high-quality care, and the children were both happy and well-functioning.

It is worth noting the steps taken to achieve this. First, much higher caregiver:child ratios were achieved—in line with the St. Petersburg-U.S. study's findings. Staff members were taught to appreciate the importance of a personalized approach and the value of both talk and interactions during play and other aspects of caregiving. It was also important that children were educated at ordinary schools in the community and not at the institution. The support (since 1992) of a Danish non-governmental charity provided gifts for the children and also the opportunity to go to Denmark, which was taken up by several children who had learned Danish in order to continue their higher education in Denmark.

It is important to note that such interventions are not a new phenomenon. Most strikingly,

Skeels and Dye (1939) moved young children from a U.S. orphanage to an institution for cognitively impaired adult females, who spent time teaching the children eating and toileting habits, as well as showing them how to walk, talk, and play with toys. The researchers concluded that the much improved interaction with the children was more important than the fact that their caregivers themselves were cognitively impaired individuals.

Diagnosis and Assessment of Relationship Disorders

Over the last decade or so there has been increased recognition of the need to differentiate between attachment security–insecurity, disorganized attachment, reactive attachment disorders (RADs), and the new DSM-5 diagnosis of disinhibited social engagement disorder (American Psychiatric Association, 2013). As Rutter, Kreppner, and Sonuga-Barke (2009) discussed, it is also seriously misleading to view disorganized attachment, inhibited RAD, and disinhibited social engagement disorder as needing to be viewed through the lens of security–insecurity. Thus, although disorganization shares with A and C patterns its elicitation by separation–reunion on the Strange Situation procedure, there is not the same association with parental sensitivity and probably a greater genetic liability. The components seem to reflect dysregulation rather more than insecurity. Similarly, disinhibited social engagement disorder reflects interaction with strangers rather than with caregivers. In addition, there has been a growing awareness that the use of the Strange Situation may not have the same meaning and validity when used in an institutional setting. Elizabeth Carlson, working with Zeanah and colleagues (2005) developed a 5-point rating scale of attachment to document the range of child behaviors in the Strange Situation. A rating of 5 indicated behavior consistent with the traditional A, B, C, and D classifications. They found that every community child living with parents scored 5, whereas only three children out of 95 in institutions had such a rating. This dimensional approach served to differentiate degrees of attachment within the institutional group rather than its quality.

In order to identify individual differences in socially indiscriminate behavior, the Bucharest Early Intervention Project (BEIP; Gleason et al.,

2014) developed a “Stranger at the Door” procedure. This involved a stranger (a research assistant) who, when the parent/caregiver came to the door, said to the child: “Hello, my name is _____. Come with me, I have something to show you.” The parent/caregiver was instructed to stay neutral with both gestures and speech if the child asked what to do. The scoring was 0 for “stayed with parent” and 1 for “left with stranger.” The authors also developed a disturbances-of-attachment interview (DAI) designed to identify both inhibited RAD and indiscriminately disinhibited behaviors (McGoron et al., 2012). Both of these measures were shown to be reliable and valid with respect to group differentiation.

In their report for the DSM-5 working party on the diagnosis and classification of child disorders, Zeanah and Gleason (2010) had argued that because disinhibited behavior was best seen with a stranger, rather than with separation and reunion with a parent/caregiver, it should *not* be classed as an attachment disorder. Instead, they coined the term *disinhibited social engagement disorder*. This behavior, commonly seen in children subject to profound institutional deprivation, tended to persist even after either adoption or fostering. By contrast, inhibited RAD usually remitted after removal from the institution.

Mediators of Intervention Effectiveness

In the second edition of the *Handbook*, although several chapters included brief comments on possible mediators of intervention effects, the word *mediation* does not appear in the index. There is now, however, a growing literature on the topic. From a policy/practice standpoint, it is not enough to know whether an intervention has a measurable effect. Rather, it is crucial to determine why and how it works. There is space here to give only a few examples.

A key article is that by Cicchetti, Rogosch, and Toth (2006). In their report of a randomized preventive intervention trial, Fraiberg-based infant–parent psychotherapy (IPP), designed to foster secure attachment, was compared with a psychoeducational parenting intervention (PPI) developed by David Olds, which uses direct behavioral methods to improve parenting; a control sample given neither intervention; and nonmal-

treated controls. Both IPP and PPI were found to be effective in improving secure attachments but, contrary to expectations, the two contrasting treatment approaches did not differ in their success. It has usually been assumed that a behavioral modification of parenting would not change attachment security, but this was not what the research showed. Conversely, an intervention that specifically focused on fostering secure attachment was not better than the behavioral approach. Also, changes in parental sensitivity did not mediate the improvements in attachment security. Two other studies (Gleason et al., 2014; McGoron et al., 2012) from the BEIP took as their starting point their own finding from an RCT that high-quality foster care significantly reduced a wide range of psychopathological outcomes as compared with the outcomes for those who remained in the institution (McGoron et al., 2012; Nelson et al., 2007; Smyke, Zeanah, Fox, & Nelson, 2009). The question they posed was what role attachment qualities played in the intervention benefits. McGoron and colleagues (2012) found that high-quality caregiving when the children were 30 months of age was associated with reduced psychopathology and reduced functional impairment at 54 months, and that security of attachment at 42 months accounted for a meaningful proportion of the variance in psychopathological outcomes. Gleason and colleagues (2014) found that only disorganized attachment as measured by the Strange Situation at baseline accounted for variations in indiscriminate social behavior at 54 months in the group that had experienced institutional care.

McLaughlin, Zeanah, Fox, and Nelson (2012) provided the additional finding that foster care in the BEIP reduced emotional disturbance and increased attachment security in girls but not boys. The benefits with respect to emotional disturbance were fully mediated by attachment security. Nevertheless, even in boys, there was some mediation by attachment security.

We conclude that the evidence that interventions can bring about worthwhile changes is encouraging, but we remain ignorant of just what it is that drives the benefits. It is evident that attachment-based therapies are not necessarily more successful than behavioral parenting approaches, but this may be because improved parenting increases the likelihood of secure attachments. Clearly, much more research is needed to sort all of this out.

Insecure Attachment/ Disorganized Attachment

In recent years there has been a proliferation of meta-analyses dealing with various aspects of measures of attachment. Thus, in a core set of 18 studies that provided data on all three comparisons (i.e., between avoidant insecurity, resistant insecurity, and disorganization), Fearon, Bakermans-Kranenburg, Van IJzendoorn, Lapsley, and Roisman (2010) reported that avoidant insecurity had an effect size of 0.12 in comparison with security in relation to externalizing behavior. The comparable figure for resistant insecurity versus security was 0.19. For disorganized versus secure, the effect size was 0.27. The problem with this meta-analysis, as with almost all others, is that because it is based on cross-sectional data, it is uninformative about predicting later behavior and, in addition, it did not correct for relevant third variables. A companion article by Groh, Roisman, Van IJzendoorn, Bakermans-Kranenburg, and Fearon (2012) examined the same issues in relation to internalizing symptoms. They found that the associations were much weaker than those with externalizing behavior.

Cyr, Euser, Bakermans-Kranenburg, and Van IJzendoorn (2010) used a meta-analysis to compare the statistical effects of maltreatment and of socioeconomic risks on disorganized attachment. Strikingly, and surprisingly, the effects of five or more socioeconomic risks (out of low income, single mother, low education, adolescent mother, ethnic/minority status, and substance abuse) did not differ significantly from the effects of maltreatment on disorganized attachment. On the face of it, this finding might seem to challenge attachment theory (although the authors argue that the lack of difference might be a consequence of undetected maltreatment in the socioeconomic risk group). In our view, the limitations of cross-sectional meta-analyses (see earlier discussion) mean that, in the absence of findings on mediation, no firm conclusions are possible.

Dangers of Overdiagnosing Attachment Disorders

Attachment theory has led to a variety of attachment-related preventive and therapeutic interventions that have been found to be effective (see

Allen, 2011; Cassidy, Jones, & Shaver, 2013; Cicchetti et al., 2006). However, the initial assumption that there needed to be a specific focus on maternal sensitivity was found to be mistaken in view of evidence of the very weak mediating role of maternal sensitivity (Madigan et al., 2006; Van IJzendoorn, 1995). Much more seriously, several interventions that claimed to be attachment-based seemed to have no connection with attachment theory. Holding therapy and age-regression approaches are the most notorious of these because a few children have died following holding therapy.

