About the Editors

Jude Cassidy, PhD, is Distinguished Scholar-Teacher and Professor of Psychology at the University of Maryland, College Park, and Director of the Maryland Child and Family Development Laboratory. Her research interests include socioemotional development from infancy through adolescence, with an emphasis on attachment and family relationships; social, cognitive, and regulatory mechanisms through which children's early family experiences come to influence later well-being and relationships; and early intervention designed to reduce the risk of insecure attachment and mental disorders. Her research has been funded by the National Institute of Mental Health, the National Institute of Child Health and Human Development, the National Institute on Drug Abuse, the Substance Abuse and Mental Health Services Administration, and the Zanvyl and Isabelle Krieger Fund. Dr. Cassidy serves as coeditor of the journal *Attachment and Human Development* and is on the editorial boards of *Journal of Clinical Child and Adolescent Psychology* and *Infant Mental Health Journal*. She is a Fellow of the Association for Psychological Science (APS) and the American Psychological Association (APA), and is a recipient of the Boyd R. McCandless Young Scientist Award from APA Division 7 (Developmental Psychology).

Phillip R. Shaver, PhD, is Distinguished Professor Emeritus of Psychology at the University of California, Davis. He has published several books and over 250 journal articles and book chapters. Dr. Shaver's research focuses on attachment, human motivation and emotion, close relationships, personality development, and the effects of meditation on behavior and the brain. He is a Fellow of both the APA and the APS, and has served as executive officer of the Society of Experimental Social Psychology (SESP) and as president of the International Association for Relationship Research (IARR). Dr. Shaver is a recipient of Distinguished Career Awards from the SESP, the IARR, and the Society for Personality and Social Psychology, and an honorary doctorate from the Faculty of Social Sciences at the University of Stockholm, Sweden.

Preface

It seems unlikely that either John Bowlby, when he first wondered about the relation between maternal deprivation and juvenile delinquency, or Mary Ainsworth, when she answered an advertisement in a London newspaper to work as a postdoctoral researcher with Bowlby, dreamed for a moment that their theoretical efforts would spawn one of the broadest, most profound, and most creative lines of research in 20th- and 21st-century psychology. Yet that is exactly what happened. Anyone who conducts a literature search on the topic of “attachment” will turn up more than 30,000 entries that have appeared since the beginning of 1975 (three times the number we discovered when preparing the 2008 second edition of this volume). And the entries are spread across scores of physiological, clinical, developmental, and social psychology journals; medical and social work journals; and authored books and edited anthologies. The literature spans everything from the prenatal period to old age and considers all kinds of relationships: parent–child, sibling, friendship, teen romance, and adult sexual.

In the study of social and emotional development, attachment theory is the most visible and empirically grounded conceptual framework guiding today’s research. In the growing clinical literature on the effects of early parent–child relationships, including troubled and abusive relationships, attachment theory is prominent. In the rapidly expanding field of research on close relationships in adolescence and adulthood—including the study of romantic, marital, or “pair-bond” relationships, and their formation, maintenance,

and dissolution—attachment theory is one of the most influential theoretical approaches, as it also is in the field of couples counseling. Among researchers who study bereavement, Bowlby’s volume on loss is a continuing source of insight and intellectual inspiration.

Attachment theory is one of the best examples of the value of deep, coherent theorizing in contemporary psychology. It is a model of the process by which scientists move back and forth between clear conceptualizations and penetrating empirical research, with each pole of the dialectic influencing the other over an extended period of time. Attachment theory today is in many respects similar to attachment theory 40 years ago, but it has become much more specific, more multifaceted, and more deeply anchored in a wide variety of powerful research methods, including new ones such as behavioral genetics and functional magnetic resonance imaging. Because the theory was remarkably insightful and accurate from the beginning, and because Ainsworth was such an effective researcher, the initial studies inspired by the theory were largely supportive of the theory’s basic ideas, but they were also surprising and provocative in certain respects. The theory encountered considerable criticism at first, as any new scientific theory should. Yet the many honors accorded to Bowlby and Ainsworth toward the ends of their careers symbolize the considerable respect their work now engenders. The present volume is further testimony to the lasting nature of their impressive contributions to psychological science.

One problem created by the enormous literature on attachment, and by attachment theory's continual evolution in the light of new research, is that few scholars, researchers, and clinicians are familiar with the entire body of work. In order to make optimal use of the theory as a researcher, clinician, or teacher, one has to know what Bowlby and Ainsworth originally said; what subsequent research has revealed; what measures of attachment have been developed and what they measure; and what recent theoretical and empirical developments contribute to our overall understanding of attachment relationships and personality development. The purpose of this third edition of the *Handbook of Attachment* is to satisfy these important professional needs. The book will prove useful to anyone who studies attachment processes, uses attachment theory in clinical work, or teaches courses and seminars that touch on, or focus on, attachment. It will be an excellent single resource for courses devoted to attachment theory and research. It will also be of great interest to anyone in the general public who wishes to think more effectively about close relationships of all kinds.

The first edition of the *Handbook*, published in 1999, was extensively read, frequently cited, and influential in affecting research and clinical applications of attachment theory and research. We were deeply gratified by the field's response to the volume, which inspired everything from graduate seminars and clinical discussion groups to theoretical debates, major new research programs, and systematic tests of clinical interventions. It helped spawn a much more diverse and deeply probing research field. The second edition of the *Handbook*, published in 2008, had the same effect, and its influence grew as attachment research and its clinical applications became better known internationally. The theory's influence is now evident all over the world, and its literature includes publications in many different languages. Because psychology and psychiatry have moved energetically in the directions of neuroscience, psychophysiology, and behavioral genetics, there are many new findings to incorporate into an expanded attachment theory. And because federal granting agencies have become increasingly interested in "translational" research—research that moves basic research findings more quickly into the realm of clinical and community applications—there is a great deal of new information about intervention procedures and outcomes.

As volume editors, we have dealt with the many new developments in two ways. First, we

have added new chapters to reflect the changing nature of the field. In 2008, new additions to the second edition included chapters on social neuroscience, affect regulation, attachment in the middle childhood years, foster care, divorce, and attachment in an aging population. In this third edition, we have retained and updated those chapters while commissioning additional new ones on attachment, genetics, and epigenetics; attachment and psychoneuroimmunology; attachment and sexual mating; attachment and empathy, altruism, and prosocial behavior; and attachment and school readiness. The volume ends with a brilliant overview and evaluation of the field, "The Place of Attachment in Development," by a distinguished attachment-research pioneer, L. Alan Sroufe.

Second, we charged the authors of previously included chapters, as well as new authors who have taken over territories covered by previous chapters, with a specific task. We asked authors to specifically describe the current state of theory and research *in comparison to that outlined in the earlier chapter*. We asked: Have new conceptualizations emerged? Have former conceptualizations dropped by the wayside? Why? Have connections with other areas of research provided new insights? What empirical progress has been attempted and made? If little progress has been made, why? In short, in the earlier editions, we portrayed "the state of the field." Now that we are on our third edition, an important goal is to present, in addition to the current state of the field, an overview of how the field has changed, stagnated, shifted, provided insights, opened up new questions, borrowed, fallen short, or failed—along with providing some guidance concerning how best to help the field move even further forward.

Part I, "Overview of Attachment Theory," provides an updated primer on the theory. The first two chapters correspond roughly to the first and second volumes of Bowlby's seminal trilogy, *Attachment and Loss*. In Chapter 1, "The Nature of the Child's Ties," Jude Cassidy explains the central construct of attachment theory, first expounded by Bowlby in the first volume of *Attachment and Loss*. In Chapter 2, "Attachment Disruptions, Reparative Processes, and Psychopathology," Roger Kobak, Kristyn Zajac, and Stephanie D. Madsen explain topics that Bowlby addressed in *Separation: Anxiety and Anger*, the second volume of his trilogy. In Chapter 3, "Attachment, Loss, and Grief: Bowlby's Views, New Developments, and Current Controversies," R. Chris Fraley and Philip R. Shaver discuss theory and research related to

topics addressed by Bowlby in the third volume of *Attachment and Loss*. Chapter 4, by Inge Bretherton and Kristine A. Munholland, deals with a core construct in attachment theory: internal working models. In this new version of their chapter, “The Internal Working Model Construct in Light of Contemporary Neuroimaging Research,” the authors focus on contributions from cognitive and affective neuroscience, scientific fields that have grown enormously in prominence during the past decade.

Part II, “Biological Perspectives,” begins with Chapter 5, by Jeffrey A. Simpson and Jay Belsky, “Attachment Theory within a Modern Evolutionary Framework.” Bowlby valued evolutionary theory and the associated ethological approach to animal research, from which he borrowed extensively—to the chagrin of some of his British psychoanalytic colleagues. This is one of several ways in which he was ahead of his time (the emphasis on cognitive “internal working models” being another). Chapter 6, by H. Jonathan Polan and Myron A. Hofer, is titled “Psychobiological Origins of Infant Attachment and Its Role in Development.” The pioneering rodent research that Hofer and his colleagues conducted over a period of decades shows that regulation of basic bodily processes in infants is multidimensional, meaning that the “attachment system” initially conceptualized by Bowlby as a single, unified system can be characterized in much greater detail.

Adding to these insights from animal research is Chapter 7, by Stephen J. Suomi, “Attachment in Rhesus Monkeys.” Bowlby and Ainsworth’s theorizing about human attachment processes was strongly influenced by primate researchers, and their perspective continues to bear fruit. In recent years, Suomi and other researchers have included in their work research on epigenetic changes related to care received from parents, offering new ways to understand the long-range effects of early social experiences on later physical and psychological health (addressed throughout this volume).

Chapters 8 and 9 are new to the *Handbook*. Chapter 8, “Attachment, Parenting, and Genetics,” by Marian J. Bakersman-Kranenburg and Marinus H. van IJzendoorn, delves further into the ideas raised by Suomi, with special emphasis on human genetics, epigenetics, and effects of early experiences with caregivers. In Chapter 9, “Attachment and Psychoneuroimmunology,” Katherine B. Ehrlich, Gregory E. Miller, Jason D. Jones, and Jude Cassidy explore connections between the quality of care one receives in at-

tachment relationships and subsequent immune functioning.

In Chapter 10, “Attachment and Temperament as Intersecting Developmental Products and Interacting Developmental Contexts Throughout Infancy and Childhood,” Brian E. Vaughn and Kelly K. Bost discuss the complex relations between attachment, viewed primarily as affected by social experiences, and temperament, viewed primarily as a product of genes and psychobiology. In Chapter 11, “Studying the Biology of Human Attachment,” Amie A. Hane and Nathan A. Fox describe both well-established and recently developed methods for studying attachment-related psychobiological processes. One of the recent methods, functional magnetic resonance imaging, is then described in much more detail in Chapter 12, by James A. Coan, “Toward a Neuroscience of Attachment.” Coan explains social baseline theory, a companion for attachment theory that focuses on the human brain’s tendency to treat social connectedness, rather than independence, as a default state.

Part III of the volume, “Attachment in Infancy and Childhood,” addresses the age periods that were the original focus of Bowlby’s theorizing and Ainsworth’s seminal research methods and findings. In Chapter 13, “Normative Development: The Ontogeny of Attachment in Childhood,” Robert S. Marvin, Preston A. Britner, and Beth S. Russell explain the species-typical development of human attachments over the first few years of life. As attachment theory has become popular worldwide and inspired scores of new measures and research streams, an increasingly small proportion of researchers know the details of the developmental processes at the heart of the theory. Marvin and colleagues provide an excellent starting point for anyone wishing to understand the early development of attachment. Chapter 14, “Precursors of Attachment Security,” by R. M. Pasco Fearon and Jay Belsky, reviews the extensive body of research on the early determinants of security and insecurity. In Chapter 15, “Attachment Relationships in the Context of Multiple Caregivers,” Carollee Howes and Susan Spieker explain what is known about the attachment-related effects of having multiple caregivers, an issue that became increasingly controversial as more women in developed societies entered the workforce. Howes and Spieker show that there is no simple answer to the question of whether early day care is “good” or “bad” for children. The answer depends on the quality of care and its temporal extent.

Among Bowlby’s main concerns were the

long-term effects of early attachment-related experiences on later personality development and long-term life outcomes. In Chapter 16, "Early Attachment and Later Development: Reframing the Questions," Ross A. Thompson explains what is known about early attachment and subsequent development. The "reframing" referred to in the chapter subtitle includes different ways of characterizing internal working models, taking continuity of sensitive or insensitive care into account, considering biological/health effects of attachment, and exploring the connections among attachment, emotions, emotion understanding, and emotion regulation.

Because Bowlby and Ainsworth focused mainly on attachment in infancy, it took some time for researchers to redirect attention to the nature and fate of attachment processes in middle childhood. That is the subject of Chapter 17, "Attachment in Middle Childhood," by Kathryn A. Kerns and Laura E. Brumariu. They show that although relations with peers become increasingly important, parents remain the principal attachment figures, even though children become more active participants in the parent-child relationship. The authors also discuss the continuing lack of resolution concerning how to measure attachment during middle childhood. The last chapter in Part III, Chapter 18, "The Measurement of Attachment Security and Related Constructs in Infancy and Early Childhood," by Judith Solomon and Carol George, deals with the extremely important issue of measurement. When Bowlby was beginning his theoretical journey as a young psychoanalyst, he was part of a psychoanalytic milieu in which several key theorists, such as Anna Freud and Donald Winnicott, were concerned with social aspects of mental development in infancy. Although they, like Bowlby, had interesting ideas based on clinical observations of children, they did not have anyone to operationalize and test those ideas empirically. By collaborating with Ainsworth, a creative and well-trained researcher, Bowlby benefited from the huge volume of scientific information being built upon Ainsworth's early work. In 1982, he revised the 1969 first volume of his attachment trilogy in light of new data. Today, attachment theory is much more firmly anchored in psychological science than the observations and insights of Bowlby's psychoanalytic peers, thanks largely to the measures described in this chapter.

Part IV, "Attachment in Adolescence and Adulthood," deals with age periods in which there has been a huge explosion of research in recent

years. This growth is indicated by the large number of chapters in this part, including a new one on attachment and sexuality. Chapter 19, "The Multiple Facets of Attachment in Adolescence," by Joseph P. Allen and Joseph Tan, covers the rise of research on adolescent attachment to parents and peers. As adolescents strive to attain greater autonomy from parents while continuing to rely on parents as a safe haven and secure base, many interesting issues come to the surface, and these have been the focus of fascinating new research. Adolescents have increasingly complex and important relationships with peers, including in many cases romantic/sexual relationships. The notion that romantic or marital relationships involve attachment was somewhat controversial when it first began to attract attention in the late 1980s. In Chapter 20, Debra M. Zeifman and Cindy Hazan consider "Pair Bonds as Attachments: Mounting Evidence in Support of Bowlby's Hypothesis," concluding that romantic relationships definitely qualify as attachment relationships. Their chapter leads smoothly into Chapter 21, "Adult Romantic Attachment: Developments in the Study of Couple Relationships," by Judith A. Feeney. She explains how the concepts of attachment and attachment relationships have inspired a monumental growth of attachment research in social and personality psychology over the past 30 years. Chapter 22, "Attachment and Sexual Mating: The Joint Operation of Separate Motivational Systems," by Gurit E. Birnbaum, summarizes this growing topic area. Because psychological scientists, like society more generally, have become aware of and interested in same-sex relationships, the study of attachment has been extended into that domain. In Chapter 23, "Same-Sex Romantic Attachment," Jonathan J. Mohr and Skyley D. Jackson summarize and comment on this research area.

Social/personality researchers who study adult attachment have been concerned with one of the key issues in attachment theory more generally: emotion regulation. Delving into this topic area allows attachment researchers to use a wide variety of methods developed by scholars who study social cognition and emotions, as well as the methods of cognitive and affective neuroscience. Mario Mikulincer and Phillip R. Shaver review the extensive recent research in Chapter 24, "Adult Attachment and Affect Regulation." Just as attachment research was gradually extended from infancy to middle childhood, adolescence, and early adulthood, it is now being pursued in studies discussed in Chapter 25, "Attachment in

Middle and Later Life,” by Carol Magai, María Teresa Frías, and Phillip R. Shaver. This topic area is likely to become much more active as large proportions of the adult populations of industrialized countries move into old age.

As already mentioned, the early science of infant–parent attachment depended heavily on Ainsworth’s creation of new measuring instruments. As research was extended into adolescence and adulthood, new measures were needed and created. One of the most influential approaches is discussed in Chapter 26, “The Adult Attachment Interview: Protocol, Method of Analysis, and Empirical Studies: 1985–2015,” by Erik Hesse. The AAI and a host of alternative measures, including many that use self-report questionnaires, are further examined by Judith A. Crowell, R. Chris Fraley, and Glenn I. Roisman in Chapter 27, “Measurement of Individual Differences in Adult Attachment.” These two chapters are must-reads for anyone wishing to conduct studies of adult attachment and related issues.

Although attachment theory is not a theory of psychopathology per se, and does not characterize insecure attachment as a form of psychopathology, many connections exist between attachment insecurity and vulnerability to psychopathology, whether mild or severe. Thus, Part V of this volume is titled “Psychopathology and Clinical Applications.” Chapter 28, by Michelle DeKlyen and Mark T. Greenberg, deals with “Attachment and Psychopathology in Childhood.” When Ainsworth created her Strange Situation procedure for coding various forms of infant–parent attachment, she designated three main patterns. Later, Main and Solomon added a fourth category, labeled “disorganized/disoriented,” now usually abbreviated as “disorganized.” Karlen Lyons-Ruth and Deborah Jacobvitz summarize the fascinating literature in Chapter 29, “Attachment Disorganization from Infancy to Adulthood: Neurobiological Correlates, Parenting Contexts, and Pathways to Disorder.” For anyone interested in links between attachment and psychopathology, or the treatment of psychopathology, this chapter is crucial.

Not every infant or young child is raised by a biological mother, as was the case in the sample that Ainsworth and her colleagues studied in the early days of attachment research. Some children are raised by someone other than a biological parent. In Chapter 30, Mary Dozier and Michael Rutter discuss “Challenges to the Development of Attachment Relationships Faced by Young Children in Foster and Adoptive Care.” Chapter 31,

in parallel with Chapter 28 on attachment and psychopathology in childhood, focuses on “Attachment States of Mind and Psychopathology in Adulthood” and was written by K. Chase Stovall-McClough and Mary Dozier. Because so much is now known about parenting influences on early attachment, there are a number of well-designed and carefully evaluated programs, discussed in Chapter 32, “Prevention and Intervention Programs to Support Early Attachment Security: A Move to the Level of the Community,” by Lisa J. Berlin, Charles H. Zeanah, and Alicia F. Lieberman. In Chapter 33, “Attachment and Adult Psychotherapy: Theory, Research, and Practice,” Arietta Slade explains how knowledge of attachment theory and research can guide psychotherapy. In Chapter 34, “Reconciling Psychoanalytic Ideas with Attachment Theory,” Peter Fonagy, Patrick Luyten, Elizabeth Allison, and Chloe Campbell explain the historical and contemporary relations between psychoanalytic approaches and attachment theory, including current integrations in which attachment theory is viewed much more favorably by psychoanalysts than it was during Bowlby’s lifetime. In Chapter 35, “Couple and Family Therapy: An Attachment Perspective,” Audrey Brassard and Susan M. Johnson explain how attachment theory has been incorporated into influential contemporary approaches to couple counseling.

Part VI, “Systems, Culture, and Context,” provides a sampling of the many other topic areas into which attachment theory and research have been extended. In a new chapter for this edition, Chapter 36, “Caregiving,” Brooke C. Feeney and Susan S. Woodhouse explain how attachment theory’s construct of the “caregiving behavioral system” is proving useful in the study of relationships of many kinds. Chapter 37, “Cross-Cultural Patterns of Attachment: Universal and Contextual Dimensions,” by Judi Mesman, Marinus H. van IJzendoorn, and Abraham Sagi-Schwartz, explores the important issue of cross-cultural similarities and differences in attachment relationships and dynamics. In Chapter 38, another new chapter created for this edition, “A Lifespan Perspective on Attachment and Care for Others: Empathy, Altruism, and Prosocial Behavior,” Phillip R. Shaver, Mario Mikulincer, Jacquelyn T. Gross, Jessie A. Stern, and Jude Cassidy review the large and growing literature linking attachment security with caring feelings and behavior across the lifespan. In Chapter 39, “Attachment and Religious Representations and Behavior,” Pehr Granqvist

and Lee A. Kirkpatrick show how the concept of attachment fits with religious notions of reliance on a personal god, and how individual differences in attachment, assessed with both interviews and questionnaires, relate to differences in religious conceptions and experiences.