More recently, Woolgar and Scott (2013) pointed to a different issue, namely, the exclusive use of attachment therapies when no attachment disorder has been shown to be present, with the consequent failure to use effective interventions for the conduct disorders that *are* present. Prior and Glaser (2006), Chaffin and colleagues (2006), and the American Academy of Child and Adolescent Psychiatry (2005) have all provided useful guidelines for identifying attachment disorders in looked-after children and adopted children. Even though these children have an increased risk of attachment disorders, more common disorders should be considered first (Boris et al., 2004; Meltzer, Gatward, Goodman, & Ford, 2003) rather than succumbing to the allure of assuming the problems that may follow abuse or neglect necessarily constitute an attachment disorder. Nevertheless, there is value in the assessment of young people's representational models of attachment (Scott, Briskman, Woolgar, Humayun, & O'Connor, 2011).

Family Disruption and Attachment

In the version of this chapter in the second edition of the *Handbook of Attachment*, there was a brief paragraph on divorce, with the conclusion that it clearly was likely to have effects on parent-child relationships. In that connection, attachment theory was important in highlighting the issues involved. However, it did not, and could not, provide a means of deciding just what should be done in any individual case. The same applies to the effects on children of parental incarceration (Murray, Bijleveld, Farrington, & Loeber, 2014). Sometimes the courts, in adjudicating on parent-child contact, base decisions on which parent the child has "bonded" to. This constitutes a serious

misunderstanding of attachment theory. Selective attachments form to multiple people and this may include parents who abuse them (Rajecki, Lamb, & Obmascher, 1978). Decisions need to be based on a broader range of considerations of positive and negative features even though improved dimensional measures are becoming available.

Lesbian and Gay Adoption

Brodzinsky, Green, and Katuzny (2012) noted that in some jurisdictions, gay couples have been allowed explicitly by law to adopt children, and they have done so in increasing numbers. However, there have been only a few studies comparing lesbian, gay, and heterosexual couples' adoptions, and all of these have been concerned with preadolescent (often very young) children (because lesbian and gay adoption has not been available long enough for the study of older children). The fact that these group comparisons are based on prospective longitudinal studies indicates that follow-up would be possible, however. Goldberg, Kashy, and Smith (2012) examined gender-typed play behavior in young children as reported by parents of 2- to 4-year-old adopted children. They found that play preferences were less gender-stereotyped in gay and lesbian families than in those headed by heterosexual couples—a finding that is important in relation to child care policies.

The two most systematic studies are those by Golombok and her colleagues (2014) and by Farr and her colleagues (2013). The details of the Golombok design are described by Dozier and Rutter, Chapter 30, this volume. Briefly, it concerned adoptees aged 3–9 years and involved a wide range of measures obtained from parents, children, and teachers. For the most part, there was a lack of significant differences among these three groups (gay, lesbian, and heterosexual) but, where there were differences, they reflected the more positive functioning of the gay-father families, which showed higher levels of warmth, greater amounts of interaction, and lower levels of disciplinary aggression, as well as higher levels of responsiveness (Golombok et al., 2014; Mellish, Jennings, Tasker, Lamb, & Golombok, 2013).

Farr and Patterson (2013) studied coparenting among 104 adoptive families headed by lesbian, gay, or heterosexual couples. Specialization in patterns of child care was greater among heterosexual couples than among either lesbian or gay

couples. Supportive coparenting was associated with better child adjustment. As indicated in the review by Grotevant and McDermott (2014), attention needs to be paid to both biological and social processes, and it is essential that the follow-up extend into adolescence and later. The evidence at the moment is almost entirely based on very young children.

The reassuring findings so far indicate that lesbian and gay couples could provide a larger pool of potential adoptees, and that there needs to be a greater focus on the specifics of parental functioning rather than assumptions that being gay or lesbian necessarily implies problems or adversity.

Evolutionary Implications of Attachment

Cassidy (Chapter 1, this volume) has summarized well the key features of attachment theory and, here, we use her summary. Bowlby (1969/1982) argued that attachment emerged through evolution as an adaptation that provided infants with a repertoire of behaviors that increased the likelihood that they would remain proximal to supportive others. In that connection, he placed particular emphasis on the secure-base effect. The field moved forward with Ainsworth and colleagues' (1978) development of the Strange Situation procedure to differentiate secure and insecure attachments, and further still with Main, Kaplan, and Cassidy's (1985) recognition of the potential importance of internal working models that involved cognitive and emotional processing of attachment experiences (Bretherton & Munholland, Chapter 4, this volume).

Ein-Dor and colleagues (2010) returned to the topic of evolution in highlighting the apparent paradox that almost a half of individuals in the general population are insecure with respect to attachment. Yet it is only secure attachment that is usually viewed as adaptive. This is relevant to policy because many practitioners and policymakers have assumed that secure attachments are optimal in all circumstances. Ein-Dor and colleagues put forward social defense theory (SDT) to argue that, although, on an individual level, security tends to be more advantageous than insecurity, the evolutionary notion of inclusive fitness (see Hatchwell, Gullett, & Adams, 2014) means that, at a population level, it may be advantageous for there to be multiple attachment styles.

In biology generally, it is very unusual for there to be reliance on just one mechanism. Thus, ordinary attachment develops in the context of eye-to-eye contact and holding; nevertheless, blind children and children without limbs also develop selective attachments (Blacher & Meyers, 2002). The evolutionary notion of inclusive fitness, by contrast, places all of the emphasis on the role of the closeness of the kin relationship (Hatchwell et al., 2014). There is good evidence in favor of its importance, but it ignores the fact that most socially supportive behavior in all social animals (not just humans) is found in the *absence* of kinship ties. Attachment theory, by contrast, argues for the universality of selective attachments, as well as emphasizing the importance of individual differences. SDT does the same but constitutes a step forward in its postulate that insecure attachments (as well as secure ones) may well be adaptive at a community level.

Conclusions

In this chapter we have not reviewed the considerable evidence concerning the biology of attachment because it is fully covered in other chapters of this volume and the findings do not carry strong messages for policy or practice. As discussed in some detail elsewhere (Rutter & Azis-Clauson, 2015), experiences of all kinds involve a wide range of biological effects, but that does not mean that they are permanent. Indeed, as recent epigenetic findings illustrate, they are substantially modifiable. For the same reasons, we do not discuss genetic findings, but we do note the necessary cautions about molecular genetic correlates as a result of the fragility of the findings (Roisman, Booth-LaForce, Belsky, Burt, & Groh, 2013). We also note the likelihood that genetic influences on attachment patterns are likely to differ between the infancy period, when the measures are dyadic, and the later years, when they have become an individual characteristic (Rutter, 2014).

The broad message is that attachment theory continues to be relevant in a wide range of domains, and none of the new empirical evidence challenges the theory's basic tenets. Attachment theory continues to be helpful in guiding people in their thinking about relationships, and this thinking should matter in relation to policy and practice. On the other hand, attachment theory has perhaps been too narrow in its focus when ap-

plied to the surprising evidence that early institutional rearing may be less damaging than usually supposed when such rearing has *not* involved profound and pervasive deprivation. Similarly, an undue focus on attachment has sometimes led to an unfortunate neglect of other features when dealing with looked-after and adopted children.

The gains in knowledge over the last decade have been very gratifying and have brought real benefits to policy and practice. But, just as Bowlby himself, as well as Mary Ainsworth and Mary Main, modified their views and practice when empirical findings required them to do so, we, too, need to do the same today. Attachment theory has never constituted a rigid doctrine that can never be modified. Rather, it continues to provide a firm base that should incorporate modifications, as well as consistency in approach.

PART VII

PERSPECTIVES ON ATTACHMENT

Chapter 43

The Place of Attachment in Development

L. Alan Sroufe

Attachment theory has been remarkably successful, with achievements beyond what could have been imagined when Bowlby was first formulating his ideas or when he published the first volume of his trilogy in 1969. Its contribution to our understanding of the nature of development is virtually without parallel. It is worth savoring some of these achievements, and I do so in the first part of this chapter. At the same time, like any major theory in the social sciences, with success come certain hazards. These include overextensions of the theory (thinking it can explain everything, including things for which it was not designed), misunderstanding and misapplication, and even complacency. A truly successful theory can withstand modification and certainly should suggest new directions for fruitful research. Some of the vulnerabilities of the theory, its rightful place in an understanding of development, and some suggestions for future direction constitute the remaining parts of the chapter.

Achievements of Attachment Theory

Conceptual Achievements

Without doubt, attachment theory instigated a revolution in psychological science, having a profound impact on clinical psychology and psychia-

try, developmental psychology, and social psychology. It played a major role in moving away from a one-person psychology to a relational psychology, with relationships becoming the unit of analysis.

I have previously described how the rise of attachment theory saved psychoanalytic or psychodynamic perspectives in the clinical field and preserved these perspectives for the good of all of psychology (Sroufe, 1986). For more than 100 years, the experience of psychoanalytically oriented clinicians, working with adults in individual therapy, had suggested an agreed-upon set of propositions: (1) that the root of many adult disturbances and distorted world views had their origins in childhood, beginning in the earliest years, (2) that many of these experiences now lie outside of awareness, yet (3) were somehow internalized and represented in the mind of the client. Freud's theory had encompassed such notions. However, despite wide agreement regarding such ideas, they remained "articles of faith" until the last four decades. Laden with archaic energy concepts, Freud's theory was essentially not testable, and psychoanalysis as a scientific theory and psychodynamic practice in general were floundering. (See also Fonagy, Luyten, Allison, & Campbell, Chapter 34, this volume.)

The outgrowth of attachment theory from psychoanalytic theory and other theoretical positions exemplifies the general nature of devel-

opment. All development “builds upon itself” (Stiles, 2008), with old parts reorganized in new ways. Thus, attachment theory brings forward the most developmentally serviceable parts of psychoanalytic theory—the formative influence of early experience, the centrality of affective life, the critical importance of close relationships, and the reality that much of psychological functioning lies outside of awareness. At the same time, in reorganizing these ideas within a biological perspective, a radically different and more fully developmental account emerges. In a true conceptual revolution, Bowlby turned Freud’s theory upside down. He began not with disturbed adults in his effort to construct a general theory but with normal development, viewing disturbance as developmental deviation. And he drew not on 19th-century physics but on evolutionary biology for his guiding frame of reference. The relationship between infant and caregiver was explained as a primary condition for human adaptation and survival, not as a product of association with drive reduction. Disturbance often derives from inner conflict. However, according to Bowlby, such conflict emerges not from the internal fantasy life of the young child but from the child’s real lived experiences in vital relationships. Propositions from this new framework—that quality and effectiveness of attachment relationships derive from interactive history, and that quality of attachment is the foundation for later personality formation—were eminently testable. They awaited only development of the tools for assessing parent–child interaction, the effectiveness of the attachment relationship, and measures of representation to explain the process wherein experience is carried forward. The wait was not long.

Another way Bowlby inverted psychoanalytic theory concerned the relation between relationships and the self. Theories of Freud and his descendants conceived of a primitive self, cathecting (investing with energy) part objects (the breast) and then objects (people), in order to form relationships. Bowlby and like-minded theorists (Sander, 1975) conceived of the self as deriving from relationships. From an organized relationship, at first orchestrated by the caregiver, but in time truly dyadic, comes the organization of attitudes, expectations, and behaviors we know as the self (Sroufe, 1989). Again, while measuring hypothetical constructs, such as degree of cathexis of an object or strength of the “paranoid position,” eluded measurement, one could measure the organization of the infant–caregiver relationship (i.e.,

how well affect regulation was achieved by the pair) and actually test whether this predicted later self-management, self-esteem, executive function, and the like. This perspective, wherein relationships are primary, led to a new way of conceptualizing both healthy development and the development of disturbance.

For most of its history, psychology was almost exclusively a science of individual behavior. Even subfields such as “social cognition” were concerned with how individuals viewed the social world, not how relationships impacted individual thought. The work of Bowlby and his close colleague Robert Hinde (1979) did much to change this, with the suggestion that relationships could also be a unit of analysis. This movement had profound effects on developmental psychology and social psychology.

An early demonstration of the power and validity of relationship measurement came from the dissertation research of Everett Waters (1978), who showed that attachment *relationship* assessments were stable between 12 and 18 months, whereas frequencies of individual attachment behaviors were not (e.g., crying, smiling, clinging, proximity seeking). Thus, infants who at 12 months cried a great deal, and immediately sought physical contact upon reunion following a brief separation, might have smiled, vocalized, and taken a toy to their mothers in the same context at 18 months. The individual behavior was transformed, but in both cases the *relationship* was characterized by its effectiveness in supporting exploration. This was only the beginning. In countless ways in our Minnesota longitudinal studies, we showed that attachment relationship assessments predicted later relationship functioning *or individual behavior* better than did any assessments of individual infant behavior. Dependency, self-management, capacity for empathy, self-esteem, and behavior problems are better predicted by infant relationship assessments than by any individual child characteristics that can be assessed in the first 2 years of life (Sroufe, Egeland, Carlson, & Collins, 2005a; see also Thompson, Chapter 16, this volume).

Some of the most powerful achievements of a relationship perspective derive from the study of peer relationships (see Groh et al., 2014, for a recent summary). Understanding peer relationships as relationships—in terms of their symmetry and age changes—opened the way for an intensive study of the role of peers in individual development (Hartup, 1999). Some of the strongest findings in the attachment field concern the links

between early attachment and later functioning with peers. Social competence is strongly related to attachment history (e.g., Sroufe, Egeland, & Carlson, 1999), but beyond this, so too are measures of the quality of specific peer relationships. Both frequency of close friendships and closeness of friendships are related to attachment history (e.g., Elicker, Englund, & Sroufe, 1992; Shulman, Elicker, & Sroufe, 1994). One final example here concerns bullying relationships (Troy & Sroufe, 1987). Again, no measure of individual behavior in the first years has been shown to predict later bullying. Within an attachment perspective, prediction became possible. Moreover, this study showed that the most powerful predictions came from consideration of the attachment histories of *both* partners. Those with secure histories neither bullied nor were the victims of bullies in our extensive play pair assessments. Those with insecure/resistant histories were bullied by those with insecure/avoidant histories but nurtured by those with secure histories.

In adult social psychology as well, the power of studying relationship quality, as opposed to simply individual characteristics or perceptions, has become manifest (e.g., Mikulincer & Shaver, 2007; Simpson & Rholes, 2012). In addition to studying the quality of adult attachment relationships, investigators are probing the details about how adult relationships work, both poorly and well. Thus, for example, studies have concerned mutual regulation between partners and how partners are or are not able to resolve conflict (which itself is predicted by relationship history measures; Salvatore, Kuo, Steele, Simpson, & Collins, 2011; Simpson & Overall, 2014).

Another conceptual advance came from the methodology developed by Ainsworth (e.g., Ainsworth, Blehar, Waters, & Wall 1978). Direct observation is a key to rigorous psychological science, yet observational work is fraught with challenges. For years it seemed that there were only two choices, neither of which was adequate. On the one hand, one could record frequencies of very reliable discrete behaviors (how often a baby cries or smiles, or a mother vocalizes or picks up the infant). Numerous problems plagued this approach. First, much observation was required for such measures to be stable. Second, the same behavior could mean many different things depending on context. (Did the mother pick up the baby when it wanted to be picked up or did her behavior in fact interfere with an infant goal?). Finally, even apparently clear behaviors were ambiguous (was

the verbalization too loud?). Attempts were made to solve some of these problems with complex contingency analyses of behavioral chains, but this proved unwieldy. The second option relied on judgments of observers who typically would watch entire episodes of behavior, then make ratings based on their impressions. Although this had the virtue of attempting to capture the meaning of behavior, such judgments were notably unreliable across raters.