Divorce, an important form of separation and loss, was not explored in detail by Bowlby and Ainsworth, but has become increasingly important as it has become more common. This kind of separation and loss is examined in Chapter 40, "Divorce through the Lens of Attachment Theory," by Brooke C. Feeney and Joan K. Monin. In Chapter 41, "Attachment and School Readiness," new to this edition, Amanda P. Williford, Lauren M. Carter, and Robert C. Pianta show that school readiness is not simply a matter of cognitive or academic preparation, but instead depends heavily on skills linked to the kind of security that attachment researchers study. Finally, Michael Rutter and Camilla Azis-Clauson discuss, in Chapter 42, "Implications of Attachment Theory and Research for Child Care Policies," the ways in which attachment theory and research could and should affect social policy.

Part VII, "Perspectives on Attachment," contains a single conceptual analysis by L. Alan Sroufe, "The Place of Attachment in Development." This chapter summarizes the many accomplishments of attachment theorists and researchers, evident in the previous chapters, but also raises some concerns. Says Sroufe, "Like any major theory in the social sciences, with success come certain hazards. These include overextensions of the theory (thinking it can explain everything, including things for which it was not designed), misunderstanding and misapplication, and even complacency" (p. 997). We are grateful to have this senior and highly awarded researcher cap the volume with important ideas for future consideration, research, and applications. As the research extends in new directions and raises new issues for consideration, we assume that the theory will continue to evolve in complexity and usefulness.

Acknowledgments

As can be discerned from its heft, this handbook is huge in scope, with thousands of references, including hundreds that are new to this edition. It has taken many talented people's time and dedication to bring it to fruition. Our first thanks go to the international cast of chapter authors—busy

people all—who agreed not only to write for the volume, but also to tailor their chapters to our specific needs. As you will see, the chapters are not like ones in the usual anthologies, in which authors simply spell out their own ideas and research programs without much regard for what other authors in the same volume are saying. Here, each author or set of authors looks seriously at the history of the area under discussion and explains how work in that area is progressing, what new conclusions are being drawn, and how the work might be applied. In many places, the authors refer to other chapters in the volume, making it easier to see how different topics are connected. Many of the chapters were vetted by colleagues, and all were carefully commented upon and edited by both of us. Several of the chapters went through multiple drafts. The chapter authors, all people with considerable experience and very high standards, were remarkably cooperative with our editorial plans and interventions. The book is unusually approachable, readable, and understandable as a result.

We had wonderful assistance from the professionals at The Guilford Press. Seymour Weingarten, Editor-in-Chief, helped conceptualize the first edition and get us involved with it; he then remained incredibly supportive, patient, and enthusiastic throughout the process of creating the second and third editions. C. Deborah Laugh-ton, Judith Grauman, and Carolyn Graham were enormously helpful on a daily basis, responding quickly and helpfully to our many queries. We were fortunate in having Marie Sprayberry serve as our copyeditor for the previous two editions, and thank Jacquelyn Coggin this time around. Laura Specht Patchkofsky was our multitalented production editor. Paul Gordon designed a lovely cover. Deanna Butler composed a very detailed subject index. Behind the scenes of any large and long effort such as this one, there are scores of other professionals who quietly do excellent work without ever personally meeting the beneficiaries of their labor. We thank them, sincerely, as a group.

We are also extremely grateful to our families. In the preface to the first edition of the *Handbook*, we noted that we had both become first-time parents while editing that initial volume; we now note that we have both become first-time parents of college students while editing this current edition. It's not easy to study and write about attachment day after day while telling your own family members that you'll be with them in a while, when

urgent editorial tasks are finished. The contradiction between sensitivity and responsiveness to chapter authors and sensitivity and responsiveness to loved ones at home is palpable. Certainly it is enlightening and personally gratifying for people who study attachment to experience its ramifications in everyday life.

Finally, we wish to thank each other. Collaborating on a large project like this is somewhat like running a family business. It requires open, honest communication about both shared and divergent opinions. Over the years of working on three editions of this book, we have been guests in each other's homes; eaten some great conference meals together; discussed every chapter in great detail; and begun to collaborate on research, not just on book editing. It's rare for two professors at universities thousands of miles apart to sustain such a good and deep working relationship, especially

when we come from different parts of psychology and conduct different kinds of research. Sharing conceptual and editing problems, thoughts about attachment theory and research, computer screens in different cities, and reactions to the book as it developed has been extremely rewarding. We heartily congratulate and thank each other.

As we did with the first edition, we dedicate this volume to the memories of John Bowlby and Mary Ainsworth. They not only had great ideas, which they were able to transform into excellent research; they provided a model of how people can work together to create a large intellectual edifice that has many beneficial consequences for other professionals and for the people whose lives they work to improve.

PART I

OVERVIEW OF ATTACHMENT THEORY

Chapter I

The Nature of the Child's Ties

Jude Cassidy

John Bowlby's work on attachment theory can be viewed as starting shortly after his graduation from Cambridge University, with the observations he made when working in a home for maladjusted boys. Two boys, both of whom had suffered disruptions in their relationships with their mothers, made important impressions on him. Bowlby's more systematic retrospective examination, published over a decade later as "Forty-Four Juvenile Thieves: Their Characters and Home Life" (Bowlby, 1944), as well as the observations of others (Bender & Yarnell, 1941; Goldfarb, 1943), convinced him that major disruptions in the mother-child relationship are precursors of later psychopathology. Bowlby's observations led not only to his belief that the child's relationship with the mother is important for later functioning, but also to a belief that this relationship is of critical immediate importance to the child. Bowlby, along with his colleague James Robertson, observed that children experienced intense distress when separated from their mothers, even if they were fed and cared for by others. A predictable pattern emerged—one of angry protest followed by despair (Robertson & Bowlby, 1952). Bowlby came to wonder why the mother is so important to the child.

At the time, the two widely accepted theories that offered explanations for the child's tie to the mother were both secondary drive theories. Psychoanalytic and social learning theorists alike proposed that an infant's relationship with the mother emerges because she feeds the infant

(e.g., Freud, 1910/1957; Sears, Maccoby, & Levin, 1957), and that the pleasure experienced upon having hunger drives satisfied comes to be associated with the mother's presence. When Bowlby was first developing attachment theory, he became aware of evidence from animal studies that seriously called this perspective into question. Lorenz (1935) noted that infant geese became attached to parents—even to objects—that did not feed them. Harlow (1958) observed that infant rhesus monkeys, in times of stress, preferred not the wire mesh "mother" that provided food, but the cloth-covered "mother" that afforded contact comfort. Soon systematic observations of human infants were made, and it became evident that babies too became attached to people who did not feed them (Ainsworth, 1967; Schaffer & Emerson, 1964). Years later, Bowlby recalled that

this [secondary drive] theory did not seem to me to fit the facts. For example, were it true, an infant of a year or two should take readily to whomever feeds him, and this clearly is not the case. But, if the secondary drive dependency theory was inadequate, what was the alternative? (1980b, p. 650)

Because he found himself dissatisfied with traditional theories, Bowlby (1969/1982) sought a new explanation through discussion with colleagues from fields such as evolutionary biology, ethology, developmental psychology, cognitive science, and control systems theory. He drew on all

of these fields to formulate the innovative proposition that the mechanisms underlying the infant's tie to the mother originally emerged as a result of evolutionary pressures. For Bowlby, this strikingly strong tie, evident particularly when disrupted, results not from an associational learning process (a secondary drive), but rather from a biologically based desire for proximity that arose through the process of natural selection. Bowlby (1958, 1960a, 1960b) introduced attachment theory in a series of papers, the first of which was "The Nature of the Child's Tie to His Mother." All of the major points of attachment theory were presented there in at least rudimentary form, providing, as Bretherton (1992) noted, "the first basic blueprint of attachment theory" (p. 762). These ideas were later elaborated in Bowlby's trilogy, *Attachment and Loss* (1969/1982, 1973, 1980a).

A member of Bowlby's research team during this period of initial formulation of attachment theory was a developmental psychologist visiting from Canada, Mary Salter Ainsworth. Her serendipitous connection with Bowlby—a friend had shown her a newspaper advertisement for a developmental research position—proved fortunate for the development of attachment theory. Ainsworth conducted two pioneering naturalistic observation studies of mothers and infants in which she applied the ethological principles of attachment theory as a framework. One of these investigations was conducted in the early 1950s in Uganda; the other was carried out in the early 1960s in Baltimore. These inquiries provided the most extensive home observation data to date and laid the foundation for Ainsworth's contributions to attachment theory, as well as for Bowlby's continued formulations. Ainsworth later created an assessment tool, the "Strange Situation," that triggered the productive flowering of the empirical study of individual differences in attachment quality—the research that is largely responsible for the place of attachment theory in contemporary psychology and psychiatry.

This chapter summarizes Bowlby's initial ethological approach to understanding the child's tie to the mother, along with elaborations based on more recent research and theorizing. First, I discuss the biological bases of attachment, describing the evolutionary roots of attachment behavior, the attachment behavioral system and its organization, the role of context in the system's operation, the role of emotion, the role of cognition, and individual differences in attachment. Second, I examine

the attachment system in relation to other behavioral systems: the exploratory, fear, sociable, and caregiving systems. Third, I consider the nature of the child's attachment bond to the people to whom he or she is attached (Bowlby called these people "attachment figures"), and describe how attachments differ from other affectional bonds. Finally, I discuss multiple attachments. Although Bowlby's idea that attachment is a lifespan phenomenon was present in his earliest writings (e.g., 1956), as was the idea that people other than the mother often serve as attachment figures (1958), his principal focus was the tie to the mother during childhood, and I maintain that focus in this chapter (but see my discussion of multiple attachments later in this chapter).

Biological Bases of Attachment Behavior

The most fundamental aspect of attachment theory is its focus on the biological bases of attachment behavior (Bowlby, 1958, 1969/1982). *Attachment behavior* has the predictable outcome of increasing proximity of the child to the attachment figure (usually the mother). Some attachment behaviors (smiling, vocalizing) are signaling behaviors that alert the mother to the child's interest in interaction, and thus serve to bring her to the child. Other behaviors (crying) are aversive and bring the mother to the child to terminate them. Some (approaching and following) are active behaviors that move the child to the mother.

An Evolutionary Perspective

Bowlby proposed that during the time in which humans were evolving substantially (he called this "the environment of evolutionary adaptedness"), genetic selection favored attachment behaviors because they increased the likelihood of child–mother proximity, which in turn increased the likelihood of protection and provided survival advantage. In keeping with the evolutionary thinking of his time, Bowlby emphasized survival of the species in his earliest theoretical formulations. By the time he revised *Attachment* (Volume 1 of his trilogy, *Attachment and Loss*; Bowlby, 1969/1982), he noted that advances in evolutionary theory included the understanding that for all behavioral systems, including attachment, "the ultimate out-

come to be attained is always the survival of the genes an individual is carrying" (p. 56). (For a more extensive discussion of attachment and this notion of "reproductive fitness," see Simpson & Belsky, Chapter 5, this volume.)

In the environment of evolutionary adaptedness, infants who were biologically predisposed to stay close to their mothers were less likely to be killed by predators, and it was for this reason that Bowlby referred to protection from predators as the "biological function" of attachment behavior. Because of this biological function of protection, Bowlby considered infants to be predisposed particularly to seek their attachment figures in times of threat or distress. In a basic Darwinian sense, then, the proclivity to seek proximity is a behavioral adaptation in the same way that a fox's white coat on the tundra is an adaptation. As Bowlby (1988) noted in his final collection of lectures, later revisions of evolutionary theory make the notion of a "principal" biological function (i.e., Bowlby's initial selection of protection) unnecessary; the multiple benefits of attachment (e.g., feeding, learning about the environment, self-regulation, social interaction) all contribute to its conveying an evolutionary advantage. Within this framework, attachment is considered a normal and healthy characteristic of humans throughout the lifespan, rather than a sign of immaturity that needs to be outgrown.

The Attachment Behavioral System

Attachment behaviors are thought to be organized within an "attachment behavioral system." Bowlby (1969/1982) borrowed the behavioral system concept from ethology to describe a species-specific system of behaviors that leads to certain predictable outcomes, at least one of which contributes to survival and reproductive fitness. The concept of behavioral systems involves inherent motivation. There is no need to view attachment as the by-product of any more fundamental processes or "drive," and children are thought to become attached to individuals irrespective of whether their physiological needs are met. This idea, as already mentioned, is supported by evidence indicating that in contrast to what secondary drive theories lead one to expect (e.g., Freud, 1910/1957; Sears et al., 1957), attachment is not a result of associations with feeding (Ainsworth, 1967; Harlow, 1962; Schaffer & Emerson, 1964). Furthermore,

findings that infants become attached even to abusive mothers (Bowlby, 1956) suggest that the system is not driven simply by pleasurable associations. Bowlby's notion of the inherent motivation of the attachment system is compatible with Piaget's (1954) formulation of the inherent motivation of the child's interest in exploration.

Central to the concept of the attachment behavioral system is the notion that several attachment behaviors are organized within the individual in response to a particular history of internal and external cues. Sroufe and Waters (1977) emphasized that the attachment behavioral system is "not a set of behaviors that are constantly and uniformly operative" (p. 1185). Rather, the "functional equivalence" of behaviors is noted, with a variety of behaviors having similar meanings and serving similar functions. As Bowlby (1969/1982) noted, "whether a child moves toward a mother by running, walking, crawling, shuffling or, in the case of a thalidomide child, by rolling, is thus of very little consequence compared to the set-goal of his locomotion, namely proximity to mother" (p. 373). The behaviors chosen in a particular context are the ones the infant finds most useful at that moment and with that caregiver. With development, the child gains access to a greater variety of ways of achieving proximity and learns which ones are most effective in which circumstances. Indeed, as Sroufe and Waters pointed out, this organizational perspective helps to explain stability within the context of both developmental and contextual changes. Thus, an infant may maintain a stable internal organization of the attachment behavioral system in relation to the mother over time and across contexts, yet the specific behaviors used in the service of this organization may vary greatly. For example, whereas a nonmobile infant may be expected to cry and reach out to the mother for contact, a mobile child may achieve the same goal of establishing contact by crawling or toddling after her.

This emphasis on the organization of the attachment behavioral system also helps to explain its operation in a "goal-corrected" manner. Unlike certain reflexes that, once activated, maintain a fixed course (e.g., sneezing, rooting), the attachment behavioral system enables the individual to respond flexibly to environmental changes while attempting to attain a goal. Bowlby used the analogy of a heat-seeking missile: Once launched, the missile does not remain on a preset course; rather, it incorporates information about changes in the

target's location and adjusts its trajectory accordingly. Similarly, the infant is capable of considering changes in the mother's location and behavior (as well as other environmental changes) when attempting to maintain proximity to her. And the flexible use of a variety of attachment behaviors, depending on the circumstances, affords the infant greater efficiency in goal-corrected responses. For instance, an infant may see the mother starting to leave in an unfamiliar environment and may desire to increase proximity to her. The infant may begin by reaching for her and then following her (changing course as she moves); if this fails, the infant may try calling or crying.

Bowlby's approach to the organization of attachment behavior involves a control systems perspective. Drawing on observations of ethologists who described instinctive behavior in animals as serving to maintain them in a certain relation with the environment for long periods of time, Bowlby proposed that a control systems approach could also be applied to attachment behavior. He described the workings of a thermostat as an example of a control system. When a room gets too cold, the thermostat activates the heater; when the desired temperature is reached, the thermostat turns the heater off. Bowlby described children as wanting to maintain a certain proximity to their mothers. When a separation becomes too great in distance or time, the attachment system becomes activated, and when sufficient proximity has been achieved, it is terminated. Bowlby (following Bretherton, 1980; see Bowlby, 1969/1982) later described the attachment system as working slightly differently from a thermostat—as being continually activated (with variations of relatively more or less activation), rather than being completely turned off at times. According to Bowlby, the child's goal is not an object (e.g., the mother), but rather a state—a maintenance of the desired distance from the mother, depending on the circumstances. Bowlby described this idea of behavioral homeostasis as similar to the process of physiological homeostasis, whereby physiological systems (e.g., blood pressure and body temperature) are maintained within set limits. Like physiological control systems, a behavioral control system is thought to be organized within the central nervous system. According to Bowlby (1969/1982), the distinction between the two is that the latter is “one in which the set-limits concern the organism's relation to features of the environment and in which the limits are maintained by behavioral rather than physiological means” (p. 372).

The Role of Context

The child's desired degree of proximity to the attachment figure is thought to vary under differing circumstances, and Bowlby (1969/1982) was interested in understanding how these different circumstances contribute to relative increases and decreases in activation of the attachment system. Thus, he described two classes of conditions that contribute to activation of the attachment system, both of which indicate danger or stress. One relates to conditions of the child (e.g., illness, fatigue, hunger, or pain). The other relates to conditions of the environment (e.g., the presence of threatening stimuli); particularly important are the location and behavior of the mother (e.g., her absence, withdrawal, or rejection of the child). Interactions among these causal factors can be quite complex: Sometimes only one needs to be present, and at other times several are necessary. In regard to relative deactivation of the attachment system, Bowlby made it clear that his approach had nothing in common with a model in which a behavior stops when its energy supply is depleted (e.g., Freud, 1940/1964). In Bowlby's ethological view, attachment behavior stops in the presence of a terminating stimulus. For most distressed infants, contact with mother is an effective terminating stimulus. Yet the nature of the stimulus that serves to terminate attachment behavior differs according to the degree of activation of the attachment system. If the attachment system is intensely activated, contact with the mother may be necessary to terminate it. If it is moderately activated, the presence or soothing voice of the mother (or even of a familiar substitute caregiver) may suffice. In either case, the infant is viewed as using the mother as a “safe haven” to return to in times of trouble. In summary, proximity seeking is activated when the infant receives information (from both internal and external sources) that a goal (the desired distance from the mother) is not met. It remains activated until the goal is achieved, and then it stops.

The Role of Emotion

According to Bowlby (1979), emotions are strongly associated with attachment:

Many of the most intense emotions arise during the formation, the maintenance, the disruption, and the renewal of attachment relationships. The formation of a bond is described as falling in love, maintaining

a bond as loving someone, and losing a partner as grieving over someone. Similarly, threat of loss arouses anxiety and actual loss gives rise to sorrow; whilst each of these situations is likely to arouse anger. The unchallenged maintenance of a bond is experienced as a source of joy. (p. 130)

It is likely that these affective responses originally resulted from evolutionary pressures. An infant predisposed to experience positive emotions in relation to an attachment and sadness with its loss may actively work to maintain attachments that in turn contribute to the infant's enhanced chances of survival and reproductive fitness.

Bowlby also viewed emotions as important regulatory mechanisms within attachment relationships, noting, for instance, that anger and protest, as long as they do not become excessive and destructive, can serve to alert the attachment figure to the child's interest in maintaining the relationship (Bowlby, 1973; see Kobak, Zajac, & Madsen, Chapter 2, this volume). More recently, attachment theorists have noted the ways in which the regulation of emotions is used in the service of maintaining the relationship with the attachment figure, and they have noted that individual differences in attachment security have much to do with the ways in which emotions are responded to, shared, communicated about, and regulated within the attachment relationship (Cassidy, 1994; Cassidy & Berlin, 1994; Cassidy & Kobak, 1988; Kobak & Duemmler, 1994; Thompson, 2013; see also Thompson, Chapter 16, this volume).

The Role of Cognition

Drawing on cognitive information theory, Bowlby (1969/1982) proposed that the organization of the attachment behavioral system involves cognitive components—specifically, mental representations of the attachment figure, the self, and the environment—all of which are largely based on experiences. Bretherton (1991) suggested that repeated attachment-related experiences become organized as scripts, which in turn become the building blocks of broader representations (see also Vaughn et al., 2006). (This emphasis on the importance of an individual's actual experiences was another way in which Bowlby's theory differed from that of Freud, which emphasized instead the role of internally generated fantasies.) Bowlby referred to these representations as “representational models” and as “internal working models.” According to him, these models allow individuals to anticipate

the future and to make plans, thereby operating most efficiently. (There is in fact evidence that even young children are capable of using representations to make predictions about the future; see Heller & Berndt, 1981.) The child is thought to rely on these models, for instance, when making decisions about which attachment behavior(s) to use in a specific situation with a specific person. Representational models are considered to work best when they are relatively accurate reflections of reality, and conscious processing is required to check and revise models in order to keep them up to date. Extensive discussion of these cognitive models is provided by Bretherton (1990; Bretherton & Munholland, Chapter 4, this volume) and by Main, Kaplan, and Cassidy (1985); see also Baldwin (1992) for a review of similarities between these models and a variety of constructs within the literatures on developmental, social, clinical, and cognitive psychology. Bowlby (1969/1982, 1973, 1979, 1980a) also discussed the role within the attachment system of other cognitive processes, such as object permanence, discrimination learning, generalization, nonconscious processing, selective attention and memory, and interpretative biases (see also Dykas & Cassidy, 2011; Sherman, Rice, & Cassidy, 2015).

Individual Differences

In extending the biological emphasis of Bowlby's initial theorizing, Main (1990) proposed that the biologically based human tendency to become attached is paralleled by a biologically based ability to be flexible to the range of likely caregiving environments. This flexibility is thought to contribute to variations associated with quality of attachment. Whereas nearly all children become attached (even to mothers who abuse them; Bowlby, 1956), not all are securely attached. Striking individual differences exist. Secure attachment occurs when a child has confident expectations of the attachment figure as available and responsive when needed. Infants are considered to be insecurely attached when they lack such confidence. Bowlby's early clinical observations led him to predict that just as feeding does not cause attachment in infants, so individual differences in feeding (e.g., breast vs. bottle feeding) do not contribute to individual differences in attachment quality. In one of his earliest writings, Bowlby (1958) predicted that the important factor is “the extent to which the mother has permitted clinging and following,

and all the behavior associated with them, or has refused them” (p. 370). This prediction has since gained empirical support (e.g., Ainsworth, Blehar, Waters, & Wall, 1978; see also De Wolff & Van IJzendoorn, 1997). (Precursors and outcomes associated with individual differences in attachment security are discussed in detail in this volume by Fearon & Belsky, Chapter 14, and Thompson, Chapter 16; see also Kobak et al., Chapter 2, and Fraley & Shaver, Chapter 3, for discussions of theory related to major separations and losses as linked to individual differences in attachment.)

Attachment in Relation to Other Behavioral Systems

The attachment behavioral system can be fully understood only in terms of its complex interplay with other biologically based behavioral systems. Bowlby highlighted two of these as being particularly related to the attachment system in young children: the exploratory behavioral system and the fear behavioral system. The activation of these other systems is related to activation of the attachment system. Activation of the fear system generally heightens activation of the attachment system. In contrast, activation of the exploratory system can, under certain circumstances, reduce activation of the attachment system. As any parent knows, providing a novel set of car keys can at least temporarily distract a baby who wants to be picked up, as long as the infant’s attachment system is not intensely activated. These two behavioral systems are discussed in this section, as are the sociable and caregiving behavioral systems.

The Exploratory System

The links between the exploratory behavioral system and the attachment behavioral system are thought to be particularly intricate. According to Bowlby, the exploratory system gives survival advantages to the child by providing important information about the workings of the environment: how to use tools, build structures, obtain food, and negotiate physical obstacles. Yet unbridled exploration with no attention to potential hazards can be dangerous. The complementary yet mutually inhibiting nature of the exploratory and attachment systems is thought to have evolved to ensure that while the child is protected by maintaining proximity to attachment figures, he or she none-

theless gradually learns about the environment through exploration. According to Ainsworth (1972), “the dynamic equilibrium between these two behavioral systems is even more significant for development (and for survival) than either in isolation” (p. 118).

The framework that best captures the links between the attachment and exploratory systems is that of an infant’s use of an attachment figure as a “secure base from which to explore”—a concept first described by Ainsworth (1963) and central to attachment theory (Ainsworth et al., 1978; Bowlby, 1969/1982, 1988). On the basis of her observations during the infant’s first year of life, Ainsworth referred to an “attachment–exploration balance” (Ainsworth, Bell, & Stayton, 1971). Most infants balance these two behavioral systems, responding flexibly to a specific situation after assessing both the environment’s characteristics and the caregiver’s availability and likely behavior. For instance, when the infant experiences the environment as dangerous, exploration is unlikely. Furthermore, when the attachment system is activated (perhaps by separation from the attachment figure, illness, fatigue, or unfamiliar people and surroundings), infant exploration and play decline. Conversely, when the attachment system is not activated (e.g., when a healthy, well-rested infant is in a comfortable setting with an attachment figure nearby), exploration is enhanced. Thus attachment, far from interfering with exploration, is viewed as fostering exploration. Bowlby (1973) described as important not only the physical presence of an attachment figure but also the infant’s belief that the attachment figure will be available if needed. A converging body of empirical work, in which maternal physical or psychological presence was experimentally manipulated, has provided compelling evidence of the theoretically predicted associations between maternal availability and infant exploration (Ainsworth & Wittig, 1969; Carr, Dabbs, & Carr, 1975; Rheingold, 1969; Sorce & Emde, 1981).

The Fear System

The fear behavioral system is also thought to be closely linked to the attachment system. For Bowlby, the biological function of the fear system, like that of the attachment system, is protection. It is biologically adaptive for children to be frightened of certain stimuli. Without such fear, survival and reproduction would be reduced.

Bowlby (1973) described “natural clues to danger”—stimuli that are not inherently dangerous, but that increase the likelihood of danger. These include darkness, loud noises, aloneness, and looming. Because the attachment and fear systems are intertwined, so that frightened infants increase their attachment behavior, infants who find these stimuli frightening are considered more likely to seek protection and thus to survive to pass on their genes for this tendency. Although Bowlby acknowledged the role of factors such as genetics, his focus was on environmental influences. The presence or absence of the attachment figure is thought to play an important role in the activation and regulation of an infant's fear system, such that an available and accessible attachment figure makes the infant much less susceptible to fear, and there is evidence that this is so (Morgan & Ricciuti, 1969; Sorce & Emde, 1981). In fact, even photographs of the mother can calm a fearful infant, as can “security blankets” for children who are attached to such objects (Passman & Erck, 1977; Passman & Weisberg, 1975).

The Sociable System

A complete understanding of the attachment behavioral system rests on an understanding of its distinction from the sociable (or “affiliative”) behavioral system.¹ Although Bowlby did not discuss this behavioral system as extensively as he did some others, he did point out, as have other theorists, that the sociable system is distinct from the attachment behavioral system. Bowlby (1969/1982, p. 229) wrote:

“Affiliation” was introduced by Murray (1938): “Under this heading are classed all manifestations of friendliness and goodwill, of the desire to do things in company with others.” As such it is a much broader concept than attachment and is not intended to cover behavior that is directed towards one or a few particular figures, which is the hallmark of attachment behavior.

According to Ainsworth (1989), it is “reasonable to believe that there is some basic behavioral system that has evolved in social species that leads individuals to seek to maintain proximity to conspecifics, even to those to whom they are not attached or otherwise bonded, and despite the fact that wariness is likely to be evoked by those who are unfamiliar” (p. 713). Harlow and Harlow (1965) described the “peer affectional system

through which infants and children interrelate . . . and develop persisting affection for each other” as an “affectional system” distinct from those involving infant and parents (p. 288). Bronson (1972) referred to affiliation as an “adaptive system” present in infancy and separate from attachment. Bretherton and Ainsworth (1974) examined the interplay among several behavioral systems in infants, including the sociable and the attachment systems, and Greenberg and Marvin (1982) examined this interplay in preschool children. Hinde (1974) described nonhuman primates' play with peers, which he identified as different from mother-child interaction, as “consum[ing] so much time and energy that it must be of crucial adaptive importance” (p. 227).

The *sociable system* is thus defined as the organization of the biologically based, survival-promoting tendency to be sociable with others. An important predictable outcome of activation of this system is that individuals are likely to spend at least part of their time in the company of others. Given evidence from the primate literature that individuals in the company of others are much less likely to be killed by predators (Eisenberg, 1966), it seems reasonable to assume that humans too would derive the important survival advantage of protection from associating with others. The sociable system is likely to contribute to an individual's survival and reproductive fitness in other important ways: Primates biologically predisposed to be sociable with others increase their ability to gather food, build shelter, and create warmth; they learn about the environment more efficiently; and they gain access to a group of others with whom they may eventually mate (see Huntingford, 1984, for a review). Strong evidence of the importance of the sociable system for the development of young nonhuman primates comes from several studies, most notably those of Harlow (1969) and his associates, in which monkeys reared with their mothers but without peers were seriously hindered in their social development and could not mate or parent effectively (see also Miller, Caul, & Mirsky, 1967).

Observations of both humans and other primates clearly show differences between the attachment and sociable systems in what activates behavior, in what terminates behavior, and in the way behaviors are organized (Bretherton & Ainsworth, 1974; Harlow, 1969; Vandell, 1980). The sociable system is most likely to be activated when the attachment system is not activated. According to Bowlby,

A child seeks his attachment-figure when he is tired, hungry, ill, or alarmed and also when he is uncertain of that figure's whereabouts; when the attachment-figure is found he wants to remain in proximity to him or her and may want also to be held or cuddled. By contrast, a child seeks a playmate when he is in good spirits and confident of the whereabouts of his attachment-figure; when the playmate is found, moreover, the child wants to engage in playful interaction with him or her. If this analysis is right, the roles of attachment-figure and playmate are distinct. (1969/1982, p. 307)

Lewis, Young, Brooks, and Michalson (1975) interpreted their observations of pairs of 1-year-olds and their mothers similarly: "Mothers are good for protection, peers for watching and playing with" (p. 56).

The Caregiving System

In one of his earliest writings, Bowlby (1956) pointed out that further understanding of attachment could be gained from examination of the mother's tie to her infant. Bowlby later (1984) wrote briefly about "parenting behavior" from a biological perspective as "like attachment behavior, . . . in some degree preprogrammed" (p. 271). He described the biologically based urge to care for and protect children, yet he simultaneously viewed individual differences in the nature of parenting as emerging largely through learning (yet see Bakermans-Kranenburg & Van IJzendoorn, Chapter 8, this volume, for recent evidence of genetic influences on parenting in humans; see also Mileva-Seitz, Bakermans-Kranenburg, & Van IJzendoorn, in press). Although Bowlby wrote little about this topic, his ethological perspective, his ideas about interrelated behavioral systems, and his interest in attachment-related processes across the lifespan lend themselves readily to an elaboration of the parental side of what he (Bowlby, 1969/1982) called the "attachment-caregiving social bond." Solomon and George (1996; George & Solomon, 1996, 2008) have filled this void, writing in detail about the "caregiving system"; see also Feeney & Woodhouse, Chapter 36, this volume).

It can be difficult to delineate precisely which aspects of parenting behavior should be considered part of the caregiving system. I propose that the term "caregiving system" be used to describe a subset of parental behaviors—only those behaviors designed to promote proximity and comfort when the parent perceives that the child is in real or po-

tential danger or distress. The chief behavior within this system is retrieval of the infant from a potentially dangerous situation (Bowlby, 1969/1982); others include calling, reaching, grasping, restraining, following, soothing, and rocking.²

Just as the child's interactions with the parent involve more than the attachment system (e.g., a child may approach the father not for comfort but for play), so other parental systems may be activated during interactions with the child (Bowlby, 1969/1982). These various behavioral systems can all be viewed as enhancing the child's survival and reproductive fitness (e.g., teaching, feeding, playing). A parent may be differentially responsive to a child when each of these different parental behavioral systems is activated (e.g., sensitive when teaching or feeding, yet insensitive when the caregiving system is activated). The predominance of each of these parental behavioral systems varies considerably both across and within cultures. For instance, as Bretherton (1985) pointed out, among Mayan Indians in Mexico, mothers rarely serve as playmates for their infants but are quite available and responsive as caregivers (Brazelton, 1977). Similarly, Ainsworth (1990) noted that "the mothers of Ganda babies who were securely attached to them almost never played with them, even though they were highly sensitive caregivers" (p. 482; see also Mesman, Van IJzendoorn, & Sagi-Schwartz, Chapter 37, this volume). Within-culture variation exists as well: Within a particular culture, one mother may be a readily available attachment figure, yet stodgy and inept in the role of playmate; another mother may be comfortable in interaction with her children only in her roles as teacher or coach when attention is focused on a task or skill, and may be uncomfortable with attachment-related interactions. Main, Hesse, and Kaplan (2005, p. 292) have proposed that such parental discomfort (anxiety) may emerge when infant behavior interferes with parents' ability to preserve "the state of mind that had seemed optimal for maintenance of the relationship to their own parents during childhood." (For additional discussion of the ways in which particular parents experience discomfort when faced with particular child behavior, see Cassidy et al., 2005; Jones, Cassidy, & Shaver, 2015.)

As is the case with the child's attachment system, the predictable outcome of activation of the caregiving system is parent-child proximity, and a central biological function is protection of the child. In most cases, both parent and child work together to maintain a comfortable degree

of proximity. If the child moves away, the parent will retrieve him or her; if the parent moves away, the child will follow or signal for the parent to return. Following Bowlby's (1969/1982) thinking, it seems likely that when the caregiving system is relatively activated, the child's attachment system can be relatively deactivated; attachment behaviors are not needed because the parent has assumed responsibility for maintaining proximity. If the caregiving system is not relatively activated, then the child's attachment system becomes activated, should the context call for it. This is one reason why the mother's leaving is particularly disturbing to a child and particularly likely to activate attachment behavior. This "dynamic equilibrium" (Bowlby, 1969/1982, p. 236) contributes to understanding the notion of the mother's providing "a secure base from which to explore." The mother's monitoring of infant-mother proximity frees the infant from such monitoring and permits greater attention to exploring. For instance, if, when visiting a new park, a mother actively follows the infant in his or her explorations, the infant is much more likely to cover a wide area than if the mother sits on a bench talking with friends. Empirical support for this proposition comes from a study in which the simple act of a mother diverting her attention away from the infant to a magazine in a brief laboratory procedure reduced the quality of infant exploration (Sorce & Emde, 1981). (As usual, the role of context is key; there are times when parental caregiving behaviors do not free the child to explore, but instead cue the child to potential danger, thereby activating the child's fear system and thus the attachment system.)

Yet parent and child do not always agree on what distance between them is desirable. For example, a mother's caregiving system may be activated (with or without her fear system) and prompt her to retrieve an infant whose activated exploratory system leads him or her to prefer to move away. Parents and their children may also differ in terms of how their priorities guide activation of their behavioral systems. For instance, when an infant's attachment system is activated in the presence of the mother, the infant's sole wish is for her to respond. Although such infant behavior is usually a powerful activating stimulus for the mother's caregiving system, the mother may choose among several competing needs and may or may not provide care (Trivers, 1974). The child's concern is immediate and focused; the mother's concerns may be more diffuse and long-range. The mother may have to leave the infant

to work to support the family (in which case activation of her food-getting behavioral system has taken precedence over her caregiving system). Or she may have several children (or a romantic partner) to whose needs she must attend. Main (1990) has proposed that from an evolutionary perspective, maternal insensitivity to a particular child may be useful to the mother if it maximizes the total number of surviving offspring (see also Simpson & Belsky, Chapter 5, this volume).

As is true for many behavioral systems, activation of the caregiving system results from both internal and external cues. Internal cues include presence of hormones, cultural beliefs, parental state (e.g., whether the parent is tired or sick), and activation of other parental behavioral systems (e.g., exploratory, food-getting, fear, attachment). External cues include state of the environment (e.g., whether it is familiar, whether there is danger, whether others are present and who these others are), state of the infant (e.g., whether the infant is sick or tired), and behavior of the infant (e.g., whether he or she is exhibiting attachment behavior). Activation of the caregiving system has crucial implications for the infant, who cannot otherwise survive. Ethologists have suggested that infants therefore have evolved characteristics that serve to activate the caregiving system: their endearing "babyish" features (the large rounded head with the high forehead, the small nose) and their thrashing arm movements. Attachment behaviors, of course, motivate parents to respond; even aversive behaviors, such as crying, typically motivate parents to provide care in order to terminate them. Given that an infant's attachment system is activated by stimuli that indicate an increased risk of danger (e.g., loud noise, looming objects), a parent who increases proximity when a child's attachment behavior is activated increases the likelihood of being able to protect the child, should the danger prove real. Similarly, when the parent perceives or expects danger that the child does not, parental proximity also increases the likelihood of survival. Thus, it is likely that the close link between the child's attachment and fear systems is paralleled by a close link between the parent's caregiving and fear systems, such that when a parent's fear system is activated, so too is his or her caregiving system.

Fear is only one of the powerful emotions likely to be linked to the caregiving system. Just as attachment is associated with powerful emotions (Bowlby, 1979), so is the caregiving system. These emotions may in fact be as strong as any an

individual experiences in his or her lifetime. The birth of a first child (which establishes the adult as a parent) is often accompanied by feelings of great joy; threats to the child are accompanied by anxiety; the death of a child brings profound grief. This intertwining of the caregiving system with intense emotions may result from selective pressures during evolution: Enhanced reproductive fitness may result when, for instance, a parent's anxiety about threats to a child prompts the parent to seek effective interventions.

The role of parental soothing as a component of the caregiving system merits consideration. Why would a parent who safely holds a crying child out of reach of a large barking dog continue to comfort the child? Why would a parent pick up a distressed child whom the parent perceives to be in no danger? What could be the role of such soothing behaviors? I propose that soothing behaviors serve indirectly to facilitate the parent's monitoring of potential or real dangers to the child. Parental provision of contact usually comforts a distressed child. If the child continues to be distressed for a substantial time following contact, there may be another threat of which the parent is unaware. Through continuing attempts to soothe the child, the parent gains information about threat to the child. The parent may not realize, for instance, that the child has a painful splinter in his or her foot. Furthermore, there are many ways in which inconsolable crying beyond early infancy can signal (or contribute to) serious health problems. And a parent will not know whether crying is inconsolable unless the parent attempts to console. Moreover, the evolution of a parental tendency to soothe is understandable to the extent that soothing returns an overwrought child to a state of equilibrium in which he or she can engage in other activities more likely to enhance reproductive fitness, such as exploration or sociability. See also Shaver, Mikulincer, Gross, Stern, and Cassidy, Chapter 38, this volume, for discussion of the evolutionary basis of parental soothing of child distress.

Important questions about the caregiving system remain, including links between the parental caregiving and child attachment systems. First, given that there are times when the child's distress does not stem from activation of his or her attachment system, research could examine whether it is best to consider parental behavior in response to such distress as part of the caregiving system. For instance, it seems plausible that a child may get upset because his or her exploratory system is

frustrated, and that the child's distress prompts the mother to pick the child up and comfort him or her. It may be that the mother's behavior then contributes to the child's attachment-related expectations about the mother's likely responses to his or her distress, and thus to the formation of the child's representational model of the mother. Second, research is needed to determine how separate the caregiving system is from other parental systems, and whether it is only the parent's behaviors within the caregiving system that affect the child's attachment system. Third, it is unclear whether it is best to think of a single parental caregiving system in humans or of separate maternal and paternal caregiving systems. Harlow has proposed separate maternal and paternal systems in primates (Harlow, Harlow, & Hansen, 1963). If two separate systems exist in humans, there must be considerable overlap, even though genetic, hormonal, and cultural factors may contribute to differences in the specific characteristics of these systems.³

The Attachment Bond

Whereas *attachment behavior* is behavior that promotes proximity to the attachment figure, and the *attachment behavioral system* is the organization of attachment behaviors within the individual, an *attachment bond* refers to an affectional tie. Ainsworth (1989) described an attachment bond *not* as dyadic, but rather as characteristic of the individual, "entailing representation in the internal organization of the individual" (p. 711). Thus, this bond is not one between two people; it is instead a bond that one individual has to another individual who is perceived as stronger and wiser (e.g., the bond of an infant to the mother). A person can be attached to a person who is not in turn attached to him or her; as described below, this is usually the case with infants and their parents.⁴

The attachment bond is a specific type of a larger class of bonds that Bowlby and Ainsworth referred to as *affectional bonds*. Throughout the lifespan, individuals form a variety of important affectional bonds that are not attachments. To make it completely clear what an attachment bond is, one needs to delineate what it is not. Ainsworth (1989) described the criteria for affectional bonds, and then the additional criterion for attachment bonds. First, an affectional bond is persistent across time, not transitory. Second, an affectional bond involves a specific person—a figure who is

not interchangeable with anyone else. This bond reflects "the attraction that one individual has for another *individual*" (Bowlby, 1979, p. 67, original emphasis). For instance, the sadness associated with the loss of a close friend is not lessened by the fact that one has other close friends. Bowlby emphasized specificity when he stated: "To complain because a child does not welcome being comforted by a kind but strange woman is as foolish as to complain that a young man deeply in love is not enthusiastic about some other good-looking girl" (1956, p. 589). Third, the relationship is emotionally significant. Fourth, the individual wishes to maintain proximity to or contact with the person. The nature and extent of the proximity/contact desired vary as a function of a variety of factors (e.g., age and state of the individual, environmental conditions). Fifth, the individual feels distress at involuntary separation from the person. Even though the individual may choose separation from the figure, the individual experiences distress when proximity is desired but prevented. In addition to these five criteria, an additional criterion exists for an attachment bond: In times of distress, the individual seeks security and comfort in the relationship with the person (Ainsworth, 1989). (The attachment is considered "secure" if one achieves security and "insecure" if one does not; it is the seeking of security that is the defining feature. See also Hinde, 1982; Weiss, 1982.) It is this final criterion that leads attachment researchers to refer to "parental bonds" to children and "child attachments" to parents: When the roles are reversed and a parent attempts to seek security from a young child, it is "almost always not only a sign of pathology in the parent but also a cause of it in the child" (Bowlby, 1969/1982, p. 377). (The situation is viewed differently later in life, when a middle-aged offspring takes care of an increasingly infirm and dependent parent; see Magai, Frías, & Shaver, Chapter 25, this volume.)