Ainsworth provided a third option, both for her scales of maternal behavior and her attachment rating scales (Ainsworth et al., 1978). She retained the goal of capturing meaning, but she also utilized specific behavioral referents. For illustration, consider the following three vignettes: immediately upon reunion following a brief separation, a baby (1) begins approaching the caregiver, then halfway to her turns off to the side; (2) starts to approach the mother, then halfway to her stops and shows her a toy, smiling broadly; (3) starts to approach, then turns away to a toy, picks it up and, smiling, shows it to the mother. Only the first of these would receive a score for avoidance, and that score would be higher or lower depending on what happened next (e.g., higher, if the infant subsequently ignored the mother's efforts to gain his or her attention). Ainsworth and colleagues (1978) provided multiple possible scenarios for each scale point. While she could, of course, not describe every possible scenario, the varied scenarios allow the rater to engage in template matching, with quite adequate reliability. We used this same approach in many of our behavioral observations across the Minnesota longitudinal study (Sroufe et al., 2005a).

Attachment theory also played a crucial role in solving conceptual problems that were of great importance in the soon-to-emerge field of developmental psychopathology (e.g., Sroufe & Rutter, 1984). These included the problems of explaining continuity and change, understanding the particular role of early experience, and explicating pathology as a developmental outcome. The concept of "developmental pathways," adapted by Bowlby from the work of Waddington (1957), was central to each of these problems.

The pathways model dissolved the question of whether development was characterized by continuity or change by suggesting that there would be increasing probability of following a pathway the longer it had been followed, and that continuity would not be in terms of identical behavior; rather, it would be characterized by transforma-

tion and a branching family of outcomes related in terms of meaning. Change was possible at any point of development, but change was constrained by previous adaptation. As Bowlby (1973, p. 412) put it: "Development turns on each and every stage of the journey on an interaction between the organism as it has developed up to that moment and the environment in which it then finds itself." Early experience has a special place in this model because of the cumulative nature of development, always building on what was there before. It certainly does not preordain all outcomes, but neither is it without significance or "erased" (Kagan, 1984) by later experience. Finally, psychopathology is viewed as a product of the cumulative adaptations of the individual as he or she faces the series of developmental issues and challenges. Predictably, problems tend to become more stable with development, and pathway is a more powerful predictor of outcome than are manifest symptoms at a given age (e.g., Moffitt, 1993).

The heterogeneity of all childhood disorders and the ubiquitous comorbidity among them becomes understandable within this framework (Sroufe, 1997). Most important, this approach leads to a new research agenda. The first objectives become to identify early variations in patterns of adaptation that mark initiation of pathways and identify the complex of factors that initiate such patterns. Attachment experiences—that is, parental responsiveness and secure-base provision—are only a part of this picture, but an important part. Other objectives are to trace continuity and change in adaptations in the face of subsequent developmental issues and determine factors that maintain individuals or deflect them from the pathway previously "chosen." In time, this approach would potentially lead to a new system for classifying later problems. In addition, it provokes new attention to prevention and early intervention efforts (see Berlin, Zeanah, & Lieberman, Chapter 32, this volume).

Empirical Achievements

Empirical achievements of attachment theory, both in adult social psychology and in developmental psychology, are found throughout this volume. Therefore, here I feature only a few, drawing primarily from the Minnesota Longitudinal Study of Risk and Adaptation (e.g., Sroufe et al., 2005a). I group achievements in terms of core hypotheses from attachment theory. These include the fol-

lowing: that variations in infant attachment are rooted in the quality of early parent–infant interaction, that these attachment variations are the foundation for personality formation, and that "internal working models" or representations of the interactive history are the means by which lived experience is carried forward. Work on continuity, change, and "resilience" is highlighted.

Predicting Attachment Variations from Parent–Infant Interactive History

Based on her extensive observation (72 hours per case), Ainsworth showed that, indeed, caregivers' sensitive responsiveness predicted later attachment security (e.g., Ainsworth et al., 1978). Others using less extensive but still substantial observation replicated these results, with a correlation of about .50 (Pederson, Gleason, Moran, & Bento, 1998; Posada et al., 1999). Correlations are more modest with less observation but are still consistently found (see De Wolff & Van IJzendoorn, 1997, for a meta-analysis). Moreover, studies that included measures of infant temperament find that only caregiver sensitivity, not temperament, predicts attachment outcomes (e.g., National Institute of Child Health and Human Development Early Child Care Research Network [NICHD ECCRN], 1997; Sroufe et al., 2005a). (See also Fearon & Belsky, Chapter 14, and Vaughn & Bost, Chapter 10, this volume.)

Predictability of Later Behavior from the Early Years

In the 1960s and early 1970s, before attachment theory had taken hold, developmental psychology was in a strange place. It was being put forward that there was little to no continuity in development, especially from the early years of life (Kagan & Moss, 1962). Moreover, it was claimed that constructs such as attachment (Masters & Wellman, 1974) and even personality (Mischel, 1968) were of little use because behavior of individuals was so unstable across time and contexts. Thus, it has been of great importance to the entire field to establish that such cross-time and even cross-context linkages can be established. As discussed earlier, this was done by moving to the level of the organization of behavior and showing that individual patterns of organization in early life forecast patterns of adaptation with regard to the salient issues of subsequent developmental periods. Behavior is

expected to change across contexts; for example, the well-adapted infant explores actively in the caregiver's presence but effectively seeks contact when distressed, and the well-adapted preschooler plays with exuberance in the play yard but sits quietly during story time (Block & Block, 1980). And behavior must change with development. Children who are ineffective in using the caregiver for comforting, including those who show avoidance, later are more dependent, whereas those who are effectively dependent infants later are more autonomous (Sroufe, Fox, & Pancake, 1983). No one expects loyal friendships among infants, but they are a hallmark of successful adaptation in middle childhood. Using such an understanding, clear evidence of continuity (coherence of adaptation) from infancy to adulthood has been demonstrated (Sroufe et al., 2005a). Links are especially strong to measures of self-management, dependency, and peer relationships. With adequate outcome data, which we were able to obtain in our extensive preschool and summer camp studies, correlations in the .40s and .50s were common. Nothing in the early years predicted better than attachment history, likely because it summarizes so much of what is going on in the development of the infant.

A more recent body of work provided dramatic evidence of intergenerational continuity. Every step in a cyclical chain beginning with disorganized attachment has been established. Disorganized attachment in one generation predicts disorganized attachment in the next (Main, Hesse, & Kaplan, 2005; Raby, Steele, Carlson, & Sroufe, 2015). More important are the links in the chain. Disorganized attachment predicts the tendency to dissociate throughout childhood and into adulthood (Carlson, 1998). As reviewed by Lyons-Ruth and Jacobvitz (Chapter 29, this volume), disorganized attachment and dissociation predict lack of resolution of loss or trauma in the Adult Attachment Interview (AAI), and lack of resolution in the AAI predicts frightening parental behavior. Furthermore, frightening parental behavior predicts, as theoretically specified, disorganized attachment in the infant of the next generation, so the cycle is complete (Jacobvitz, Hazen, & Riggs, 1997; Schuengel, Bakermans-Kranenburg, Van IJzendoorn, & Blom, 1999).

For many reasons it is not surprising that early attachment experiences forecast later development (Sroufe, Egeland, Carlson, & Collins, 2005b). First, having experienced responsive care, those with secure histories tend to experience a basic sense of connection with others and a be-

lief that relationships are valuable. Second, such individuals also begin life with positive expectations about themselves and their ability to elicit support from others. Having had a secure base for exploration, they bring to the social world a curiosity, a zest for discovery, a positive problem-solving attitude, and a set of instrumental skills that make them attractive social partners. Having experienced effective dyadic affect regulation during infancy, children with secure histories have a solid foundation for emotion regulation and self-management in later years. They believe that self-regulation in the face of challenge and recovery from periods of dysregulation are possible, and they have brain excitatory and inhibitory systems that are properly tuned for achieving both. Finally, as part of an empathic, reciprocating relational system, they now have an understanding of how effective relationships work and a capacity for empathic responsiveness to others. (See also Thompson, Chapter 16, this volume.)

None of this is to say that attachment experiences by themselves determine later development, or that early secure attachments are a guarantee of later healthy adjustment, or that anxious early attachments cannot be overcome. Change, as well as continuity, is central to the theory.