The existence of an attachment bond cannot be inferred from the presence or absence of attachment behavior. To begin with, it is important to remember that most behaviors can serve more than one behavioral system (Bretherton & Ainsworth, 1974; Sroufe & Waters, 1977). Thus, for instance, every approach does not serve the attachment system; even though approach can be an attachment behavior, it can also be an exploratory or sociable behavior. Yet it is also the case that distressed infants separated from their mothers may seek comfort from strangers (Ainsworth et al., 1978; Bretherton, 1978; Rheingold, 1969).

Nonetheless, an enduring attachment bond of an infant to a stranger cannot be assumed to exist, and it is thus possible for an infant to direct attachment behavior to an individual to whom he or she is not attached. Some babies will stop crying when comforted by a stranger, but observations in the Strange Situation reveal that this comfort is generally not as satisfying as that provided by the mother (Ainsworth et al., 1978).

Similarly, even during a period when the child is directing no attachment behavior to the parent, the child is still attached. When, for instance, a contented child is in comfortable surroundings with the mother present, the attachment system is not likely to be activated to a level that triggers attachment behavior. Thus, activation of attachment behavior is largely situational; it may or may not be present at any given time. The attachment bond, however, is considered to exist consistently over time, whether or not attachment behavior is present. Bowlby (1969/1982) pointed out that even the cessation of behavior during a long separation cannot be considered an indication that the attachment bond no longer exists.

The strength of attachment behaviors is sometimes mistakenly regarded as reflecting the "strength" of the attachment bond. There are striking variations in strength of activation of attachment behaviors across contexts and across children. Yet no evidence exists that these variations in themselves map onto variations in child-mother attachment in any meaningful way. According to Ainsworth (1972, p. 119),

to equate strength of attachment with strength of attachment behavior under ordinary nonstressful circumstances would lead to the conclusion that an infant who explores when his mother is present is necessarily less attached than one who constantly seeks proximity to his mother, whereas, in fact, his freedom to explore away from her may well reflect the healthy security provided by a harmonious attachment relationship.

Ainsworth characterized individual differences in relationships with an attachment figure as variations in quality rather than in strength. Similarly, it is a mistake to label as "very attached" a young child who clings fearfully to the mother; such attachment behavior may reflect insecure attachment or secure use of the mother as a safe haven, depending on the context.

Given that the strength of attachment behaviors should not be confused with the strength

of an attachment bond, is strength nonetheless a useful dimension on which to consider an attachment bond? One might assume that Bowlby's proposition that children develop "attachment hierarchies" (discussed in the following section) implies that some attachments are stronger than others. Although Bowlby himself did occasionally use this terminology—for example, "How do we understand the origin and nature of this extraordinarily strong tie between child and mother?" (Bowlby, 1988, p. 161)—such usage was relatively rare, particularly when he was comparing one attachment with another (when doing so, he referred instead to "secure" and "insecure" attachments). Ainsworth (1982a) suggested that Hinde's (1979) notion of "penetration," as opposed to notions of either strength or intensity, provides a more useful framework for characterizing an attachment bond. According to Hinde, penetration is a dimension of relationships that describes the centrality of one person to another's life—the extent to which a person penetrates a variety of aspects of the other person's life. Ainsworth pointed out that the concept of penetration is particularly useful when considering the changing nature of a child's attachment to the parent as the child grows older. She proposed that it may be more appropriate not to talk of the bond as becoming "weaker," but rather as characterizing a relationship that penetrates fewer aspects of the growing child's life as he or she comes to spend more time away from the parents and to develop new relationships.

For Bowlby (1969/1982), there are two important propositions about the nature of the attachment bond within the larger context of a relationship. First, the attachment bond reflects only one feature of the child's relationship with the mother: the component that deals with behavior related to the child's protection and security in time of stress. The mother may serve not only as an attachment figure but also as playmate, teacher, or disciplinarian. These various roles are not incompatible, and it is possible that two or more roles may be filled by the same person. Thus, for example, a child may direct attachment behavior to the mother when he or she is frightened, yet at other times interact with her in ways relatively unrelated to attachment (e.g., play). Consequently, it would be a mistake to label as an attachment behavior a child's approach to the mother in order to engage in peekaboo. As Bretherton (1980) noted, a behavior may serve different behavioral systems at different times, even when it is directed to the same individual. Yet it is important to note that

even though a mother may be a frequent playmate for her 5-year-old, it does not negate the fact that this relationship is essentially characterized as an attachment relationship. Bowlby (1969/1982, p. 378) summarized his position on this issue: "A parent-child relationship is by no means exclusively that of attachment-caregiving. The only justification, therefore, for referring to the bond between a child and his mother in this way is that the shared dyadic programme given top priority is one of attachment-caregiver."

Second, an attachment bond cannot be presumed to exist even though a relationship may contain an attachment component. As noted earlier, the fact that a 1-year-old distressed about separation from the mother will direct his or her attachment behaviors to a friendly stranger does not mean that the relationship with the stranger involves an attachment bond. This is true even in more ongoing relationships, such as relationships with peers. A young child may routinely direct attachment behavior to a close friend and feel comfort in the friend's presence (particularly in a context such as school, when a parent is not present), without that relationship's involving an attachment bond. This is evident from the fact that the loss of such a friend usually does not have the devastating effects on the child that loss of a true attachment figure (e.g., a parent) has. Thus, even though children may at times turn to friends for comfort (Hazan & Zeifman, 1994), these friendships need not be attachment relationships.

Multiple Attachments

Bowlby stated three principal propositions about multiple attachments in infancy. First, most young infants are thought to form more than one attachment. According to Bowlby (1969/1982), "almost from the first, many children have more than one figure to whom they direct attachment behavior" (p. 304).⁵ Indeed, empirical observations have revealed that the majority of children become attached to more than one familiar person during their first year (Ainsworth, 1967; Schaffer & Emerson, 1964). According to Bowlby (1969/1982), "responsiveness to crying and readiness to interact socially are amongst the most relevant variables" (p. 315) in determining who will serve as an attachment figure. In most cultures, this means that the biological parents, older siblings, grandparents, aunts, and uncles are most likely to serve as

attachment figures. Generally, the mother's role as an attachment figure is clear. The father is also particularly likely to become an additional attachment figure early in the infant's life. Observational studies have revealed that fathers are competent caregivers (Belsky, Gilstrap, & Rovine, 1984), and that children use their fathers as attachment figures (Ainsworth, 1967). Ainsworth noted the special infant–father relationship that sometimes emerged in Uganda:

It seemed to be especially to the father that these other attachments were formed, even in the cases of babies who saw their fathers relatively infrequently. One can only assume that there was some special quality in the father's interaction with his child—whether of tenderness or intense delight—which evoked in turn a strength of attachment disproportionate to the frequency of his interaction with the baby. (p. 352)

Furthermore, there is evidence that individual differences in quality of infant–father attachment are related to paternal behavior: Infants are more likely to be securely attached to fathers who have been sensitively responsive to them (see Van IJzendoorn & De Wolff, 1997, for meta-analytic findings). Evidence has also emerged that siblings (Stewart & Marvin, 1984; Teti & Ablard, 1989) and day care providers (Ahnert, Pinquart, & Lamb, 2006) can serve as attachment figures. In unusual and stressful situations, infants can even become attached to other infants (see A. Freud & Dann's [1951] observations of child survivors of a concentration camp). Howes and Spieker (Chapter 15, this volume) provide an extensive discussion of multiple attachment figures.

Second, although there is usually more than one attachment figure, the potential number of attachment figures is not limitless. Bretherton (1980, p. 195) has described the infant as having a “small hierarchy of major caregivers,” which is in contrast to the larger group of individuals with whom the infant has other sorts of relationships (Weinraub, Brooks, & Lewis, 1977). Marvin, VanDevender, Iwanaga, LeVine, and LeVine (1977) reported that most Hausa infants observed in Nigeria were attached to no more than three or four attachment figures; Grossmann and Grossmann (1991) reported similar observations for a sample of German infants.

Third, although most infants have multiple attachment figures, it is important not to assume that an infant treats all attachment figures

as equivalent, or that they are interchangeable; rather, as mentioned earlier, an “attachment hierarchy” is thought to exist. According to Bowlby (1969/1982), “it is a mistake to suppose that a young child diffuses his attachment over many figures in such a way that he gets along with no strong attachment to anyone, and consequently without missing any particular person when that person is away” (p. 308). Bowlby proposed that this strong tendency for infants to prefer a principal attachment figure for comfort and security be termed “monotropy” (see also Ainsworth, 1964, 1982b).⁶ Bowlby cited as evidence of this phenomenon the tendency of children in institutions to select, if given the opportunity, one “special” caregiver as their own (see Burlingham & Freud, 1944). Ainsworth (1982b, p. 19) described responses to major separations from and losses of attachment figures as further support for the idea that a hierarchy exists: “The child would tolerate major separations from subsidiary figures with less distress than comparable separations from the principal attachment figure. Nor could the presence of several attachment figures altogether compensate for the loss of the principal attachment figure.”⁷ (For similar findings, see Heinicke & Westheimer, 1966.)

Also consistent with this hierarchy notion are data from observational studies of both mothers and fathers, which show that most infants prefer to seek comfort from their mothers when distressed; in the mother's absence, however, an infant is likely to seek and derive comfort and security from other attachment figures as well (Kagan, Kearsley, & Zelazo, 1978; Lamb, 1976a, 1976b, 1978; Rutter, 1981; see also Ainsworth, 1967; Schaffer & Emerson, 1964). For a review of the relatively few experimental studies examining attachment hierarchies, and a discussion of the relevant methodological issues, see Colin (1996; for data and discussions of attachment hierarchies beyond infancy, see also Kobak, Rosenthal, & Serwik, 2005; Kobak, Rosenthal, Zajac, & Madsen, 2007; Rosenthal & Kobak, 2010).

What determines the structure of an infant's attachment hierarchy? Colin (1996) listed a likely set of contributing factors: “(1) how much time the infant spends in each figure's care; (2) the quality of care each provides, (3) each adult's emotional investment in the child, and (4) social cues” (p. 194).

Why would monotropy have evolved as a tendency of human infants? Neither Bowlby nor Ainsworth addressed this question. I propose three possibilities, all of which may operate simultane-

ously. The fact that there may be multiple ways in which the tendency toward monotropy contributes to infant survival and reproductive fitness increases the likelihood of its emerging through genetic selection. First, the infant's tendency to prefer a principal attachment figure may contribute to the establishment of a relationship in which that one attachment figure assumes principal responsibility for the child. Such a relationship should increase the child's likelihood of survival by helping to ensure that care of the child is not overlooked. This system seems more practical than the alternative, wherein a large number of caregivers have equal responsibility for a large number of offspring; this latter system might leave any individual child "falling between the cracks."

Second, monotropy may be most efficient for the child. When faced with danger, the child does not have to make a series of assessments and judgments about who may be most readily available, most responsive, and best suited to help. Rather, the child has a quick, automatic response to seek his or her principal attachment figure.

Third, monotropy may be the child's contribution to a process I term *reciprocal hierarchical bonding*, in which the child matches an attachment hierarchy to the hierarchy of the caregiving in his or her environment. Evolutionary biologists writing on parental investment (e.g., Trivers, 1972) have suggested that adults vary in their investment in offspring largely as a function of the extent to which this investment contributes to the transmission of the adults' genes (i.e., their reproductive fitness). Following this reasoning, it should be most adaptive for the child to use as a principal attachment figure the person who, correspondingly, is most strongly bonded to him or her (i.e., the person who provides the most parental investment and has the most to gain—in terms of reproductive fitness—from the baby's healthy development). In most cases, it is the biological mother who has the greatest biological investment in the child. With the exception of an identical twin, there is no one with whom the child shares more genes than the mother (50%). Although the biological father and siblings also share 50% of their genes with a child, their investments are nonetheless considered to be less because (1) only the mother can be certain of a true biological connection; (2) the mother devotes her body and bodily resources to the infant for 9 months of pregnancy and often nurses the child for a considerable period thereafter; and (3) the mother has fewer opportunities to produce additional offspring than fathers and siblings do.

If this process of reciprocal hierarchical bonding exists, it may help to explain not only monotropy, but also, in part, why the biological mother is generally the principal attachment figure.

The infant's selection of the principal attachment figure occurs over time, and it is important to consider why it takes a period of time for this centrally important attachment to crystalize rather than happening immediately, as it does in some other mammals. Jay Belsky (personal communication, October 15, 2007) has proposed two possible explanations, in addition to the obvious fact that human newborns do not possess the skills needed to form attachments because of their immature status at birth. First, the mother may not survive childbirth; many surely did not do so during our ancestral past. Second, the infant needs to be able to discern which individual is making the intensive investment upon which he or she is so dependent—a judgment that is likely to take some time.

Given the existence of multiple attachments, what is the course of their development across the lifespan? As noted earlier, two or three attachments usually develop during the infant's first year. These are usually with other family members or other people closely involved in the child's care. By middle childhood, when the child is spending more time with people outside the family, opportunities for new attachments may arise. In adolescence and young adulthood, individuals usually begin to develop attachments to sexual partners. Although attachments to parents typically remain throughout life, the later attachments may become the most central ones in the individual's adult life.

When considering multiple attachments, theorists are faced with several sets of questions. One of these has to do with similarities versus differences in quality across different attachments (i.e., concordance rate). To what extent are a child's attachments to different caregivers similar? Studies examining concordance rate yield inconsistent results. Some studies reveal independence of attachment across caregivers (Belsky & Rovine, 1987; Grossmann, Grossmann, Huber, & Wartner, 1981; Main & Weston, 1981); other studies reveal similarity of attachment across caregivers (Goossens & Van IJzendoorn, 1990; Steele, Steele, & Fonagy, 1996); and two meta-analytic studies have revealed significant but weak concordance between attachment to mother and attachment to father (Fox, Kimmerly, & Schafer, 1991; Van IJzendoorn & De Wolff, 1997; for additional discussion, see Berlin, Cassidy, & Appleyard, 2008).

Another question relates to the integration of multiple attachments. If a child's attachments are similar, he or she may develop a consistent set of internal working models of attachment figures, him- or herself, and relationships. Yet what if the child is faced with attachments that contribute to conflicting models? What if the child's experiences with one parent contribute to a model of the attachment figure as sensitively responsive and of the self as worthy of such care, but negative experiences with the other parent contribute to very different models? If differing models of attachment figures eventually become integrated, how does this happen? In relation to models of the self, Bretherton (1985) asked over two decades ago: "Is an integrated internal working model of the self built from participation in a number of nonconcordant relationships? If so, how and when? Or are self models, developed in different relationships, only partially integrated or sometimes not at all?" (p. 30). Researchers have made little progress in answering these questions.

Still another question about multiple attachments relates to the issue of how these different attachments influence children's functioning. It could be that the attachment to the principal attachment figure, usually the mother, is most influential. On the other hand, it could be that one attachment is most influential in some areas and another is most influential in other areas. Or perhaps having at least one secure attachment, no matter who the attachment figure is, serves as a protective factor to facilitate the child's functioning across areas. Relatively little empirical work has addressed these possibilities, given that most research examining the sequelae of attachment focuses only on infant-mother attachment. The research that is available suggests that when a child is securely attached to one individual and insecurely attached to another, the child behaves more competently when the secure relationship is with the mother than when it is with the other attachment figure (Easterbrooks & Goldberg, 1987; Howes, Rodning, Galluzzo, & Myers, 1988; Main et al., 1985; Main & Weston, 1981; Sagi-Schwartz & Aviezer, 2005). These same studies indicate, however, that the best-functioning individuals have two secure relationships, whereas the least competent children have none. Mesman and colleagues (Chapter 37, this volume) review the cross-cultural data and report similar evidence that multiple secure attachments enhance children's functioning; more extensive discussion of models of the influence of multiple attachments can be found in that chapter.

Summary and Theoretical Extensions

This chapter has addressed the issues that Bowlby presented in his initial ethological approach to understanding the nature of a child's tie to the mother. Bowlby's observations led him to be dissatisfied with the explanations provided by existing theories and prompted him to consider alternative explanations. Drawing on the thinking of evolutionary biologists, cognitive scientists, control systems theorists, and developmental psychologists, he initiated what proved to be one of the earliest and most influential of the neo-Darwinian theories of evolutionary psychology, tackling the problem of the ways humans evolved to master the primary task of genetic transmission: survival through infancy and childhood to reproductive age (see Simpson & Belsky, Chapter 5, this volume).

For this third edition of the *Handbook of Attachment*, authors were asked to consider changes, or the lack thereof, that have occurred since earlier *Handbook* editions. Given the historical nature of this chapter, I approach this task in terms of considering current perceptions of the original theory. Perhaps one day I will write: "We now know that Bowlby's initial theory was incorrect in the following ways." This is not yet the case. Although it is likely I am plagued by the restricted vision that characterizes "insiders" in most fields, my view is that Bowlby and Ainsworth's original ideas have held up well, while providing a remarkably fruitful foundation for related ideas and studies.

Bowlby's original focus was on the then radical ideas about the evolutionary underpinnings of human attachments and the importance of individual variation in the quality of these attachments for subsequent development. Because Bowlby understandably devoted his attention to setting the foundations of his revolutionary ideas, he left considerable room for deeper examination of the underpinnings and connections of components of his theory, and extensions into new territory.

Although nothing that has emerged from the thousands of studies produced over the past 40 years has led to a serious challenge to the core theory, what has changed since the time of Bowlby's initial writings, and indeed during the 15 years since the initial edition of this handbook, is that subsequent theorists and researchers have extended and enriched Bowlby's thinking. I mention only a few of these extensions here.

Some of the most important theoretical advances relate to greater specificity of the *mecha-*

nisms through which early attachment experiences influence so many aspects of later child and adult functioning (see Thompson, Chapter 16, for discussion of these influences). As described earlier, the central mechanism on which Bowlby focused was the experience-based internal working model (IWM; see Bretherton & Munholland, Chapter 4, this volume). Yet despite his claim of the causal importance of IWMs, Bowlby never wrote a sole definitive work about this purported mechanism of influence. Rather, his formulation of the building, revising, and maintenance of IWMs is distributed across multiple works (Bowlby, 1969/1982, 1973, 1979, 1980a, 1988). Bretherton and Munholland (2008) noted that Bowlby's thinking about IWMs "was not a fully worked-out theory, but a promising conceptual framework to be filled in by others" (p. 103). Thus, subsequent theorists have offered varied conceptualizations of IWMs (Bretherton, 1990; Main et al., 1985; Thompson, 2006; Weinfield, Sroufe, Egeland, & Carlson, 2008; see Sherman et al., 2015, for theory and a review of research about infant capacities during the first year of life necessary to support the development of the IWM). Moreover, Bretherton's elegant analysis of how the capacities involved in the IWM are associated with neural processes is a substantial new contribution to the theoretical understanding of IWMs (Bretherton & Munholland, Chapter 4, this volume; see also Coan, Chapter 12, this volume).

Two other important theoretical extensions also relate to potential mechanisms linking early attachment experiences with later psychological functioning, one of which involves physiological processes. At the same time that experiences with caregivers are contributing to the formation of IWMs, they are also likely to set into motion a variety of nonrepresentational, physiological regulatory processes that play important roles in children's developing attachment systems. These physiological processes in turn can explain how early attachments come to influence child functioning, including greater understanding of the link between the attachment and fear behavioral systems. For instance, there is now evidence that experiences within the attachment relationship can influence the functioning of the hypothalamic-pituitary-adrenal (HPA) axis and child stress reactivity (Bernard & Dozier, 2010; Luijk et al., 2010; Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996; Spangler & Grossmann, 1993; see Hane & Fox, Chapter 11, this volume). The fact that Bowlby paid relatively little attention to these infant physiological processes is surprising given that he studied medicine as an undergraduate stu-

dent at Cambridge, and given that the education about ethology that he received largely from Robert Hinde was so central to his early theorizing about why humans become attached to their caregivers. Yet Bowlby's focus on mental representations is understandable considering that much of his writing took place during a time when many branches of science were focused on the "cognitive revolution," and most of the research related to physiology in the mother-infant relationship in humans was not yet available. Attention to the role of noncognitive processes in explaining the link between early experience and later functioning, as well as the interconnections between cognitive and noncognitive processes, has grown in recent years; this focus extends Bowlby's theory to a new level of specificity without contradicting his initial perspective (Polan & Hofer, Chapter 6, this volume; see also Cassidy, Ehrlich, & Sherman, 2013).

A third mechanism through which early attachment experiences influence later functioning is emotion regulation. Although Bowlby talked extensively about emotions (and indeed the concept of IWM is thought to contain both cognitive and affective components), the concept of emotion regulation was not as well developed when Bowlby was writing as it is currently. The notion that children's emotion regulation capacities develop within the context of attachment relationships, and then mediate the link between attachment and social functioning, for both children and parents, is now widely accepted across developmental, clinical, neuroscience, and social psychological perspectives (Calkins & Leerkes, 2011; Cassidy, 1994; Thompson, 2013; see Shaver et al., Chapter 38, and Thompson, Chapter 16, both this volume).

The continued rigor of attachment theory requires that it be able to incorporate theoretical and empirical advances from other areas of science. I mention three of these, with a focus on infancy and childhood. First, because attachment theory is so firmly based in evolutionary theory, continuing revision of evolutionary theory brings with it a need to rethink some components of attachment theory. Simpson and Belsky (Chapter 5, this volume) focus on these considerations, and I do not review them here. Second, the recent conceptualization of genetically based differential susceptibility to environmental influence has implications for attachment theory. It is reasonable to expect that Bowlby, like most developmentalists of his time, assumed that environmental factors affect most children in similar ways; more recent theory and research suggest that this is not the case (Van

IJzendoorn, Belsky, & Bakermans-Kranenburg, 2012). Attachment theory can readily incorporate ideas of differential susceptibility (in this volume, see Bakermans-Kranenburg & Van IJzendoorn, Chapter 8, and Vaughn & Bost, Chapter 10, for discussions of attachment and the notion of differential susceptibility).

Third, the empirical work most likely to have an important impact on the understanding of attachment is that concerning epigenetic processes. Just as Darwin speculated about genes while not understanding how they actually work, so Bowlby, while focusing on the environment, recognized the existence of a role for genes without understanding what this role might be. Certainly he did not realize that the environment could bring about changes in gene expression. It was not until Meaney's research (e.g., Caldji et al., 1998; Francis, Diorio, Liu, & Meaney, 1999) on maternal licking and grooming, and arched-back nursing, which affects the demethylation of genes related to receptor sites in the hippocampus, that scientists began to focus on environmental, including social, influences on genetic processes. The work of Meaney and his colleagues opened the door for research into what experiences contribute to the expression of particular genes in humans, and whether attachment experiences can moderate gene expression. Again, however, this exciting new development does not alter the main tenets of attachment theory.

In summary, Bowlby and Ainsworth's initial ideas and the newer extensions of them, some of which I have mentioned here, have inspired the creation of the huge research literature discussed throughout this volume. The torrent of new ideas, studies, and research methods shows no sign of letting up, and it is likely to continue enriching rather than overturning attachment theory.

Acknowledgments

The writing of this chapter was supported by Grant Nos. RO1-MH50773 from the National Institute of Mental Health and RO1-HD36635 from the National Institute of Child Health and Human Development.

Notes

1. See Greenberg and Marvin (1982; also Ainsworth, 1989) for discussion of the advantages of the term *sociable system* rather than *affiliative system*. For data and more extensive discussion related to the interplay of the sociable system with other behavior sys-

tems, see Ainsworth and colleagues (1978), Bretherton (1978), Bretherton and Ainsworth (1974), Cassidy and Berlin (1999), and Greenberg and Marvin (1982).

2. This perspective differs somewhat from that of Bowlby (1969/1982, p. 240), who described "maternal retrieval behavior" as distinct from other parenting behavior, with the former having the predictable outcome of proximity and the biological function of protection. It is unclear, however, what for Bowlby would constitute a behavioral system. The position taken here is that retrieval is the parental equivalent to child proximity seeking; it is a behavior, not a behavioral system. The relevant behavioral system would be what here is called the "caregiving system," which includes a variety of behaviors, one of which is parental retrieval of the child. This perspective, along with that of Solomon and George (1996), also differs from the one proposed by Bretherton, Biringen, and Ridgeway (1991). Their view incorporates the notion of a "parental side of attachment," in which the parent's bond to the child is considered part of the attachment system, in part because of its great emotional power.
3. Within the modern evolutionary perspective, the existence of separate maternal and paternal caregiving systems is readily understood. Both mothers and fathers are concerned with their own reproductive fitness. Yet because mothers and fathers may differ substantially in the extent to which the survival of any one child enhances this fitness, their parenting behavior may differ. Compared to fathers, mothers have more to gain in terms of reproductive fitness from each child, for several reasons (e.g., mothers' certainty about parental status, shorter reproductive lifespan, longer interchild intervals, and greater energy expenditure per child during pregnancy and lactation; see Trivers, 1972).
4. Consensus is lacking about terminology related to the attachment bond. The description provided here is Ainsworth's (1989) and reflects Bowlby's most common usage. Yet in the second edition of the first volume of his trilogy, *Attachment and Loss*, Bowlby (1969/1982) described a bond as "a property of two parties," and labeled the child-parent bond as the "attachment-caregiving" bond (p. 377). In contrast to the implied notion of an "attachment relationship," Ainsworth (1982b) stated:

That there is a "relationship" between mother and child, in Hinde's (1979) sense, from the time of the infant's birth onward, and that the nature of this relationship stems from the interaction between them, is not to be gainsaid, but neither the mother-to-infant bond nor the emergent infant-to-mother attachment seems to me to comprehend all the important aspects of this relationship. (p. 24)

Bretherton (1985) also pointed out the limits of considering an attachment to be a "property of two parties": "A representational view of relationships . . . underscores that the two partners have, in another sense, two rela-

tionships: the relationship as mentally represented by the attached person and by the attachment figure" (p. 34). Ainsworth (personal communication, June 15, 1986) suggested that the most appropriate way to consider an "attachment relationship" is as a "shorthand" designation for "a relationship in which the attachment component is central" (see also Ainsworth, 1990).

5. There has been some confusion over Bowlby's position on this issue. Lamb, Thompson, Gardner, and Charnov (1985), for instance, mistakenly stated, "Bowlby was firmly convinced that infants were initially capable of forming only one attachment bond" (p. 21). In fact, from his earliest writings on (1958, 1969/1982), Bowlby described the role of multiple attachment figures. Bowlby (1969/1982) noted that "it has sometimes been alleged that I have expressed the view . . . that mothering 'cannot be safely distributed among several figures' (Mead, 1962). No such views have been expressed by me" (p. 303).
6. Starting with his earliest writings, Bowlby (e.g., 1958) used the term *principal attachment-figure* or *mother-figure* rather than the term *mother*. This usage underscored Bowlby's belief that although this figure is usually the biological mother, it is by no means necessarily so. From the beginning, Bowlby recognized that the figure's status (father, adoptive parent, grandmother, aunt, nanny) is less important than the nature of the figure's interactions with the infant.
7. One of the most moving passages of Bowlby's writing illustrates how one attachment figure can be more centrally important to a child's well-being than others:

About four weeks after mother had died, [4-year-old] Wendy complained that no one loved her. In an attempt to reassure her, father named a long list of people who did (naming those who cared for her). On this Wendy commented aptly, "But when my mommy wasn't dead I didn't need so many people—I needed just one." (Bowlby, 1980a, p. 280).

Chapter 2

Attachment Disruptions, Reparative Processes, and Psychopathology

Theoretical and Clinical Implications

Roger Kobak
Kristyn Zajac
Stephanie D. Madsen

In the *Separation* volume of his attachment trilogy, Bowlby (1973) dramatically expanded his theory to account for the contribution of attachment processes to personality development, defensive processes, and psychopathology. In the first section, “Security, Anxiety, and Distress,” he used young children’s responses to separations to illustrate how a child’s perception of a threat to a caregiver’s availability elicits feelings of anxiety, anger, and sadness. The second section, “An Ethological Approach to Human Fear,” highlighted how lack of access to an available caregiver amplifies the normal fear response to dangerous situations and contributes to pathological levels of fear and anxiety. The final section, “Individual Differences in Susceptibility to Fear: Anxious Attachment,” considered how severe or prolonged threats to caregiver availability could contribute to anxious attachment. Bowlby posited that these attachment disruptions become internalized as working models, shape negative interpersonal expectancies, and increase risk for adult psychopathology. In many respects, the theoretical advances in the *Separation* volume established the framework for the next four decades of research on attachment and psychopathology.

We review in this chapter the three major theoretical advances in the *Separation* volume and their implications for the role of attachment in the development and maintenance of psychopathology. We begin with Bowlby’s (1973) and Ainsworth’s (1990) views that the attachment behavioral system monitors a caregiver’s *availability and responsiveness*. This perspective dramatically shifted the focus of attachment research from the study of young children’s separations from caregivers to investigations of the quality of *emotional communication* in maintaining attachment bonds. We stress that momentary threats to caregiver availability or responsiveness typically activate *reparative processes* that serve to restore confidence in the attachment bond. Second, Bowlby used young children’s reactions to prolonged physical separations from caregivers as a prototype for explaining how more prolonged or severe threats to caregiver availability contribute to anxiety, defenses, and symptomatic expressions of attachment needs. We suggest that these more severe threats to caregiver availability or responsiveness represent a broader class of *attachment injuries or disruptions*. Furthermore, when these injuries remain unrepaired or unresolved, they increase an individual’s vulnerability

for psychopathology. Finally, Bowlby used working models or internalized expectancies for caregiver availability and responsiveness to explain both continuity and change in an individual's developmental pathway. We conclude with suggestions for how further investigation of emotional communication, attachment injuries, reparative processes and internalized expectancies for caregivers can guide clinical assessment and treatment of attachment problems experienced by young children, adolescents, and adults.

We note that in order to focus on these three theoretical advances of Bowlby's *Separation* volume, we omit major portions of our previous chapter in the second edition of the *Handbook of Attachment*. That earlier chapter (Kobak & Madsen, 2008) provided an account of the historical context that shaped the evolution of Bowlby's thinking and led up to his clarification of the attachment system's set-goal. Our account in that chapter also highlights Ainsworth's contributions to attachment theory. By translating theory into empirical observations and research methodology, Ainsworth tested and refined Bowlby's ideas and succeeded in communicating the core premises of attachment theory to a much wider audience. Readers interested in Bowlby and Ainsworth's contributions to the evolution of attachment theory may want to return to our earlier chapter.

Emotionally Attuned Communication and Reparative Processes Maintain Secure Attachment Bonds

The *Separation* volume marked a critical shift in defining the set-goal of the attachment system. The early studies of young children's reactions to prolonged physical separations from their caregivers implied that the set-goal of the child's attachment system was monitoring simple physical proximity to a caregiver (Sroufe & Waters, 1977). However, by 3 or 4 years of age, physical separations no longer elicited the same reactions nor presented as serious a threat to the child's bond with a parent. Even in the case of infants, naturalistic observations provided compelling evidence that children monitored not only their caregivers' physical proximity but also their *responsiveness* or ability to provide protection and support during moments of danger, distress, or high need (Ainsworth, 1962). As a result, throughout the *Separation* volume,

Bowlby (1973) stressed a new and broader view of the attachment system. In addition to monitoring the caregivers' whereabouts and physical proximity, Bowlby referred to the attachment system as designed to continuously monitor the caregiver's *availability and responsiveness* (Bowlby, 1969/1982).

The expanded view of the child's attachment system shifted attention from observing reactions to separations to observing patterns of *emotional communication* in caregiver-child dyads. In Bowlby's (1969/1982) view, the child's emotions served essential motivational and communicative functions in maintaining the child's attachment set-goal within a comfortable range. For Ainsworth and the researchers who followed, the child's emotional signals and behaviors became a window to the attachment system and provided a context for observing caregiver sensitivity to those signals and behaviors (Ainsworth, Blehar, Waters, & Wall, 1978). When access to a sensitive caregiver was assured, infants could comfortably attend to other matters, such as exploring, affiliating, or resting. However, if the child became distressed, he or she would initiate behaviors to gain assurance and comfort from the caregiver. If efforts to reestablish contact failed or resulted in an insensitive response from the caregiver, infants would protest and direct *anger* toward the caregiver or, alternatively, develop avoidant strategies.

Careful consideration of the motivational and communicative functions of emotions allowed Ainsworth to make inferences about other behavioral systems, such as fear, exploration, and affiliation. As a result, a caregiver's interpretations of a child's displays of fear, anger, or sadness had to be understood as reflecting the child's goals in a particular context. In addition to monitoring a caregiver's availability and responsiveness, young children use emotions to signal how they monitor danger in the environment, explore new learning opportunities, and enjoy social exchanges. Fear signals the child's appraisal of danger, anger signals frustration at the interruption of an enjoyable or goal-directed activity, and sadness signals the child's despair at losing a desired toy or object. Ainsworth's sensitivity ratings focused on how caregivers attended to, interpreted, and responded to their infants' signals in a variety of contexts that took into account children's changing signals and motivational goals. Sensitivity to infant signals required caregivers continually to adapt their inferences about the child's emotional cues to account for the degree to which the child's attachment, exploration, and fear behavioral systems were acti-

vated (Ainsworth & Wittig, 1969). The interplay between the attachment and exploration systems was described as the infant's use of the mother as a "secure base" from which to explore. This balance between the attachment system, whose function is protection, and the exploration system, whose function is learning, provided a mechanism that allowed the child to learn and develop without straying too far away from the caregiver or remaining away for too long (Ainsworth et al., 1978).

Subsequent researchers have struggled with capturing the full complexity of Ainsworth's sensitivity construct and its ratings of acceptance–rejection, accessibility–ignoring, cooperation–interference, and sensitivity (Bretherton, 2013). For example, a caregiver might correctly interpret and respond to the child's signals of distress, yet fail to recognize the child's exploratory behaviors, resulting in an intrusive response. Another caregiver might be quite responsive to the child's exploratory activity but be averse to close bodily contact that would provide the child with a sense of comfort and protection when distressed. At the heart of Ainsworth's sensitivity construct was the notion that the caregiver could make accurate inferences about the child's emotional state and respond appropriately. To read an infant's signals accurately, make inferences about the infant's motivational states, and respond appropriately, caregivers need to adopt the child's perspective. This capacity for *empathic reading and responding* to an infant's changing needs and motivations has been described as *mentalizing* or accurately drawing inferences about the child's wishes, desires, and intentions (Sharp & Fonagy, 2008). This mentalizing capacity has been studied in terms of "mind-mindedness" or the caregiver's ability to understand accurately and comment on the child's mind (Meins, 2013). Research assessing individual differences in mentalizing capacities relies on what caregivers say when interacting with or discussing their child after watching brief replays of video clips featuring their child (Oppenheim & Koren-Karie, 2013).

Emotionally Attuned Communication and Reparative Processes in Childhood and Adolescence

Efforts to study emotionally attuned communication with older children and adults require observ-

ing interactions that test caregiver sensitivity and the child or adult's appraisals of the caregiver's availability and responsiveness. Because the attachment system is less frequently activated in older children and adults (Ainsworth, 1990), assessments of emotionally attuned communication can benefit from more structured laboratory or home observations. These paradigms can be designed to elicit interactions that allow observers to rate caregiver sensitivity and the child or adult's expectancies for caregiver availability and responsiveness. In many respects, these structured paradigms draw on particular aspects of daily interactions that Ainsworth observed in the home or village settings. *Safe haven episodes* provide a prototype for activating the attachment systems with cues to danger or threats to a caregiver's availability posed by brief physical separations. These episodes are defined by interactions in which the individual becomes distressed, injured, frightened, or endangered, and actively seeks comfort and protection from the caregiver. Some investigators have used intimidating laboratory equipment or discussions of distressing events to evaluate emotional communication (Simpson, Collins, Tran, & Haydon, 2007). From a behavioral systems perspective, these interactions represent the synchronous operation of the fear and attachment systems. Emotionally attuned interactions can be evaluated by attending to how the individual signals a need for contact and comfort, and the caregiver's response to those signals.

In contrast to safe haven episodes, *secure base episodes* are subtler and occur when the individual faces uncertainty in new or challenging situations. In these situations, an available and responsive caregiver typically responds with encouragement and support. From a behavioral systems perspective, these episodes require the individual to balance exploratory, fear, and attachment motivations in ways that use the caregiver as a resource to support new learning and master new challenges. These situations may become more salient at later phases of development as the individual becomes more self-reliant and less exposed to emergency situations that call for protective responses from the caregiver (Waters & Cummings, 2000). As a result, these types of interactions may play an increasingly important role in shaping the individual's expectancies or forecasts regarding his or her caregiver's availability and responsiveness beyond infancy.

Beginning in early childhood, interactions that require cooperative *negotiation of goal conflicts* play an increasingly important role in maintaining

attachment bonds (Kobak & Duemmler, 1994). The nature of these goal conflicts changes with development. In early childhood, conflicts often involve coordinating the child's need for autonomy and self-assertion with the parent's goal of providing rules to ensure safety and encouraging the internalization of those rules to foster self-regulation (Kochanska & Murray, 2000). In adolescence, the child's need for autonomy must be coordinated with the caregiver's need to monitor, reduce risky behaviors, and ensure safety (Smetana, 2010). In adult attachment relationships, conflicts often center on managing finances, child-rearing differences, or communication. To maintain a "goal-corrected partnership," these goal conflicts require that both individuals engage in cooperative conversations (Bowlby, 1969/1982) that test each individual's capacity to communicate his or her own perspective while empathizing and reflecting on the partner's goals, needs, wishes, and desires. Observational coding of these conversations has consistently linked cooperative negotiation of differences to secure expectancies for caregiver availability and responsiveness (Allen, Moore, Kuperminc, & Bell, 1998; Kobak, Cole, Ferenz-Gillies, Fleming, & Gamble, 1993; Obsuth, Henninghausen, Brumariu, & Lyons-Ruth, 2014).

Momentary threats to caregiver availability or responsiveness present frequent challenges to maintaining emotionally attuned communication in attachment dyads. These momentary threats, including brief separations, goal conflicts, or competing demands on the caregiver's time and attention, are common in all attachment relationships. Furthermore, such threats typically initiate *reparative processes* that are motivated by a desire to reestablish contact and restore confidence in the relationship. To restore confidence in the caregiver effectively, the individual must directly signal distress and initiate contact; subsequently, the caregiver must accurately read these signals and empathically respond to the individual's need for contact and comfort. An attuned and timely caregiver response typically completes the reparative episode and restores confidence in the caregiver's availability and responsiveness. These *reparative episodes* have been well documented among infants and their caregivers. For instance, laboratory paradigms have used the "still face procedure" to test the infant's reaction to a nonresponsive caregiver (Tronick, 2007). In this procedure, after a period in which the infant becomes distressed and dysregulated, the caregiver and the infants quickly reestablish synchronous interaction, thus restoring

the child's confidence in the caregiver's availability. Ainsworth's Strange Situation also illustrates how the infant's confidence in the caregiver can be restored following the distress induced by being left alone in a strange environment (Ainsworth et al., 1978). Following this perceived threat to the caregiver's availability, secure children actively seek contact with the caregiver, effectively gain comfort, and restore their confidence in the caregiver's availability and responsiveness.

Severe or Prolonged Disruptions, Defensive Process, and Psychopathology

States of anxiety and depression that occur during the adult years, and also psychopathic conditions, can, it is held, be linked in a systematic way to the states of anxiety, despair, and detachment described by Burlingham and Freud.

—JOHN BOWLBY (1973, pp. 4–5)

In contrast to the relatively brief threats to caregiver availability that typically activate repair processes, *attachment disruptions* are defined as prolonged or severe threats to a caregiver's availability or responsiveness that create fundamental fear and uncertainty about the caregiver's availability or capacity to respond in moments of danger. When disruptions remain unrepaired, the individual becomes vulnerable to persistent feelings of fear, anger, or sadness, and to defensive strategies that reduce the individual's ability to engage in emotionally attuned communication with caregivers. At moments of high stress, the defenses are likely to break down and result in symptomatic expressions of attachment needs and feelings. In contrast to common forms of insensitive care and insecure attachment, attachment disruptions represent severe threats to the attachment bond and constitute a significant risk for the development and maintenance of psychopathology.

Dysfunctional Emotional and Defensive Responses to Attachment Disruptions

The mechanisms linking attachment disruptions to psychopathology can be found in Bowlby and Robertson's close observations of 2- to 4-year-old children's reactions to prolonged separations from their caregivers (e.g., Bowlby, Robertson, &

Rosenbluth, 1952; Robertson, 1953, 1962). Their descriptions provide a prototype for how disruptions elicit emotional reactions and defensive processes that impair relationship functioning and distort expressions of attachment needs. The observations documented how children's emotional reactions may become dysfunctional when they no longer serve a reparative function of signaling and eliciting a comforting response from a caregiver. These phases, labeled "protest," "despair," and "detachment," echoed many of the descriptions of children's responses to separation provided by other observers (e.g., Burlingham & Freud, 1944; Heinicke & Westheimer, 1966).