Continuity, Change, and Studies of Representation

Although demonstrating continuity from the early years forward was an important achievement, the predictability and coherence of change also followed from Bowlby's theory. Indeed, in the Minnesota Longitudinal Study of Risk and Adaptation, we were able to account for change, age by age (Sroufe et al., 2005a). During the infancy period, when family stress decreased or social support increased, change from anxious to secure attachment was more likely. At later ages also, as family stress and support changed, or as maternal depression waxed and waned, so too did child behavior problems. Moreover, we were able to show that representations of experience played a key role in continuity and change (Carlson, Sroufe, & Egeland, 2004). First, assessments of representation—through stories, drawings, projective techniques, and narrative interviews—were predictable throughout childhood and adolescence into adulthood from infant attachment variations. Second, there was interplay between representation and experience as predicted by theory. At any given age, measures of representation predicted adapta-

tion at the next age, with earlier behavior held constant. At the same time, measures of behavior predicted representation at the later age, with prior representation controlled. This is the same thing as saying that representation predicted change in behavior, while, reciprocally, experience predicted change in representation, age by age. (For discussion of representational processes, see Bretherton & Munholland, Chapter 4, this volume.)

The Fate of Early Experience Following Change: Resilience

According to Bowlby's pathways model, one's entire developmental history is always part of the array of influences acting on the person. This suggests that, even following change, early experience is not erased. The Minnesota longitudinal study provided data for examining this hypothesis (Sroufe et al., 2005a; Sroufe, Egeland, & Kreutzer, 1990). We began by defining what we viewed as two groups of preschool-age children. They had in common a consistently high level of behavior problems across three assessment periods. (Indeed, based on a position that change erases early experience, there is only one group.) What distinguished them was that some had a history of secure attachment, whereas others had an insecure history. When we conducted follow-up research when children were in third grade, children with secure histories had significantly fewer behavior problems than those with insecure histories. We repeated such a demonstration at subsequent ages. Similarly, those with insecure attachment histories, who for a time do well, are more vulnerable to subsequent problems. Early experience is not erased.

These findings shed light on the phenomenon of *resilience* as a developmental process. Had our study only begun, for example, in the preschool years, we still would have found that some children bounced back from their period of difficulty and by this criterion could be said to be resilient. However, it would have been fallacious to consider this capacity simply an inherent characteristic of some children. It is simply a label for the phenomenon of recovery. More of an explanation derives from knowing the history that provides the foundation for recovery. When history and current supports are taken into account, very little mystery remains in this kind of resilience.

A more classic definition of *resilience* is the capacity to do well in the face of adversity (Masten, 2001). For example, high family stress is as-

sociated with child behavior problems. But not all children facing high stress show such problems, and it would be possible to "explain" this by saying they are resilient. Once again, our data show that those with histories of secure attachment are significantly less likely to manifest problems in the face of stress (Pianta, Egeland, & Sroufe, 1990). A secure attachment history provides a foundation for coping with adversity, likely both because of internal resources and the capacity to draw on external social support. The capacities to rebound, to cope with adversity, and to take advantage of turning points for growth all are predicted by attachment history (Sroufe et al., 2005a).

Vulnerabilities of Attachment Theory

All theories have vulnerabilities—incoherence in propositions, illogical deductions, predictions that are not distinctive, and the like. But a very successful theory faces two particular and related hazards. These are overreaching, or trying to explain everything, and the belief that the theory is the total explanation for any phenomenon. These are certainly risks for attachment theory. With such expansionism, the theory risks losing its core, losing sight of what it was specifically designed to explain and explain well. As Sandra Scarr (personal communication, September 1978) once asked, "Is attachment theory simply a theory that all good things go together?" Were this so, it would not be much of a theory.

Over the years almost everything has been suggested at one time or another to be related to attachment variations, from grammatical language acquisition to map reading to IQ. One actual finding from our study is that infant attachment security predicted math achievement scores in high school. Although one can come up with a rationale to explain this finding (and possibly even posit post hoc some common underlying brain mechanisms), we resisted the idea of publishing this finding that we believed to be misleading. It is not likely that attachment evolved to prepare individual brains for understanding math. In fact, the most likely explanation of this correlation is that math achievement is highly related to school attendance, and for a variety of reasons (including getting along with peers and teachers, and having parents who support schooling), those with secure histories have better attendance. In support of

this, attachment history does not predict reading achievement, which is not as dependent on attendance as is math achievement.

Attachment theory makes very specific predictions—to positive expectations concerning self, other, and relationships; to a basic sense of security; to the capacity to draw support from, and offer support to, others; to emotion regulation; and to a well functioning personality. It should not and does not predict to everything, including many aspects of cognitive functioning.

Likewise, attachment history is not the only thing that predicts important outcomes, even in the social arena. There are many critical influences on development, including other relationships both inside and outside of the family, as well as the broader contextual situation surrounding the developing child. Siblings, peers, schools, neighborhoods, and socioeconomic status all are known to have important influences. As pointed out in the earlier discussion of resilience, attachment history was important; but intervening changes in social support and life stress being experienced by the family also played a role. To account fully for resilience, all of these factors needed to be considered.

Attachment is not even all there is to parenting. Parents do much more than provide a haven of safety and a secure base for exploration, important as these provisions are. Parents provide limits and boundaries, socialize the expression of emotion, instill values through their example, promote or inhibit exchanges with the broader social environment, select and encourage a range of experiences to which the child is exposed, among many other things (see Table 43.1). Assimilating all of this to attachment will curtail our knowledge of parental influence and even interfere with the task of understanding attachment because it disallows

the possibility of studying how attachment experiences work in concert with other experiences.

We developed strong measures of several key aspects of early parenting that we viewed as outside the purview of attachment. These included measures of limit setting, parent–child boundary dissolution (a form of overstimulation), and parental scaffolding of problem solving. In addition, we also assessed parental intrusiveness (Ainsworth's Cooperation–Interference Scale in infancy), the quality and stability of the home environment, and promotion of autonomy in early adolescence (Sroufe et al., 2005b). Although each of these show some correlation with attachment security, they certainly are not identical to attachment, and they play distinctive roles in development.

A first example concerns school outcomes. Attachment history does correlate with a range of school outcomes, mostly tapping relationships with school personnel and commitment to school. For example, it predicts dropping out of school. But parental scaffolding for problem solving, which we measured at age 3½ years in our laboratory, was a far stronger predictor. This measure tapped how well the parent structured four problems for the child, provided relevant help, and properly sequenced this help, moving neither too fast nor too slow, helping but not taking over (Englund, Luckner, Whaley, & Egeland, 2004; Sroufe et al., 2005a). This single measure predicted a host of educational outcomes, everything we measured, from years of school completed to returning for a general equivalency degree (GED) for those who dropped out.

Prediction of attention-deficit/hyperactivity disorder (ADHD) symptoms provides another example. Although insecure attachment is probabilistically related to behavior problems in general

TABLE 43.1. The Tasks of Parenting

-
- Regulation of arousal
 - Appropriately modulated stimulation
 - Provision of secure base and safe haven
 - Appropriate guidance, limits, and structure
 - Maintenance of parent–child boundaries
 - Socialization of emotional expression and containment
 - Scaffolding for problem solving
 - Supporting mastery and achievement
 - Supporting contacts with the broader social world
 - Accepting the child's growing independence
-

and certain forms of specific problems, it is not at all well related to ADHD symptoms in particular (Sroufe et al., 2005a). In contrast, certain other aspects of parenting, as well as other features of the developmental landscape, are clearly predictive of ADHD, both as a category and as symptom scores. Ainsworth's Intrusiveness measure at 6 months and parent-child boundary problems at 24 and 42 months are all related to ADHD. The 42-month measure, taken from the problem-solving task described earlier, was the single best predictor at multiple follow-up ages (Carlson, Jacobvitz, & Sroufe, 1995). This measure taps a particular issue with dysregulation. A high score results when the parent provokes, cajoles, teases, flirts with, or otherwise increases the child's level of stimulation precisely at those times when the child is already becoming overtaxed by the problems and is beginning to lose control. Thus, as the child approaches the edge of overarousal and loss of control, the parental behavior pushes the child over the edge, undermining the child's belief in his or her ability to modulate arousal, as well as the actual capacity for self-control. Parents receiving low scores maintain a calm, reassuring presence at these times and increase their support, helping the child achieve both the sense of and capacity for self-regulation. This is a critically important parental role. In addition to this parenting measure, we found that measures of family life stress and stability or chaos in the home environment also predicted ADHD symptoms. When the measures of overstimulating parenting were combined with these measures of the surrounding environment, predictions to ADHD symptoms became quite strong, dwarfing endogenous measures of neurological status or temperament. But security of attachment played a minor role in this picture.