Protest is the initial phase, typically lasting from a few hours to a week or more. For example, in one of Bowlby's and Robertson's observations, protest began at the moment a parent prepared to leave a child at the nursery or hospital. The child signaled separation distress in a variety of ways, such as crying loudly, showing anger, following the mother, pounding the door, or shaking his or her cot. Any sight or sound might produce a temporary respite, as the child eagerly checked to see whether it was a sign of the mother's return. The dominant attitude during this phase was hope that the mother would return, and the child actively attempted to regain contact with her. During this phase, efforts by alternative adults to comfort or soothe the child typically were met with little success, and some children actively spurned potential caregivers. Although crying gradually subsided over time, it commonly recurred, especially at bedtime or during the night. Searching for the missing parent often continued on a sporadic basis over a number of days. During the protest phase, the dominant emotions were fear, anger, and distress. Fear and distress signaled a child's appraisal of danger at being separated from a primary attachment figure, while anger served to mobilize and sustain the child's efforts to reestablish contact with the mother.

The despair phase, which succeeded protest, was marked by behaviors suggesting increased hopelessness about the mother's return. Although a child might continue to cry intermittently, active physical movements diminished, and the child withdrew or disengaged from people in the environment. Bowlby (1973) compared this phase to deep mourning, in that the child interpreted the separation as a loss of the attachment figure. He suggested that adults often misinterpreted the reduced activity and withdrawal as signs of the child's recovery from the distress of separa-

tion. Sadness accompanied this withdrawn state. Heinicke and Westheimer (1966) also noted that hostile behavior, directed toward another child or toward a favorite object brought from home, tended to increase over time.

A child's active turning of attention to the environment marked the final phase, detachment. In this phase, the child no longer rejected alternative caregivers, and some children even displayed sociability toward other adults or peers. The nature of this phase became most evident during reunion with the mother. A child who reached the phase of detachment showed a striking absence of joy at the mother's return; instead of enthusiastically greeting her, the detached child was likely to appear apathetic. In the Heinicke and Westheimer (1966) study, varying degrees of detachment were reported among 10 children following separations that lasted from 12 days to 21 weeks. On their initial reunion, two of the children seemed not to recognize their mothers, and the other eight children either turned or walked away from their mothers. Children often alternated between crying and showing blank, expressionless faces. Some degree of detachment persisted following the reunions, with five of the mothers complaining that their children treated them like strangers. For many children, detachment and neutrality alternated with clinging and showing fear that the mother might leave again. Following the reunions, children appeared to feel frightened by home visits from observers they knew from the nursery.

Attachment Disruptions among Older Children, Adolescents, and Adults

The phases of protest (anger), despair (sadness), and defensive detachment observed in young children's reactions to prolonged separations from their caregivers provided a prototype for understanding older children's and adults' emotional responses to other types of attachment disruptions. The dysregulated emotions, interpersonal difficulties, and symptomatic expressions that accompany severe threats to caregiver availability often contribute to psychopathology (e.g., Adam & Chase-Lansdale, 2002; Carlson, Egeland, & Sroufe, 2009; Kobak, Little, Race, & Acosta, 2001). Unfortunately, in many cases, the problematic reactions, feelings, and behaviors that result from attachment disruptions are often more evident than the threats to caregiver availability that contributed to

those problems. As a result, the role that attachment disruptions play in the emergence of psychopathology may remain undetected by standard psychiatric assessments and procedures.

In reviewing the literature on older children, adolescents, and adults, it is useful to distinguish between two types of pathogenic attachment disruptions. One type is analogous to the threat to caregiver availability encountered by young children who experience prolonged separations. Although older children and adults are much less likely to perceive prolonged physical separation as a threat to the attachment bond, these individuals remain vulnerable to fears of abandonment or loss of a caregiver. Examples of these disruptions include unexplained separations, perceived loss of the caregiver through desertion or death, and lack of access to a caregiver in a moment of high need. The second type of attachment disruption results from a breakdown in the caregiving system that leads to nearly complete failure of the caregiver to provide protection and guidance. These disruptions represent severe threats to the caregiver's responsiveness and include abdication of the caregiving role, betrayal, and threatening or frightening behavior. Such threats allow the individual to develop strategies for maintaining the relationship with a caregiver who is physically available but unable to serve as a source of safety and protection.

Severe or Prolonged Threats to Caregiver Availability

The perception of physical accessibility remains the most fundamental appraisal of an attachment figure's availability. With age, there are dramatic advances in the cognitive mapping of the attachment figure's whereabouts, the resources for seeking proximity, and the types of distal communication with the attachment figure. Although these advances make distance less of an obstacle to maintaining an attachment bond, the notion that the individual can reunite with the attachment figure if necessary remains a crucial aspect of the caregiver's availability. Furthermore, when lines of communication are closed or cut off, older children and adults can perceive physical separations as a major threat to maintaining an attachment bond. For instance, separations in which a caregiver leaves in an angry or unexplained manner may disrupt a child's ability to plan for reunion and leave the child uncertain about the parent's whereabouts. Bowlby (1973) cited a research study

by Newson and Newson (1968) describing how a 4-year-old had become anxious and clingy following her father's desertion of the family 3 months earlier. The child's mother speculated that her child's difficulty with staying at day care resulted from her fear that the mother would also not come back—a speculation supported by the child's repeatedly saying to the mother, "Do you love me? You won't leave me, Mummy, will you?" (Bowlby, 1973, p. 214).

Witnessing violence between parents may also threaten a child's confidence in the parents' availability (Davies & Cummings, 1995, 1998). The child's appraisal of marital violence is likely to include fear that harm may come to one or both parents. In addition, parents living with constant conflict and fear are likely to have reduced capacities to attend to the child. Thus, in addition to fear of harm to the parents, attachment anxiety is increased by uncertainty about the parents' ability to respond to the child's distress and the lack of open communication with both parents. Even in situations with less extreme conflict, parents who become emotionally disengaged from one other and decide to separate or divorce may create fears in the child that the parents will also decide to leave the child. The notion that a parent may leave and not return creates a fundamental threat to physical accessibility. Most parents who divorce make efforts to communicate with the child and reassure the child of their continued availability, which substantially reduces the perceived threat (Bretherton, 1995; see also B. C. Feeney & Monin, Chapter 40, this volume).

Hostile verbal communication creates additional possibilities for attachment disruptions. For instance, without actually leaving, a parent can threaten to leave or to send the child away. Such behavior may occur in disciplinary contexts when the parent has become angry and exasperated with the child. As an example, Bowlby quoted a mother from the Newson and Newson (1968; emphasis added) study:

"I used to threaten him with the Hartley Road Boys' Home, which isn't a Home anymore; and since then, I haven't been able to do it; but I can always say I shall go down town and see about it you know. And Ian says, "Well, if I'm going with Stuart (7) it won't matter"; so I say, "Well, you'll go to different ones—you'll go to one Home, and *you'll* go to another." But it really got him worried, you know, and I really got him ready one day and I thought I'll take him a walk round, as if I was going, you know, and he really was worried. In fact, I had to bring him home, he started

to cry. He saw I was in earnest about it—he *thought* I was, anyway. And now I've only got to threaten him. I say "It won't take me long to get you ready."

It is difficult to document the frequency of such statements because many parents are ashamed to admit them to researchers. However, in his review of parenting studies, Bowlby reported that the incidence of such statements was as high as 27% in the Newson and Newson (1968) study of families in England and 20% in a study of parents in the United States (Sears, Maccoby, & Levin, 1957).

Threats of suicide by a desperate parent may elicit even greater anxiety about the parent's availability. In addition to the obvious threat to the parent's physical accessibility, the child is faced with the fear of violence and the prospect of loss. These threats often occur in the context of hostile and conflict-filled relations, which may create the impression that the child's angry feelings toward the parent are responsible for the parent's desperation and despair. Bowlby noted that many children are not only exposed to threats of suicide, but may also actually witness suicide attempts. A parent may also make statements that attribute responsibility for future abandonment to the child. Statements to the child, such as "You will be the death of me," or threats of abandonment that follow a child's misbehavior are likely to confound attachment-related fears with feelings of guilt. This kind of attribution not only shakes the child's confidence in the parent's availability but also leads to negative perceptions of the self.

Over 400,000 children in the United States currently experience prolonged physical separations from biological parents (Zeanah, Shauffer, & Dozier, 2011). Because foster care families have replaced residential nurseries for children removed from the care of their biological parents, new questions about the effects of attachment disruptions with biological parents and the potential formation of bonds to foster parents have been investigated (Stovall-McClough & Dozier, 2004; see Dozier & Rutter, Chapter 30, this volume). These studies suggest that infants and young children in foster care will display attachment behaviors toward their new caregivers within the first few weeks of placement; however, it is uncertain whether such behaviors necessarily indicate the formation of an attachment bond because they do not predict the long-term stability of the placement. In contrast, the foster parent's "commitment" to the foster child measured early in the relationship is a

strong predictor of the long-term stability of the placement and of adoption (Dozier & Lindhiem, 2006). These findings illustrate that assessment of foster parents' feelings of commitment to the child yield a better prediction of bond formation than either home or laboratory assessments of the foster child's attachment behavior. The importance of maintaining an enduring attachment bond is further highlighted by a prospective study of foster and maltreated children. Higher rates of behavior problems were found in children who had been placed in foster care compared with children who remained placed with maltreating caregivers, with whom they presumably had maintained an attachment bond (Lawrence, Carlson, & Egeland, 2006). Children who enter the child welfare system not only experience prolonged separation from their biological parents but also face the challenge of repairing the bonds with biological parents or developing an attachment with an alternative caregiver.

Severe or Chronic Threats to Caregiver Responsiveness

The complete absence of an appropriate caregiving response in situations that normally call for nurturance or guidance constitutes a severe threat to confidence in the caregiver's responsiveness to the child's attachment needs. Main and Solomon (1986) first called attention to this type of disruption when they observed a relatively small group of infants who showed unusual behaviors in the Strange Situation, marked by fear, freezing, and disorientation. They assigned these infants to a new classification: "disorganized/disoriented" (D).

The infant D classification has been consistently linked to a variety of adjustment difficulties and to psychopathology (Groh, Roisman, Van IJzendoorn, Bakermans-Kranenburg, & Fearon, 2012; Lyons-Ruth & Jacobvitz, Chapter 29, this volume). In a 6-year longitudinal study, children who were classified as D in infancy developed aggressive behavior problems in preschool and elementary school at much higher rates than other children (Lyons-Ruth, 1996; Lyons-Ruth, Alpern, & Repacholi, 1993; Moss, Cyr, & Dubois-Comtois, 2004; Moss et al., 2006). Longitudinal data from the Minnesota Longitudinal Project indicate that the infant D classification predicts adjustment problems consistently from childhood through adolescence, and that it specifically predicts dissociative symptoms (Carlson, 1998; Sroufe, 2005).

Main and Hesse (1990) traced infants' disorganized behavior to children's perceptions of their caregivers as "frightened or frightening," signaling severe threats to caregiver responsiveness. A potential explanation for caregivers' difficulty in responding to their children's attachment needs was uncovered in interviews about their own childhoods. Parents of D infants showed unusual difficulties discussing loss and trauma during the Adult Attachment Interview (AAI; Hesse & Main, 2006; see Hesse, Chapter 26, this volume). These difficulties were evident from momentary lapses in "monitoring discourse or reason" that included disorientation, loss of monitoring of discourse, and reports of extreme behavioral reactions. The internal focus of these parents, resulting from their own preoccupation with unresolved loss and traumatic experience, was thought to interfere drastically with their capacity to respond to their infants (Main & Hesse, 1990).

Subsequent researchers have further investigated the links among caregiver behavior, severe threats to a caregiver's responsiveness, and disorganized attachment among older children and adolescents (Solomon & George, 2011). Prolonged failure to respond appropriately to the child's needs has been described by George and Solomon (2008) as *caregiver abdication*. This term describes a general breakdown in the caregiving system that includes frightening, maltreating, neglecting, or failing to protect children. These caregiving failures are thought to result from caregivers being flooded and overwhelmed by their own fears, resulting in feelings of helplessness in caring for their children. As children mature, they develop new capacities to manage the feelings of confusion, fear, anger, and sadness that accompany perceptions of the caregiver as frightened or frightening. As a result, older children who perceive severe threats to caregiver responsiveness may develop "controlling strategies" for managing their relationship with the caregiver. These strategies may reduce the child's feelings of confusion and helplessness and provide more predictable interactions with the caregiver that ensure maintenance of the attachment bond. Two types of controlling/disorganized strategies have been observed in caregiver-child interactions: a controlling-hostile pattern and a controlling-caregiving pattern (Lecompte & Moss, 2014; Main & Cassidy, 1988; Obsuth et al., 2014; Solomon & George, 2011; Zanetti, Powell, Cooper, & Hoffman, 2011; see also Solomon & George, Chapter 18, this volume). These patterns have been consistently associated with increased risk for child and adolescent psychopathology.

In addition to the disorganized patterns observed in caregiver-child dyads, severe threats to caregiver responsiveness may also undermine trust and communication in adult attachment relationships. For instance, disruptions in adult relationships are often marked by intense negative affect and by the adults' feelings of helplessness and anger in attempting to respond to their partners' needs. A common dysfunctional pattern of interaction occurs when one partner rigidly pursues the other in a manner that is perceived as critical or nagging, and the partner responds by emotionally disengaging. Such disengagement can take a variety of forms, including contemptuous or aloof responses, silent stonewalling, or actual physical withdrawal from the partner (Gottman, 1994). Although this disengagement may be an effort to escape from a painful interaction, it paradoxically heightens anxious and angry feelings associated with a perceived threat to the partner's availability or responsiveness (Johnson & Greenman, 2006; see Brassard & Johnson, Chapter 35, this volume). Unfortunately, fear of losing the partner or of being hurt is often mixed with defensive anger. As a result, events that have been perceived as threats to the partner's availability or responsiveness are often hidden behind cycles of blame and defensive responses that dominate much of a distressed couple's interactions.

Internal Working Models: Continuity and Change in Developmental Pathways

Bowlby (1973) viewed the transaction between the individual's internal working models and the caregiving environment as the central dynamic that shapes an individual's developmental pathway from infancy through adulthood (Kobak, Cassidy, Lyons-Ruth, & Ziv, 2006). His developmental pathways model accounted for both continuity and change in adaptation. Continuity in a developmental pathway was maintained by internalized expectations for caregiver availability and responsiveness that in turn shaped the individual's interpretation of behavior with caregivers and partners in close relationships. Confident expectancies in a caregiver's availability tended to promote adaptive functioning, while negative or insecure expectancies tended to leave an individual vulnerable to subsequent difficulties. The model also allowed for changes in a pathway. For instance, changes in the caregiving environment could alter an individual

pathway in both positive and negative directions, leading to subsequent revisions in an individual's internal model. Attachment disruptions in childhood, adolescence, or adulthood could have profound effects in shifting an individual's trajectory regarding relationship difficulties and psychopathology.

Internal Working Models and Attachment Disruptions

Bowlby posited internal working models as a mechanism through which interactions with caregivers are internalized. These "working models" or expectancies forecast the caregiver's availability and responsiveness, and allow individuals to adapt their communications with caregivers to assure maintenance of the attachment bond. Expectancies form the core of internal working models and anticipate how the caregiver will respond in variety of contexts given the individual's changing needs and goals. A child who experiences consistent responses that are attuned to his or her changing motivational states will develop confident expectancies in the caregiver's availability and responsiveness. These expectancies conform to a "secure base script" that anticipates how attachment-related events with a particular caregiver typically unfold (e.g., "If I am distressed, I can go to my mother and she will comfort me"; Bretherton & Munholland, 2008; Cassidy, Jones, & Shaver, 2013; Mikulincer, Shaver, Sapir-Lavid, & Avihou-Kanza, 2009; Waters & Rodrigues-Doolabh, 2001; Waters & Waters, 2006).

Internal working models that are organized by secure base scripts provide individuals with valuable resources for coping with attachment disruptions. Secure expectancies predispose individuals toward openly signaling their needs and assuming that these signals will elicit a timely and effective caregiver response. As a result, emotions are more likely to serve their adaptive functions of motivating effective behavior and signaling needs to others. This sense of emotional efficacy in turn allows individuals to develop confidence to explore new situations and master new skills. Thus, nonattachment motivational systems such as exploration and affiliation can take precedence over attachment concerns to facilitate new learning and social interaction (Waters & Cummings, 2000). Older adolescents and adults who have developed the internal resources associated with secure internal working models are likely to show more resilience when they encounter a threat to caregiver availability, as well as a reduced risk for developing psy-

chopathology (Carlson et al., 2009). In contrast, those with insecure internal models may be particularly vulnerable to attachment disruptions and at greater risk for emotional and defensive reactions that undermine relational functioning and increase symptomatic expressions of attachment needs.

Ainsworth's patterns of attachment in the Strange Situation provided initial evidence for the development and assessment of internal working models. Her laboratory observations demonstrated that, by 1 year of age, infants had begun to internalize expectancies for caregiver availability and responsiveness, subsequently organizing how they communicated and behaved toward the caregiver when they were distressed. Later researchers (e.g., Bretherton, 1985; Main, Kaplan, & Cassidy, 1985) extended the assessment of internal models to older children and adults (see Bretherton & Munholland, Chapter 4, this volume). Many of the assessments designed to infer expectancies for caregiver availability and responsiveness share a common strategy of eliciting narratives of events that would typically activate the attachment system and lead an individual to seek protection or comfort from the caregiver. The AAI uses structured prompts designed to elicit memories of times when an individual would normally need comfort or support from the caregiver. Other assessments rely on projective methods or word prompts to generate narratives that can be coded for their degree of adherence to or deviation from the secure base script. Expectancies for caregiver responsiveness can be inferred at the level of behavior or by observing how individuals communicate when they are distressed or in need of support (Kobak & Duemmler, 1994).

Much of the research that followed Ainsworth's work assumed considerable continuity in internal working models from infancy through adulthood (Kobak & Zajac, 2011). Although longitudinal research generally yielded some support for the continuity hypothesis, these effects tend to be quite modest and suggest that internal working models are open to considerable change and revision between early childhood and late adolescence (Booth-LaForce et al., 2014; Haydon, Roisman, Owen, Booth-LaForce, & Cox, 2014; Sroufe, Egeland, Carlson, & Collins, 2005). This substantial instability highlights the need to consider how ongoing experiences in attachment relationships, as well as an individual's exposure to attachment disruptions, may create "lawful discontinuities" in internal working models. In Bowlby's view, internal working models become not only more complex over the course of childhood and adolescence but also more resistant to change. However, even

in adulthood, these models may be amenable to change resulting from new experiences in relationships with partners.

The internal working model concept is essential to understanding the resources an individual brings to coping with attachment disruptions. Expectancies that organize the internal working model that predate the disruption can amplify or reduce the response to the disruption and its impact on relationship functioning and psychopathology. Individuals with secure internal models (organized by confident expectancies for caregiver availability) are likely to bring more resources to interpreting and coping with the relationship disturbance. Not only does a secure internal model enable the individual to cope more effectively, but it is also likely to facilitate more direct emotionally attuned communication with caregivers. The capacity for communicating vulnerable emotions and attachment needs may be very useful in gaining comfort and protection from alternative caregivers or in signaling the individual's need to restore confidence in the disrupted relationship. In situations where alternative caregivers are not available, the confident expectancies and emotional self-efficacy that characterize a secure model may be useful in helping the individual understand the source of the disruption and to maintain resilience in managing attachment-related distress. Unfortunately, the effects of attachment disruptions such as loss or trauma often co-occur with insecure models and expectancies for insensitive care (Zajac & Kobak, 2009). As a result, the insecure models will amplify problematic reactions to attachment disruptions. These models are more likely to activate defensive processes resulting in distorted and symptomatic expression of the anger, fear, and sadness that accompany severe threats to caregiver availability or responsiveness.

The Caregiver's Capacity for Repairing Attachment Disruptions

The caregiver's capacity to empathize and respond sensitively to feelings of hurt, anger, and sadness is the other major factor that moderates the impact of attachment disruptions on relationship functioning and psychopathology. Efforts to assess the contributions of the caregiving environment to continuity and change in developmental pathways have lagged behind efforts to measure internal working models. The degree to which a caregiver's ability or inability to provide sensitive care remains stable across development requires further

study, as does the chronic versus transitory nature of factors that overwhelm caregivers and lead to abdication of the caregiving role. The caregiver's capacity to restore trust following an attachment disruption is premised on the notion that the caregiver can recover from (or effectively manage) the factors that produced the disruption. Examples of events that are more amenable to recovery include a caregiver's serious illness or hospitalization, psychological or substance abuse disorders that lead to treatment or remission, and major transitions in adult relationships (e.g., separation and divorce) that allow the caregiver to reestablish a stable support network. Factors that are more chronic and less amenable to recovery include economic adversity, personality disorders that undermine stable relationship functioning, and repeated exposure to loss and/or trauma (Kobak, Cassidy, & Ziv, 2004).

When a caregiver can overcome or manage the adversity that contributed to separation from the child or caregiving abdication, repair is possible. For instance, if an available and responsive caregiver were able to attend to the relationship following a disruption, the disruption could be repaired and confidence in a caregiver's availability and responsiveness restored. The caregiver's central challenges in repairing a disrupted attachment are understanding and empathizing with the child's injured feelings, even when those feelings may be hidden by defensive detachment or expressed in angry and distorted ways that initially distance the caregiver. Responding to these challenges tests the caregiver's ability to be the stronger and wiser person in a damaged relationship (Zanetti et al., 2011). Whereas reestablishing contact and effectively gaining comfort from the primary caregiver might repair some disruptions, other disruptions may be resolved by establishing or strengthening an attachment relationship with an alternative caregiver. These efforts are likely to be most successful when supported by other adults in the caregiver's life or possibly by help from a professional therapist or coach.

Therapeutic Change: Repairing or Resolving Attachment Disruptions

Attachment-based therapies share the common goal of increasing security in attachment relationships, so that those relationships can serve as a resource for helping the individual to manage major sources of stress more effectively. These treatments may target the caregiver and the caregiver's capacity to empathize with the child, emotionally at-

tuned communication in the attachment dyad, and the child or adult's internal working model of the caregiver (Kobak, Zajac, Herres, & Krauthamer-Ewing, 2015). The extent to which attachment disruptions are implicated in attachment-based treatments vary along a continuum (Kobak et al., 2006). On one end are individuals with secure or mildly insecure relationships who encounter severe stress or adversity and require support in managing these problems. These individuals have not likely been exposed to a major disruption, and treatments can focus on improving communication. On the other end of the continuum are individuals who have experienced prolonged or severe threats to caregiver availability and responsiveness, and have developed rigid defenses that distort expressions of attachment needs and feelings. These individuals may require more supportive exploration of attachment disruptions and internal working models in order to repair negative expectancies and defensive reactions that accompany the disruption.

Bowlby (1988) wrote most extensively about individual therapy with adults. The goal of his approach was (1) to provide a secure base from which to access painful expectancies regarding caregiver availability that had been shut away from conscious processing and (2) to allow the client to test the validity of those expectancies in light of current experience. This type of treatment often begins by linking symptomatic expressions of fear and anger to disturbances in attachment relationships. In doing so, a clinician can help the client experience and integrate painful experiences to gain control over symptoms. Accessing previously avoided experiences makes it possible for the individual to update working models and reduce defensively distorted emotions that contribute to miscued communication. Although this description of adult therapy focuses on intrapersonal working models, intrapersonal change is premised on the notion that the interpersonal relationship with the therapist provides a model of open communication about attachment-related experiences (see Slade, Chapter 33, this volume).

Treatments for Caregivers of Young Children

Two of the major attachment-based therapies for young children provide support for caregivers on both ends of the continuum of attachment disturbances and child psychopathology. The Attachment and Biobehavioral Catch-Up (ABC) program focuses on identifying, commenting on,

and reinforcing caregiver sensitivity at moments when the child needs comfort; in this way, parents are encouraged to take initiative in the interaction (Bernard et al., 2012; Bernard, Meade, & Dozier, 2013). This intervention has proven effective at increasing caregivers' ability to respond sensitively to children's signals for nurturance and reciprocal interaction in ways that produce enhanced biological regulation for the child. Similarly, the Circle of Security project encourages caregivers to explore how their internal worlds shape their perceptions and reactions to their child (Marvin, Cooper, Hoffman, & Powell, 2002; Powell, Cooper, Hoffman, & Marvin, 2013). In doing so, the intervention is intended to enhance caregivers' capacities for self-regulation, self-awareness of filters that interfere with accurately reading the child's signals, and empathic attunement and response to the child's attachment and exploratory signals. Research has demonstrated the effectiveness of the Circle of Security in changing children's attachment classifications from disorganized to organized (Hoffman, Marvin, Cooper, & Powell, 2006). Other attachment interventions such as toddler-parent psychotherapy focus more on the impact of parents' working models derived from childhood experience on current parent-child interactions (Lieberman, 1992). This approach has produced increased attachment security in a randomized trial with mothers diagnosed with major depressive disorder (Toth, Gravener-Davis, Guild, & Cicchetti, 2013; see Berlin, Zeanah, & Lieberman, Chapter 32, this volume, for a review of early intervention programs designed to enhance attachment security).

Attachment-Based Treatment for Adolescents and Adults

Adolescents and adults have established internal working models that have become more resistant to change over the course of development, thus complicating attachment-based therapy. Furthermore, the negative expectancies that organize internal models are often distorted by well-established defensive strategies that make attachment needs and feelings less apparent to caregivers or therapists. The challenge for attachment-based therapists is to support caregivers in seeing beyond these defensive processes to underlying attachment needs. Connect, a group program for the caregivers of antisocial adolescents, approaches this problem with an extensive 10-session program designed to direct caregivers' attention to adolescents' hidden

attachment needs (Moretti & Obsuth, 2009). In doing so, the curriculum encourages an empathic shift in caregivers that recognizes adolescents' vulnerability and allows for more attuned responding to adolescents' attachment and autonomy needs.

Attachment-based family therapy (ABFT) is designed to uncover adolescents' attachment disruptions or threats to caregiver availability or responsiveness in order to structure a reparative conversation with the caregiver (Diamond et al., 2010). ABFT was designed to treat depressed and suicidal adolescents, using the adolescent's suicidal despair to understand why the he or she could not rely on the caregiver at a moment of distress. After eliciting attachment narratives that support negative expectancies for caregiver availability or responsiveness, the therapist prepares the adolescent to discuss these episodes directly with the caregiver. Caregivers are given advance preparation to support a validating and empathic stance toward the adolescent's vulnerability and attachment needs. The goals of the reparative conversation are to allow the adolescent to signal attachment needs directly and to encourage the caregiver to shift from seeing a depressed and suicidal adolescent to seeing a child in need of understanding, protection, and comfort. Once the therapist establishes a reparative conversation, treatment centers on conversations about the adolescent's challenges and difficulties outside the family, allowing the caregiver to provide a secure base for understanding and support.

Attachment-based marital therapists face similar challenges in treating distressed couples. Marital distress is presumed to be motivated by fears about a partner's availability and responsiveness. As a result, the therapist is faced with the challenge of uncovering "attachment injuries" or perceived threats to a partner's availability and responsiveness (Kobak, Hazan, & Ruckdeschel, 1994; see also Brassard & Johnson, Chapter 35, this volume). Shifting from an externally focused attentional set, in which a partner is viewed as primarily a source of danger, to a more internally focused awareness of the fear and distress caused by the threat to the attachment relationship can be a critical step in marital therapy. When the fears that accompany perceived threats to a partner's availability are openly communicated, the high level of conflict and disengagement found in distressed marriages can be deescalated (Johnson, 1996, 2003). Johnson's approach uses emotion-focused techniques to help distressed partners access attachment fears and vulnerabilities that are

hidden behind angry and defensive interaction sequences. This approach has produced increased levels of marital satisfaction in the majority of couples completing treatment (Makinen & Johnson, 2006; see also Brassard & Johnson, Chapter 35, this volume).

Summary

Bowlby's *Separation* volume established the framework for understanding how disturbances in attachment relationships are implicated in the development and maintenance of psychopathology. Although insensitive care and insecure attachment have provided much of the focus for attachment research in nonclinical populations, Bowlby was concerned with more extreme breakdowns in caregiving that we have termed "attachment disruptions." These severe or prolonged threats to a caregiver's availability or responsiveness activate defensive process and symptomatic expressions of attachment-related anger, fear, and sadness that severely compromise an individual's ability to cope with normal stressful and developmental challenges. Caregivers and therapists who work with individuals who have experienced attachment disruptions can use Bowlby's framework to assess the nature of the disruption, determine the degree to which disturbance is implicated in presenting problems, and, most importantly, to develop treatment designed to repair or resolve injuries resulting from attachment disruptions.

Chapter 3

Attachment, Loss, and Grief

Bowlby's Views, New Developments, and Current Controversies

R. Chris Fraley
Phillip R. Shaver

For most of his life, evolutionary theorist Charles Darwin—one of John Bowlby's intellectual heroes—suffered from a perplexing set of symptoms, including recurrent and persistent gastric pains, nausea, and heart palpitations. These are common symptoms of hyperventilation syndrome, a condition that can be triggered by trauma, stress, or bereavement. In Bowlby's (1990) final book, *Charles Darwin: A New Life*, he attributed Darwin's symptoms to suppressed and unresolved grief following the death of his mother when he was 8 years old. Bowlby emphasized that Darwin's father did not allow his children to speak about their deceased mother following her death, and that Darwin suffered fainting spells and other signs of hyperventilation from then on.

Bowlby believed that the suppression of grief inhibits a sequence of painful emotional reactions that, unless allowed to run their natural course, can lead to psychological and physical ill health. Although his final book was primarily concerned with understanding Darwin's loss in particular, Bowlby had been deeply concerned with the psychological consequences of loss more generally throughout his own career. In his first empirical study, Bowlby (1946) argued that loss of a primary attachment figure is a predisposing factor in juve-

nile delinquency. Decades later, in his landmark trilogy, *Attachment and Loss*, bereavement and grief were the focus of the entire third volume, *Loss: Sadness and Depression* (Bowlby, 1980).

Although Bowlby's ideas about grief changed over the course of his career, he continued to view loss of an attachment figure as an important influence on personality development. He considered suppressed and unresolved grief to be pathogenic forces, and portrayed grief itself as a natural feature of what he called the "attachment behavioral system"—a system "designed" by natural selection to discourage prolonged separation of an individual from his or her primary attachment figures (see Cassidy, Chapter 1, this volume).

Our main aim in this chapter is to summarize Bowlby's contributions to the study of bereavement. In addition, we review research, theoretical developments, and controversies that have emerged recently in the study of bereavement, and we discuss the implications of these developments for attachment theory. We begin with a brief overview of the volume *Loss: Sadness and Depression*. We discuss Bowlby's thoughts about the function and course of mourning, patterns of "disordered" mourning, and how these patterns may be products of the way the attachment system is orga-

nized. We then discuss recent themes in the study of bereavement that are inspired by or relevant to Bowlby's theory. Specifically, we discuss recent criticisms that the phases of grief that Bowlby discussed were too rigid. Next, we discuss current controversies concerning complicated grief and whether it is distinct from other psychological disorders. We also review how these controversies are playing out in diagnostic reform efforts. Next, we review debates about the absence of grief and how recent research on patterns of bereavement can be integrated with Bowlby's ideas to provide a more nuanced view of what the relative absence of grief does and does not reveal about psychological adaptation. We also review empirical research on how individual differences in attachment organization are related to grief reactions and highlight what we consider to be some of the advances in this area, as well as the gaps that require further research. We also return to the issue of continuing bonds—a theme that was discussed in depth in the 1999 and 2008 editions of this chapter. Finally, we review a recent theoretical model of bereavement that integrates many of Bowlby's ideas concerning bereavement with emerging themes in the study of autobiographical memory, identity, and complicated grief reactions.

An Attachment Perspective on Separation and Bereavement

Bowlby's thoughts on loss and grief were developed over several decades, but they were expressed most completely in his 1980 volume, in which he addressed a wide range of issues (e.g., whether children are capable of grieving, and whether they can harbor multiple conflicting representations of loss events). Two of Bowlby's aims are particularly relevant to this chapter. First, he wished to show that seemingly irrational or "immature" reactions to loss, such as disbelief, anger, searching, and sensing the continued presence of a lost attachment figure, are understandable when viewed from an ethological or evolutionary perspective. Second, he wished to show that how an individual responds to loss stems partly from the way his or her attachment system has become organized over time. He thought that people whose attachment systems are organized in such a way that they chronically anticipate rejection and loss (i.e., those who are anxious with respect to attachment concerns) or defensively suppress attachment-related feelings

(i.e., avoidant or compulsively self-reliant individuals) are likely to suffer from psychological and physical distress following bereavement.

The Function and Course of Mourning in Infancy and Adulthood

One of Bowlby's most important contributions to the literature on bereavement was his ethological perspective on attachment and loss. He observed that in order to survive, infants of many species require protection and care from older individuals. To obtain this protection, evolution has resulted in infants having several physical adaptations (e.g., large eyes and facial expressions of emotion) and behavioral adaptations (e.g., crying and reaching) that attract and hold the attention of potential caregivers. In addition to these more basic adaptations, infants possess a motivational system (the attachment system) designed by natural selection to regulate and maintain proximity between infants and their caregivers (see Cassidy, Chapter 1, this volume). When an attachment figure is judged to be sufficiently available and responsive, an infant is thought to experience what Sroufe and Waters (1977) called *felt security*, allowing the infant to explore the environment and engage in playful social interactions. In contrast, when the attachment figure is judged to be inaccessible or unresponsive, the infant experiences anxiety and vigorously attempts to reestablish contact by protesting, searching, approaching, and clinging.

The following passage illustrates the protest of a 16-month-old girl after learning that her father would be leaving her in the nursery for an extended time.

When Dawn sensed that her father was leaving, she again whined "Mm, mm, mm," and as he got up she broke into a loud cry and clutched him around the neck. Father became upset, put her down and tried to console her. . . . As he was departing through the door, she almost knocked her head on the floor. When the nurse picked her up, she continued to scream but later comforted herself by sucking her finger and some candy. (Heinicke & Westheimer, 1965, pp. 94–95)

According to Bowlby (1969/1982), these "protest" reactions are biologically functional because in the environment of evolutionary adaptedness they would have kept infants close to their protective attachment figures (see also Archer, 1999). This natural anxiety and yearning for an attachment figure motivate continued searching and calling

until either success is attained or all efforts are exhausted. Viewed in this light, many of the seemingly perplexing reactions to separation and loss (e.g., continuing to yearn and search even when a lost caregiver is objectively irretrievable) appear more reasonable and, in many situations, adaptive. By doing everything possible to prevent the loss of attachment figures or by successfully reuniting with temporarily absent or distracted attachment figures, infants would have substantially increased their chances of survival, and ultimately their reproductive fitness.

During the protest phase of separation and loss, infants generally react very forcefully. However, the intensity of these reactions eventually wanes if the separation is extended, as is the case following a caregiver's death. Anxiety, anger, and denial give way to sadness and hopelessness. This second phase, which Bowlby (1980) called "despair," is thought to be a natural result of failure to bring about the attachment figure's return. A third phase, which Bowlby at first called "detachment," marks an apparent recovery and gradual renewal of interest in other activities and social relationships. The term *detachment* is misleading, however, because Bowlby (e.g., 1973) and his coworkers provided evidence that reunion with a lost attachment figure, who may at first be treated coolly or warily, can suddenly cause a powerful upsurge in attachment behavior (e.g., crying, persistent following and clinging). The apparent "detachment," therefore, is not a simple wearing away or diminishing of the attachment bond; it is a sign of defensive suppression of attachment responses that have repeatedly failed to bring about the attachment figure's return.

Although Bowlby was primarily concerned with understanding infant-caregiver attachment, he considered adult romantic or pair-bond relationships within the same theoretical framework he used to explain infant attachment. Bowlby (1969/1982, 1980) and his colleagues (e.g., Parkes, 2006; Parkes & Weiss, 1983; Weiss, 1975) observed that adults who lose or are separated from their romantic attachment figures (e.g., a spouse) undergo a series of reactions similar to those observed in infants. As an illustration, consider the following passage from *Death's Door* (Gilbert, 2006), a book about grief and the autobiographical literature it has spawned:

In an account of his 34-year-old wife's death from breast cancer, the memoirist David Collins summarizes with poignant precision the rationale underlying

his feeling that "I wanted to die too—so I could be with her." Explaining "so freshly present she seemed [that] I had this thought: *I could follow her*," he adds, "I just wanted to go after her, not let her get away. I wanted to find her again. Hadn't I found her once [before]?" (p. 3, original emphasis)

When a separation turns into a permanent loss, the protest phase may be marked by enduring preoccupation with the missing person. It is not uncommon for people—even adults—to experience intense yearning for a lost mate, and to continue for some time to find it surprising or disquieting when aspects of the normal routine are interrupted by the attachment figure's conspicuous but still shocking absence.

The hardest thing for me, I think, is at night. We have a neighbor [who] works the second shift and we hear his pickup truck every night. And my husband would always say something like, "When's he going to get his brakes fixed?" And every night I'm sitting here when he comes along, and that's when I really think about my husband, because he would always say something. (Parkes & Weiss, 1983, p. 87)

Once the bereaved individual realizes that the partner will not be returning (which can sometimes occur even before the partner dies, if he or she has suffered a long and irrevocable decline because of a terminal illness; e.g., Bonanno, Moskowitz, Papa, & Folkman, 2005), some degree of sadness and of mental or physiological disorganization is likely. For both adults and children, this phase is characterized by sleeping and eating disturbances, social withdrawal, loneliness, and dysphoria. (In some cases, the stress may hasten the bereaved individual's own death; Hart, Hole, Lawlor, Smith, & Lever, 2007; see M. Stroebe, Schut, & Stroebe, 2007, for a review.) As Weiss (1973) noted, the feelings of loneliness stem specifically from the absence of the attachment figure and cannot be fully alleviated by the presence of others (see W. Stroebe, Stroebe, Abakoumkin, & Schut, 1996, for empirical evidence on this point). Although many bereaved individuals definitely derive comfort from the presence of close, supportive friends or family members, who can be viewed as parts of a hierarchy of attachment figures (Bowlby, 1969/1982), a support network does not necessarily fill the emotional gap left by a specific missing attachment figure. According to Bowlby, attachment bonds are person-specific and involve many memories and feelings unique to a history of interactions with that particular person.

Bowlby's (1980) writings about loss in adulthood were based on the phases of mourning observed in young children (protest, despair, and detachment). But he supplemented these phases with a new initial phase, "numbing." This phase was added because research and clinical observations indicated that mourners often fail to register the loss of the attachment figure at first, presumably because the event is too painful to accept or it seems cognitively incomprehensible. The following example describes the initial numbing reaction of a woman whose husband died suddenly and unexpectedly. At the morgue, she found it difficult to acknowledge that her husband was dead.

I didn't believe it. I stayed there for twenty minutes. I rubbed him, I rubbed his face, I patted him, I rubbed his head. I called him, but he didn't answer. And I knew if I called him he'd answer me because he's used to my voice. But he didn't answer me. They said he was dead, but his skin was just as warm as mine. (Parkes & Weiss, 1983, p. 84)

Importantly, on the basis of adults' ability to talk about their troubling experiences and to deal cognitively and emotionally with loss, Bowlby used the term *reorganization* rather than *detachment* to characterize the way people come to terms with loss. As we explain in detail later, this change is important because it reflects Bowlby's belief that many mourners do not, and do not wish to, "detach" defensively from their lost attachment figure; instead, they rearrange their representations of self and the lost figure so that a continuing bond and adjustment to post-loss circumstances are possible.

As might be expected, given Bowlby's ethological perspective on separation and loss, there is considerable evidence that grief responses are characteristic of many species, not just humans (Archer, 1999). For animals born without the capacity to care for themselves, the loss of a primary attachment figure evokes intense protest, and leads eventually to what seems to human observers to be sorrow and despair (see Bowlby, 1969/1982). For example, in one of the earliest studies on attachment in rhesus macaques, Seay, Hansen, and Harlow (1962) separated 5-month-old rhesus infants from their mothers for a 3-week period. The infants reacted at first with extreme signs of protest and agitation, including screeching and attempting to break the barriers separating them from their mothers. When these attempts failed to es-

tablish contact, the infants became lethargic and withdrawn. Such responses are also characteristic of some nonprimate species that exhibit attachment behavior (including elephants; e.g., Poole, 1996). Konrad Lorenz (1963), one of the ethologists whose work influenced Bowlby's ideas, provided an illustration of these emotional reactions in the greylag goose:

The first response to the disappearance of the partner consists in the anxious attempt to find him again. The goose moves about restlessly by day and night, flying great distances and visiting all places where the partner might be found, uttering all the time the penetrating trisyllabic long-distance call. . . . The searching expeditions are extended farther and farther, and quite often the searcher himself gets lost, or succumbs to an accident. . . . All the objectively observable characteristics of the goose's behaviour on losing its mate are roughly identical with those accompanying human grief. (pp. 200–201)

Cross-cultural research on humans also attests to the prevalence of these emotional and behavioral responses to loss (Rosenblatt, 2008; Rosenblatt, Walsh, & Jackson, 1976). As W. Stroebe and Stroebe (1987) observed, however, the specific ways in which grief is manifested vary substantially across cultures. Some societies are structured in ways that accentuate, and perhaps romanticize, the anxiety, anger, and yearning experienced after a loss. For example, Mathison (1970) described the rituals of certain Trobriand Islanders. As part of mourning, a widow is expected to cry for several days. In contrast, the display of emotion is restricted to a brief period among the Navajo. After this time, a widow is expected to return to her normal everyday activities and not to speak of the deceased (Miller & Schoenfeld, 1973). Nevertheless, despite the variability in mourning rituals observed by cultural anthropologists, the loss of a loved one appears to be very distressing in every part of the world and throughout recorded history (Rosenblatt et al., 1976).