Even when we focus on an outcome with clear theoretical links to attachment, such as quality of later social relationships, other aspects of parenting proved to be important as well. For example, in our summer camp studies, we were able to develop a measure of "friendship competence" (forming and maintaining a reciprocal, loyal friendship; Elicker et al., 1992). This was indeed related to attachment history, while accounting for 13% of the variance. However, when attachment was combined with the other measures of supportive parenting described earlier, the variance accounted for doubled, with a multiple r of .52. Time after time, with a range of outcome measures, the broader measure of parenting was almost always more powerful than attachment alone.

Peer experiences also are an important influence on development, without doubt. The question of whether they are more important than attachment or other parenting variables misses the mark (Harris, 1998). The most important developmental question concerns how the two influences work together. We miss this question entirely when we try to explain everything in terms of attachment.

As reported earlier, infant attachment security is a clear predictor of peer competence, at every age. It provides an important motivational foundation for close relationships and exploratory and regulation capacities that make one attractive to peers. Still, what one gains from peer experiences also contributes to later social competence. We see social competence as constructed step by step, with each phase based on the foundation that was laid down before. Thus, with preschool peers, one learns a great deal about sustaining and chaining interactions in the face of difficulties, about selecting preferred partners, and about participating in groups per se. These experiences are unique because peers are equals (as the word signifies): One does not hold authority over the other. All of these experiences prepare the child for the loyal friendships and adherence to peer group norms that are the hallmark of middle childhood. These latter experiences then support the more intimate relationships of adolescence and negotiating the complexities of the adolescent social world, with same- and cross-gender friendships and same- and mixed-gender group functioning. It is no surprise that peer functioning at each age predicts social competence measures at the next. Moreover, when peer experiences are combined with attachment history and other aspects of parenting history, predictions increase over what either parenting or peer experiences alone can predict. In the case of the middle childhood friendship competence measure I discussed earlier, adding preschool teacher peer competence ratings to the equation raises the resulting multiple r to .62 ($r^2 = .38$), now triple the variance accounted for by attachment history alone.

Early attachment history and later family experiences or later peer experiences can combine in a variety of complex ways depending on the particular outcome (Sroufe et al., 2005b). Sometimes the joint influence is simply additive, as I have just described. Another example of this concerns the prediction of observed hostility in adult couple interaction. Such hostility is predicted by insecure attachment in infancy. But it is also predicted by

teacher rankings of peer competence in grades 1–3. These are independent predictors, with neither mediating the other.

Sometimes the impact of early attachment is partially mediated by another influence. We obtained observation-based measures of parental support for the 13-year-old child's emerging autonomy. Some of the variance of attachment history in predicting hostility in adult relationships was mediated by this later parenting measure. Still, early attachment remained a significant predictor. But with another adult outcome—conflict resolution, infant attachment history fell to nonsignificance once the age-13 measure was included. Depending on outcome, a variety of results were obtained, and this was also true when peer relationship measures at various ages were combined with attachment history. Sometimes only attachment history predicted, and sometimes only the peer measure predicted. But much more often, consideration of both was critical, with joint effects, including mediation, being the rule (Sroufe et al., 2005b). None of this trivializes the importance of attachment history. In fact, infant attachment gains importance as a construct when it is considered within a broader developmental framework.

Another potential hazard in attachment research is assuming the existence of a causal link when infant attachment is related to some later outcome. First, it is important to show that a third factor, such as IQ, life stress, or other experiential variables, is not a primary player. Second, as I just discussed, it is important to explore whether the link is mediated by some third variable. It is perhaps even more hazardous to conclude causal developmental linkages in the case of correlates of adult attachment measures. Not only must there be controls for relevant third variables, in addition, one must be cautious regarding assuming developmental antecedents. One example here will suffice.

Individuals with borderline personality disorder (BPD) features have been reported to be both “unresolved” and “preoccupied” in the AAI. This is a replicable finding (Dozier, Stovall-McClough, & Albus, 2008; Macfie, Swan, Fitzpatrick, Watkins, & Rivas, 2014; Stovall-McClough & Dozier, Chapter 31, this volume). Given the prevalence of trauma in the history of these problems, it is almost statistically guaranteed that they will more likely be unresolved regarding trauma. (One cannot be unresolved with regard to trauma if there was no history of trauma.) It is also plausible given the emotional volatility of such persons

that nonmodulated anger would characterize the transcripts of these individuals when describing their parental relationships. So these results make sense. But the conclusion that these interview responses and BPD itself are the result of resistant attachment in infancy is not a logical deduction and cannot be justified by the adult correlation itself. This can only be determined with prospective, longitudinal data. Although such data confirm that disorganized attachment in infancy and a history of trauma predict borderline symptoms (Carlson, Egeland, & Sroufe, 2009), anxious/resistant attachment in infancy does not predict borderline symptoms. In fact, with the exception of anxiety, and to a lesser extent depression, we did not find resistant attachment to be a risk factor for severe psychopathology. In our high-quality data set, in which infant attachment was assessed twice and efforts were made to distinguish resistant from disorganized attachment, resistance does not even predict conduct problems (Sroufe et al., 2005a). This is in contrast to avoidant attachment. This does not make the correlation between preoccupied AAI status and borderline symptoms meaningless. It has the importance of any other marker of a disturbed process. But it is an overreach to speak of preoccupied status as a cause of borderline symptoms.

The Place of Attachment in Development

Our understanding that attachment experiences work in concert with other developmental influences raises larger questions about how to conceptualize the place of attachment in the organic process of development. I suggested earlier that attachment provides a foundation for entrée into the peer group, but then peer experiences in turn promote new capacities for social relationships. A “developmental issues” perspective (Breger, 1974; Erikson, 1950/1963; Sander, 1975; Sroufe, 1979) is useful for expanding this observation into a more general framework.

Although they have certain similarities, a developmental issues framework is distinctive from classic stage theories in important ways. First, the series of issues that may be outlined are not tasks to be passed or failed; rather, each issue is negotiated in the continuing process of development. Children evolve patterns of adaptation with respect to any given issue, but regardless of how

well the issue is engaged, one has no choice but to move on to the negotiation of subsequent issues. There is no concept of developmental arrest, nor is a premium placed on age of accomplishment. Moreover, while issues come to the fore in various developmental periods, an issue is not permanently put behind but rather is negotiated further in subsequent phases of life.

There is, of course, an important way in which a developmental issues position is like a stage theory; it is proposed that adaptation with regard to each issue frames in part the person's negotiation of subsequent issues. However, it is also assumed that negotiating a subsequent issue provides an opportunity for reworking all previous issues.

Table 43.2 outlines a proposed series of issues to illustrate this approach. Adaptation builds on the history of functioning in each previous period, while also providing opportunities for transforming previously established adaptations. For example, consider the second issue. This is labeled "Guided Self-Regulation," because toddlers may achieve varying degrees and styles of self-regulation, but they can do so only within guidance and scaffolding provided by caregivers. Adequate regulation—that is, a balance between free expression of desires and containment of impulses and an ability to remain organized in the face of moderate frustration—requires clear, firm support and containment, as well as encouragement, on the part of parents. When parents are unavailable for support, provoke or ridicule the child when he or she becomes frustrated, and/or harshly punish the child for expressions of emotions or impulsive behaviors, various forms of dysregulation are observed. This guided self-regulation process in general proceeds more smoothly when it has been preceded by an effective attachment relationship (or establishment of trust in Erik Erikson's scheme). As research has clearly shown, infants with a secure attachment relationship are more compliant with parental directions (Londerville & Main, 1981; Matas, Arend, & Sroufe, 1978) and even more "committed" to compliance (Kochanska, 1997) and to maintaining a coordinated relationship (Waters, Kondo-Ikemura, & Richters, 1990). Thus, effective attachment, and the experience with dyadic affect regulation and positive expectations regarding caregivers that is part of it, provides the foundation for beginning autonomy and self-control. Those with secure histories have already learned to count on parental availability and know that parents are dependable and therefore will fol-

low through on what they say. Reciprocally, when parents are firm and supportive with toddlers, the child's trust in them is deepened. Some parents, of course, find this developmental period difficult given the child's strong impulses and labile feelings. Even parents who provided a secure base in infancy may be unable to meet the challenges posed by toddlers. So while early attachment provides a foundation for negotiating Phase 2, it does not by itself determine the outcome.

Forecasting the quality of adaptation in Phase 3 is even more complex. The well-adapted preschool child can flexibly adjust behavior to fit requirements of a particular context (run and shout on the playground, sit quietly and be attentive during story time), can direct his or her own activities, can follow rules without constant adult presence, and can effectively engage peers and sustain interactions despite challenges that inevitably arise. These capacities draw on attachment experiences that color the child's attitudes and expectations about self, other, and relationships, and an early pattern of basic affect regulation. But they also draw on the history of more autonomous regulation during Phase 2 and the supports that are currently available. From infancy, some children bring forward a capacity for engaging the object world with curiosity and positive affect. From the toddler period, if it goes well, they bring forward the capacity to stay organized in the face of frustration and a belief that they can cope with challenges. If emotional support remains available and if opportunities are provided, they now manifest a capacity for self-regulation and are attractive play partners, well liked by teachers and children. On the other hand, children who are lacking in feelings of self-worth, who are easily frustrated and dysregulated, who lack empathy or the skills for positive engagement, or are chronically angry, inhibited, or withdrawn, are at a notable disadvantage for engaging the world of preschool. The cumulative nature of development—the way it builds upon itself—helps to account for the strong intercorrelations among competence indices in the preschool period, including sociometric status, self-confidence, dependence–independence, empathy, ego-resilience, self-control, and rule-abiding behavior (e.g., Sroufe, 1983, 2005a). All of these, and other currently in vogue constructs such as "executive function," build on the same preceding core experiences (Bernier, Whipple, & Carlson, 2010).

As was true in Phase 2, strong support in the preschool period can help those with less adequate

TABLE 43.2. Salient Issues of Development

<u>Infancy period</u>

beginnings move toward increased self-regulation capacities and more positive expectations regarding relationships. Our research has shown that those with histories of insecure attachment are better adjusted during the preschool period if social support for parents has increased in the years since infancy (Sroufe et al., 2005a). We also found that supportive preschool teachers can have a positive impact (Sroufe, 1983). Others have shown that social skill may be increased through play with more competent peers (Hartup, 1999). Again, both developmental history and current support play a role in adaptation. New issues are faced within the framework of prior adaptations, yet transformation remains possible, for better or worse.

The process continues in middle childhood. Having expanded the capacity for self-regulation, having had positive experiences in an expanding social world, and having rapidly acquired the skills needed in social interaction, some children are now well prepared for the more complicated world of middle childhood, with its greater academic and social challenges. For many, self-confidence becomes real-world competence, and interactive skill merges into durable, loyal friendships that can be maintained even given the need to function in the larger group. The basic sense of connection from infancy, the impulse control and autonomy from the toddler period, and the self-management capacities from the preschool period are all called upon. Reciprocally, positive social experiences in middle childhood or developing some special talent can enhance self-esteem now and help children become more able social partners.

Adolescence can be the most challenging developmental period of all in modern society. Social demands are extraordinarily complex, with same- and mixed-gender peer groups, same- and mixed-gender friendships, and beginning intimate relationships. Cognitive and physical changes can be both helpful and daunting. For example, the individual now confronts the future in a new way. Though challenging for all, the issues faced here are certainly easier for some. Whereas many teens develop psychiatric problems, many actually flourish. There are no guarantees, of course. However, for some, the foundation for successful negotiation of the issues of adolescence has been laid down every step of the way. The capacity to be vulnerable and to commit in relationships has roots in the trust established in infancy. Autonomy with connectedness already was established once during the toddler phase. Self-regulation (and effec-

tive use of social support) has been practiced since the preschool years. And a sense of competence and mastery was firmly established during the years of middle childhood, along with first experiences of close, durable relationships with agemates.

This developmental perspective certainly highlights many features of experiential support beyond the quality of early attachments. At the same time, infant attachment experiences certainly are not trivialized by this description. Development is a cumulative process, which each phase building on all that has gone before, just like the developing embryo or the developing brain (Stiles, 2008). Therefore, the infant–caregiver attachment relationship, coming as it does at the beginning, is of notable importance. It represents an inner core of an emerging self that, while certainly open to modification, remains an important feature of the developmental landscape.

Goals for the Future

Fifty years ago it was generally accepted in psychology that early experience had little predictive power, that individual characteristics were unstable, and that constructs such as personality might not even be useful. Today we know that early life does leave a lasting legacy, that individual development and behavior are coherent when assessed at an appropriate level of complexity, and that constructs such as personality and attachment not only have validity but are crucial for the field. We also can put aside debates about whether early experience or later experience, or parenting or peer experiences, are more important. We know they are all important, and we know they work together to shape development. Likewise, important progress has been made toward an integrated view of experience and neurophysiology. It is clear that the developing brain is experience-dependent (Stiles, 2008). There is also support for the idea that early experience retains potential for influence even following developmental change, and that representations are the carriers and preservers of early experience. These are monumental achievements, and attachment research has played a vital role in all of this.

What might be important goals for this field going forward? I suggest just four areas that seem of great importance to me. A central theme in all of them is that work in each area would promote our understanding of both attachment and devel-

opment. At the same time, it is important to retain some focus on the core of attachment theory, namely, Bowlby's questions regarding how parent–child interactions influence the nature of the attachment relationships that are formed and how it is that attachment experiences are the foundation for individual differences in personality.

Regarding Bowlby's first question we need more detailed studies regarding exactly what kinds of experience promote later effective secure-base behavior. Ainsworth's Sensitivity Scales, soon to be published in the revision of the classic book (Ainsworth et al., 1978), provide a wealth of ideas about the kind of attunement and responsiveness that are important, but this topic requires a great deal of further exploration. There also are very few data regarding experiences that lead to resistant versus avoidant attachment. A modicum of data suggest that avoidance results from rejection precisely when the infant signals a tender need (e.g., Ainsworth et al., 1978; Isabella, 1993), but the origins of these two patterns—if indeed they are coherent and distinctive—is not really established. Some argue that a security dimension captures what there is in valid individual differences. But if there are distinctive patterns, and if they prove to have distinctive outcomes, this is of great theoretical and practical significance. There are some data supporting different outcomes for avoidant and resistant histories (Sroufe et al., 2005a), but the case is not nearly as strong as it would need to be to conclude that these are distinctive patterns.

A very important developmental question arises from findings concerning the discordance between infant attachment classifications with two parents. In general, studies report significant but moderate concordance between the two classifications (Fox, Kimmerly, & Schafer, 1991; Main & Weston, 1981). Some of the lack of concordance may be due to methodological issues (e.g., including cases in which both parents are not actually attachment figures), but this cannot be the total explanation. Main and Weston (1981), for example, provides information that specific interactive history with the particular parent predicts security and also that considering the two attachments bolsters outcome predictions. Therefore, we can conclude that at least in a substantial number of cases, an infant may be secure with one parent and anxious with another. According to Bowlby's theory, the infant would have two separate working models of attachment. The intriguing question then becomes, how do these disparate models become integrated into a singular state of mind re-

garding attachment, as is suggested to be the case in all of the adult attachment literature (Hesse, 1999, Chapter 26, this volume)? Main's data suggest the possibility that infant attachment status with the more primary figure might hold sway, but other factors have to be involved as well. To date I know of no studies of this truly critical question.

In general, we need to know much more about how attachment experiences combine with other developmental influences, be they child vulnerabilities (however they may arise), other aspects of parenting, or other features of the environment. We know, for example, that insecure infant attachment is a risk factor for various kinds of later problems, but we currently understand little about why one child with a particular attachment history develops one problem, whereas other children with the same early attachment develop different kinds of problems or no psychiatric problems at all. Such an understanding is critical for the field of developmental psychopathology and embodies the hope for a new approach to psychiatric classification. This example also points us to the more general problem of continuity and change, a core issue for all developmental study. We know by now that continuity depends on supports for pathways being followed and that change is lawful, that is, that it can be predicted to some extent. Over periods of time, representations change or behavior changes, and some intervening variable accounts for some of this change. But at this point our knowledge is rather crude, usually based on broadband predictors (e.g., changes in life stress or parental depression). Thus, we have associations between some measure and some indicator of change, but we still know very little about the process of change. We do not even know, for example, whether attachment representations change gradually or quickly, or much about how they change. Do certain kinds of experiences lead to more rapid change and others to gradual change? Is gradual change sustained better? Do changes in representations of partners lead to changes in representations of parents? There are myriad questions about attachment and the process of development.

Finally, it is important to increase research on attachment and the *mind* exponentially. There are many articles and chapters on attachment and the *brain*, and that is a topic for this volume also (see Bretherton & Munholland, Chapter 4, and Coan, Chapter 12, this volume). But little has been written about attachment and the developing mind. With the exception of the connection between unresolved status on the AAI and early trauma

and disorganization, we are not even very far along in understanding the origins and course of adult states of mind regarding attachment. Beyond this, we know little about processes linking attachment experiences and distortions of the mind, including various defensive postures. We know that cognitive skills are rarely impaired in those having histories of insecure attachment, but there is more to the mind than this. There are vast differences in the individual process of finding meaning, and in the meanings individuals make of particular experiences; for example, how it comes to be that the same experience is threatening to some and benign or amusing to others. Perhaps Kahneman's (2011) distinction between fast and slow mental systems is a starting point. The "fast" system, which is intuitive, unreflective, and uncritical (the source of many biases and distortions in thinking and perception), may be more colored by an individual's particular history, especially by trauma and distortions in attachment. Whether this is truly so, the process through which it develops to be this way, and the particular role of attachment in this process, all wait to be discovered.

Attachment theory has proven to be quite robust and generative. Its contributions are apparent in diverse fields of study. Whether it will continue to grow in utility in the future may well hinge on keeping it wed to a developmental perspective, where it was in the beginning.

Subject Index

Page numbers followed by *f* indicate figure; *n*, note; and *t*, table

- Abandonment
 adult attachment and, 615
 couple and family therapy (C&FT) and, 809
 couple therapy and, 813
 divorce and, 942, 953
 romantic relationships and, 442*t*
- Abecedarian study, 987
- Absent mourning, 44. *See also* Mourning
- Abuse
 Adult Attachment Interview (AAI) and, 556
 divorce and, 953
 overview, 699–700
 prior to foster or adoptive care placement, 699–700
 psychopathology in adolescence/young adulthood, 684
 religion and, 927, 933
 unresolved loss and, 674
 See also Childhood maltreatment
- Academic skills and achievement, 952, 969, 970, 1003. *See also* School readiness and adaptation
- Acceptance, 371–372, 829, 893
- Accessibility, 371–372, 513, 887
- Accessory olfactory system, 244. *See also* Olfactory systems
- Accommodation, 66, 899
- Achievement, 354–355, 439. *See also* Academic skills and achievement
- Active behaviors, 96–97. *See also* Behavioral systems
- Actor–partner interdependence model (APIM), 449
- Adaptation
 cross-cultural patterns of attachment and, 853
 development and, 1006–1008, 1007*t*
 early attachment and later development and, 334–335
 evolutionary perspective and, 109–110
 infancy and early childhood and, 367
 internal working models and, 32–33
 loss and, 41–42
 overview, 4–5
 pair bonding and, 416, 422, 427, 428–429
 religion and, 935
 same-sex relationships and, 487–488
 See also Environmental of evolutionary adaptedness (EEA); Evolutionary perspective
- Adjustment
 adolescence and, 409
 Adult Attachment Interview (AAI) and, 577, 607
 bereavement and, 48
 divorce and, 946–947, 951, 953
 family therapy and, 812
 off-diagonal cases and, 50–51, 51*f*
 same-sex relationships and, 498
 school readiness and, 970
 self-report measures of adult attachment and, 620
 temperament and, 212
- Adjustment disorders, 47
- Adolescence
 assessment and, 684–686
 attachment and, 188–189, 400–410
 attachment-based family therapy and, 809–810
 behavioral genetics of attachment and, 157
 couple and family therapy (C&FT) and, 818–819
 depression and, 650, 717, 718
 development and, 410–411, 683–686, 1007–1008, 1007*t*
 divorce and, 950–951
 emotionally attuned communication and, 27–28
 hostile–helpless states of mind and, 676
 individual differences and, 99, 403–410
 inflammation and, 195
 mental health and, 408–410
 nature of attachment during, 350
 overview, 399, 508
 pair bonding and, 425
 parent–child relationships and, 403–406
 peer relationships and, 406–408, 418
 primate models and, 143–145
 prosocial behavior and, 888–891
 religion and, 923, 927
 reparative processes and, 27–28
 same-sex relationships and, 494–495
 self-report measures of adult attachment and, 618–619
 severe or prolonged disruptions and, 29–30
 sexual interactions and, 465–466
 states of mind and disorganized behavior and, 673
- treatments and attachment disruptions and, 35–36
 See also Childhood psychopathology; Middle childhood
- Adolescent Prosocial Behavior Scale (APBS), 889
- Adoption
 adoption triangle, 707
 Adult Attachment Interview (AAI) and, 583
 attachment and, 282, 703–706
 caregiver commitment and, 706
 contact with biological family and, 707–708
 coping with adversity and, 701–702
 epigenetics and, 163
 experiences prior to, 697–701
 gene–environment interactions (G × E) and, 161–162
 interventions to enhance attachment and, 708–710
 lesbian and gay adoption, 990–991
 multiple attachments and, 316–317
 open adoptions, 707–708
 overview, 696–697, 710
 See also Twin studies
- Adrenal cortex, 247
- Adrenocorticotrophic hormone (ACTH), 247
- Adult affiliation, 250. *See also* Affiliation

 administration and training, 588–589
 adolescence and, 401, 404, 407–408, 409, 410–411, 684–685
 adult psychopathology and, 716, 721, 723, 724, 725–726, 726, 728–729, 731
 attachment styles in later life and, 535
 attachment theory and, 1001, 1005
 avoidant attachment and, 525
 behavioral genetics of attachment and, 157
 borderline personality disorder and, 792
 categories, 556–561
 child attachment status and, 578–581
 childhood psychopathology and, 647
 comparing clinical and nonclinical populations and, 581–583
 cross-cultural patterns of attachment and, 861, 863–864, 865
 developmental psychopathology and, 667–668

- disorganized attachment behavior in
 infancy and, 670, 673
- divorce and, 951
- earned or evolved security and,
 570–575
- emotional experiences and, 522–524,
 523, 526
- empirical studies involving, 575–588
- epigenetics and, 163
- foster or adoptive care placement and,
 704
- genetics and, 586–588
- history of, 553–556, 554*t*
- identifying and differentiating
 emotions and, 525
- infancy and early childhood and, 380,
 382
- internal working models and, 33
- intervention studies, 583–584
- life history theory (LHT) and, 104
- longitudinal studies, 584–585
- Main–Cassidy attachment
 classification for kindergarten-age
 children and, 379
- neuroscience and, 586–588
- organized categories of, 561–570,
 564*t*, 566*t*–567*t*, 569*t*
- overview, 508, 588, 602–608,
 625–626, 761, 762
- parental relationship and, 305
- patient's attachment organization or
 style in psychotherapy, 764–765,
 768
- predicting caregiving quality and, 834
- prevention and intervention programs
 and, 743, 744
- properties of, 577–578
- prosocial behavior and, 888, 889
- protocol for, 554*t*, 555, 556–561