Bowlby's Conceptualization of Disordered Mourning

Bowlby expected the majority of people who lose someone they love to experience and express negative feelings, revise and reorganize relevant internal working models, and eventually establish a satisfactory way of moving on with life. But given his clinical interests, Bowlby was also concerned

with understanding disordered forms of mourning. His analysis of these disordered forms suggested that they can be arrayed along a single conceptual dimension running from “chronic mourning” to “prolonged absence of conscious grieving” (Bowlby, 1980, p. 138).¹ Chronic mourning is characterized by protracted grief and prolonged difficulty in normal functioning. Individuals who suffer in this way may find themselves overly preoccupied with thoughts of their missing partner and unable to return to normal functioning for months or even years after the loss. In contrast, an absence of grief is characterized by a conspicuous lack of conscious sorrow, anger, or distress. According to Bowlby, individuals exhibiting this pattern may express relatively little distress following the loss, continue in their jobs or activities without any noticeable disruption, and seek little support or solace from friends and family. It was Bowlby’s belief that this manner of reacting to loss can lead to difficulties in long-term adjustment if a person has lost someone to whom he or she is deeply attached.

For a while, modern clinicians agreed with Bowlby’s description of these patterns of grief (e.g., Middleton, Raphael, Martinek, & Misso, 1993; W. Stroebe & Stroebe, 1987). According to Middleton and colleagues (1993), most clinicians distinguished between two forms of disordered mourning: chronic and delayed. *Chronic mourning* is characterized by prolonged symptoms of depression and anxiety, possibly also with aspects of post-traumatic stress disorder (PTSD). Chronic mourning might also include what some clinicians and attachment researchers call *unresolved grief* (e.g., Ainsworth & Eichberg, 1991; Main & Hesse, 1990; Zisook & DeVaul, 1985), although the precise meaning of this term varies across theorists. As we discuss later, the form of chronic mourning that Bowlby emphasized is currently generating a great deal of attention among clinicians and bereavement researchers because, in the extreme, it represents a debilitating condition.

Similar to Bowlby’s description of a prolonged absence of conscious grieving, *delayed mourning* is characterized by denial of distress and a continuation of normal affairs without substantial disruption. This category of disordered mourning is similar to what Parkes (1965) referred to as “inhibited” mourning and what Deutsch (1937) called “absent” mourning. As we discuss later, there is disagreement among contemporary bereavement scholars as to whether delayed or absent grieving is a “disordered” form of grief (e.g., Bonanno, 2009).

It is noteworthy that variants of the two

major endpoints of Bowlby’s (1980) continuum of grief patterns have been identified in multiple ways throughout the history of attachment research. In the literatures on both infant and adult attachment relationships, researchers have focused on individuals who experience intense distress after losing attachment figures and on those who apparently experience little distress following loss or separation. Although this research has not focused exclusively on irretrievable losses (e.g., death of a spouse), it provides important insights into the nature of bereavement because, according to Bowlby, the same psychological mechanisms underlie reactions to both brief and permanent separations.

One of the earliest researchers to study reactions to separation from an attachment figure was Mary Ainsworth. As Solomon and George describe (Chapter 18, this volume), Ainsworth developed the Strange Situation assessment procedure (Ainsworth, Blehar, Waters, & Wall, 1978) to investigate the interplay of attachment and exploration in a controlled laboratory setting. She and her colleagues identified three major patterns of infant–mother attachment: secure, resistant, and avoidant. Of special interest here is the fact that these patterns can be arrayed along a dimension ranging from intense and chronic distress to an absence or avoidance of distress.

Resistant infants in the Strange Situation exhibit a tendency to remain focused on their attachment figure (rather than playing wholeheartedly with attractive toys provided by the experimenter), to cry profusely during separations, and to refuse to calm down once their attachment figure returns. In other words, they exhibit a miniature version of grief, becoming extremely distressed by separation, then finding it impossible to “resolve” this distress when conditions seem to call for resolution. Avoidant infants in the Strange Situation are marked by what might be called a cool, if somewhat tense, nonchalance regarding their attachment figure’s whereabouts, and—at least in some cases—an active ignoring of her or him when the figure returns following a separation. This can be viewed as a small, short-term version of failure to become anxious, angry, or bereft in the face of loss. Secure infants fall somewhere in between the two major insecure groups, often reacting with distress to separations but also being quick to achieve resolution once their attachment figure returns.

Research on adults’ reactions to separation from or loss of attachment figures also indicates that responses can be arrayed along a conceptual dimension running from absent to chronic dis-

tress. As noted earlier, research by Parkes and his colleagues (Parkes, 1965, 2006; Parkes & Weiss, 1983) suggested that some individuals experience chronic anxiety, whereas others report little impact of the loss on their well-being. In our own research on relationship breakups (Fraley, Davis, & Shaver, 1998) and marital separations (Fraley & Shaver, 1998), we have also identified reactions falling along this dimension. Specifically, after separation from a romantic partner or spouse, some individuals report experiencing intense anxiety and depression. Moreover, naturalistic observations indicate that these individuals are likely to cling to their partners and actively resist separation (Fraley & Shaver, 1998). In contrast, some individuals appear less distressed when separated from their romantic or marital partner. They are unlikely to protest separation and appear to be relatively unaffected by it. (See Sbarra & Emery, 2005, for an intensive longitudinal investigation of the emotional sequelae of relationship dissolution; also, see Sbarra & Hazan, 2008, for an integrative overview of research on the experience of and recovery from relationship breakups and losses.)

Chronic Grief and the Organization of Attachment

One of Bowlby's key ideas was that whether an individual exhibits a healthy or problematic pattern of grief following separation depends on the way his or her attachment system has become organized over the course of development. Individuals who experience chronic grief are thought to have organized their attachment behavior around the implicit belief that attachment figures will not be consistently accessible or dependable. As Bowlby argued, these expectations have their roots in an individual's history of attachment experiences.

By persistently searching for an attachment figure and doing everything possible to prevent separation, the anxious-ambivalent individual increases the chance that he or she will be able to retain the attachment figure's attention and care. Thus, the individual's mind is organized in a way that keeps him or her chronically "searching" for cues regarding the attachment figure's availability and presence. When the attachment figure's availability is questionable, this hypervigilance manifests itself in clinginess, jealousy, and inability to focus or concentrate on other activities. In the absence of the attachment figure, however, this vigi-

lance manifests itself in persistent searching behavior, yearning, anxiety, and depression. Because the mind has become organized to detect cues of unavailability or unresponsiveness, a real loss continues to prime the attachment system, making extreme anxiety and sorrow difficult to avoid.

Following bereavement, adults characterized as insecure, dependent, anxious, or fearful are often those who suffer from chronic mourning (Parkes & Weiss, 1983). Parkes (1965; Parkes & Weiss, 1983) described the "grief-prone personality," a construct modeled after Bowlby's description of anxiously attached individuals and empirically associated with poor outcomes in Parke's studies. These individuals were intensely anxious, yearned deeply for their lost spouses, and had extreme difficulty in adjusting to prior losses.

The Absence of Grief and the Organization of Attachment

Bowlby (1980) believed that the prolonged absence of conscious grieving was a defensive reaction to loss, one that has the potential to break down and give rise to intense feelings of grief and sorrow. He also entertained the possibility that the suppression of grief can have adverse effects on physical health, as illustrated by the example of Charles Darwin that opens this chapter.

According to Bowlby, the relative absence of grief exhibited by some individuals following loss is a facet of a more general pattern of personality organization, which he called "compulsive self-reliance." He believed that that compulsive self-reliance stems from early attachment experiences in which the expression of emotion was discouraged: "Not infrequently, it seems, a person who grows up to assert his independence of affectional ties has [grown up in a context where] affectional bonds are little valued, attachment behavior is regarded as childish and weak and is rebuffed, all expression of feeling is frowned upon and contempt expressed for those who cry" (1980, pp. 224–225). Bowlby believed that, over time, such experiences can lead an individual to assert his or her independence and self-sufficiency, even in situations involving permanent losses.

In Chapter 4 of *Loss*, Bowlby (1980) offered a sophisticated account of the defense mechanisms that may regulate an individual's experience of grief and sorrow, and explained why these mechanisms may pose problems for psychological well-being. He believed that the process of *defensive*

exclusion—a deliberate or automatic redirection of attention away from painful thoughts and feelings about the loss—can eventually lead to the development of dissociated memory systems for the loss experience. Because these memories still exist, albeit in an unintegrated form, they can continue to influence emotion and behavior without the person understanding how or why.

Bowlby believed that people who fail to acknowledge the implications of a loss have the potential to be vulnerable to subsequent physical and psychological distress for two reasons. First, if representations of the experience become relatively dissociated from other representations in memory, people may have a difficult time sensitizing themselves to the events and thoughts surrounding the loss; they tend not to work through the walled-off memories and expectations. Because the dissociated representations are infrequently activated, it is difficult to habituate naturally to the emotions associated with them. When this is the case, it may take no more than subtle, but personally meaningful, stimuli to reactivate representations of the attachment or the loss and to bring about feelings of anxiety and distress. As an example, Bowlby noted that individuals who fail to express grief in the early months of bereavement may break down when an anniversary takes place or when some other reminder of the attachment figure summons to mind fragmented memories and feelings for the deceased. For a less defensive individual, these events may not elicit heightened distress because the meaning of the events and their connections to other aspects of the individual's life have been integrated into current representations of the world. For the defensive person, in contrast, these unintended reactions have the potential to be disarming or disorienting.

Bowlby also believed that dissociated or segregated memory systems can lead to long-term physical or psychological distress because their partial activation continues to prime the attachment system—a theme that is reemerging in recent models of bereavement (see Maccallum & Bryant, 2013). For example, seemingly mundane events, such as making dinner, can elicit stressful reactions and tax a person's physical resources if those activities were previously organized around the now-deceased attachment figure. A bereaved individual, however, may not recognize the source of these reactions if he or she has not fully acknowledged the loss or come to recognize the loss-related meaning implicit in these activities. Repeated activation of inexplicable and partially

suppressed negative emotions may eventually have a negative impact on psychological or physical well-being.

Current Research Issues and Perspectives

Stages of Grief

One controversy that continues to hold a visible place in the bereavement literature concerns the extent to which people move through discrete phases or stages of grief. Critics of stage models have often identified Bowlby as an advocate for these models due to the fact that he called attention to the phases of numbing, protest, despair, and reorganization (e.g., Klass, Silverman, & Nickman, 1996; Wortman & Boerner, 2007). As several researchers have observed, however, the stage model does not seem to characterize the mourning process adequately (Wortman & Boerner, 2007). Some people, for example, seem to move in and out of various phases over the course of bereavement. Moreover, there appears to be considerable variation in how people respond to loss, both cross-culturally and at the level of individual differences. These kinds of observations have led several scholars (e.g., Wortman & Boerner, 2007) to reject the stage model and to seek alternative ways of understanding the bereavement process (e.g., Neimeyer, 2012).

Although we agree that overly rigid interpretations of stage models have been influential in popular culture (see Konigsberg, 2011, for a discussion), it is a mischaracterization of Bowlby's views to associate him with a rigid stage perspective. It is clear from Bowlby's writings that he believed that there are different phases of mourning, and that some phases (e.g., numbing) are more likely to peak shortly after a loss rather than later. But Bowlby clearly did not believe that people needed to pass through one phase before entering another. Nor did he believe that these phases were mutually exclusive, such that a person experiencing a yearning for his or her partner could not also be experiencing despair, loneliness, and depression. For example, in his 1980 volume he wrote, "Admittedly these phases [of numbing, protest, despair, and reorganization] are not clear cut, and any one individual may oscillate for a time back and forth between any two of them" (p. 85). The reason Bowlby called attention to these phases is that he viewed them as reflecting different functions with-

in his ethological framework. Protest responses, for example, represent attempts to reunite with a missing attachment figure. And reorganization reflects the challenging process of trying to make sense of the world and one's place in it without the lost attachment figure. When viewed from this perspective, the adaptive function of the phases discussed by Bowlby can be better appreciated.

In short, the phases Bowlby (1980) described were attempts to characterize the way in which people tend to experience separation and loss. Most of the data he drew upon came from samples of relatively young people from North America, Australia, and Great Britain, and he acknowledged the limitation of such data for generalizing beyond those samples (pp. 84–85). Although some scholars find it convenient to associate Bowlby with a rigid stage perspective (e.g., Holland & Neimeyer, 2010), we believe that doing so undermines his emphasis on the function of these responses and ties him to a particular perspective that was foreign to him.

Complicated Grief and The DSM

Recent research suggests that the majority of bereaved individuals experience negative emotions, physiological disorganization, and health problems to only a modest or moderate degree, and that they react with considerable acceptance and resilience (Bonanno, 2004; Bonanno et al., 2002, 2005). Nevertheless, about 10–15% of individuals suffer more extreme grief reactions (Bonanno & Kaltman, 2001; Lichtenthal, Cruess, & Prigerson, 2004). In recent years, one of the most active areas of research in the study of bereavement has been concerned with understanding these extreme grief reactions and identifying ways to define, measure, and treat complicated or prolonged grief. This work is especially pertinent to Bowlby's theory because of his emphasis on chronic grief and his attempts to understand its origins.

The fourth, text revised edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR; American Psychiatric Association, 2000) classified negative reactions to bereavement under such rubrics as depression, PTSD, or adjustment disorders. To the extent that normal grieving does not involve reactions extreme enough to warrant a clinical label or clinical intervention (Bonanno, 2004), it seems important to distinguish normal grieving from more extreme reactions. As such, there has been a substantial amount

of discussion and debate about how to define and measure such reactions and whether complicated grief reactions warrant their own DSM diagnostic classification (Prigerson et al., 2009; Shear et al., 2011; M. Stroebe et al., 2000).

Debates about the boundaries of complicated grief and its status as a psychological disorder became especially pronounced in the years leading up to the publication of DSM-5 in 2013. Two issues, in particular, captivated much scholarly attention among bereavement researchers. The first was the controversial removal of the “bereavement exclusion” (BE) that was present in the previous two DSM editions. The BE holds that an individual should not be diagnosed as having a depressive disorder if he or she has recently lost a loved one. The rationale for this exclusion is that depressive symptoms are common following loss and may not be indicative of a psychological disorder that requires intervention. As Shear and colleagues (2011) note, the BE was designed to limit overdiagnosis of depression. But the proposed (and eventual) removal of the BE from the DSM-5 generated considerable controversy. Some writers—especially those in the popular media—perceived it as an attempt to pathologize bereavement (Adler, 2012). But others defended the revision, noting that the removal of the BE does not compel clinicians to diagnose a bereaved person as having major depressive disorder (MDD); instead, the removal of the BE provides an opportunity to ensure that someone who might need additional treatment has the opportunity to obtain it. Removal of the BE has the potential to be useful because loss is a significant life stressor and can potentially be a trigger for MDD among those with an existing vulnerability (Bowlby, 1980). Moreover, removal of the BE seems appropriate from an attachment-theoretical perspective on loss because although grief itself is a natural response to the loss of an attachment figure, it has the potential to become crippling and to interfere with adaptation. In such cases, it would be useful for those experiencing complicated grief to get treatment.

The second major issue concerns whether complicated grief itself merits its own diagnostic category. Although some scholars have been making a case for the new category for decades (e.g., Horowitz et al., 1997), there was an especially large amount of work on this topic in anticipation of DSM-5. Shear and colleagues (2011) observed that complicated grief meets many of the criteria that are commonly used to identify psychological disorders. For example, one of the consequences

of complicated grief is clinically significant distress or disability. Moreover, complicated grief appears to be distinct from other psychological disorders, such as MDD and PTSD. People experiencing MDD, for example, often have profound feelings of self-doubt and low efficacy. In contrast, self-esteem is not typically impaired among those suffering from prolonged grief.

Researchers who advocate a separate diagnostic category for complicated grief have developed inventories, such as the commonly used Inventory of Complicated Grief (ICG; Prigerson et al., 2009), which can be used for both research purposes and diagnostic purposes. Moreover, several recommendations exist on how to classify a person as suffering from complicated grief (Forstmeier & Maercker, 2007; Horowitz et al., 1997; Prigerson, Vanderwerker, & Maciejewski, 2008; Shear et al., 2011). Prigerson and colleagues (2009), for example, proposed that people be classified as experiencing complicated grief if they have the following symptom set: severe yearning at least 6 months following the loss of a loved one, as well as five of nine other symptoms: emotional numbing, being stunned, feeling life is meaningless, mistrust of others, bitterness, difficulty accepting the loss, identity confusion, avoidance of the reality of the loss, and difficulty moving on with life.

Factor-analytic studies support the claim that complicated, prolonged grief is separable from depression and anxiety (e.g., Boelen, van den Bout, & de Keijser, 2003; Ogrodniczuk et al., 2003; Prigerson et al., 1996). A few studies have shown that various indicators of adjustment—psychological, behavioral (e.g., friend or observer reports), and physiological—are predicted by measures of complicated or prolonged grief, even after researchers statistically control for scores on measures of other clinical conditions, such as depression and PTSD (e.g., Bonanno et al., 2007; Simon et al., 2007). In short, much of the empirical research on these issues seems consistent with the notion that complicated grief (1) can be debilitating, (2) is not isomorphic with depression and anxiety, and (3) may be treatable using interventions that target the lost relationship and the feelings people have regarding the loss (e.g., Sandler et al., 2008).

Despite the advocacy for complicated grief as a DSM diagnostic category, complicated grief was not, in fact, included in the 2013 revision of the DSM. (It was discussed in the Appendix but not formally recognized as a diagnostic category.) We suspect that many researchers will continue to fight for its inclusion in future revisions. The World

Health Organization is currently developing the *International Classification of Diseases*, version 11. One of the proposed additions is prolonged grief disorder (Maercker et al., 2013), defined in ways that are highly similar to other characterizations of complicated grief.

The Absence of Grief

Another theme that we highlighted in the 1999 and 2008 editions of this chapter, absence of grief, continues to be salient in bereavement research. When Bowlby was originally formulating his thoughts on attachment and loss, there were relatively few large-scale empirical studies available on the topic, and much of his inspiration regarding absent grief came from clinical case studies on loss, such as those by Deutsch (1937).

This is important because contemporary bereavement researchers have highlighted the numerous limitations of trying to understand various forms of grieving, such as relative absence of grief, using clinical case studies and nonprospective designs. One such limitation is that cases often come to the attention of clinicians and health care workers because a bereaved client is struggling emotionally or interpersonally; that is, the outcome (e.g., difficulties with depression or anxiety) is already known. It is tempting in such circumstances to conclude that the relative lack of grief symptoms at a prior point in time may have been a predictor of pathology on the client's part. But the counterfactual is missing. Without an estimate of the proportion of people expressing a relative lack of grief symptoms that do not come to the attention of clinicians or health care workers, there is no basis for assuming that the absence of grief is a prospective indicator of adjustment difficulties post-loss. Another limitation is that much of the early research that inspired Bowlby was not based on prospective designs. It often drew on retrospective accounts (which may be of questionable accuracy) and did not allow individuals' long-term outcomes to be tracked.

One of the important features of recent bereavement research is the use of prospective designs and nonclinical populations (e.g., Carnelley, Wortman, Bolger, & Burke, 2007). This is crucial for our purposes because it enables researchers to examine the long-term outcomes of people who express relatively few symptoms of grief, depression, and anxiety shortly after the loss of a loved one. Bonanno and his colleagues have done some

of the most important work in this area (for reviews, see Bonanno, 2009; Wortman & Boemer, 2007). One of the key contributions of this work is the documentation of heterogeneity in the ways people respond and adapt to loss. To appreciate the richness of the various patterns, it is useful to consider grief symptoms at two points in time: shortly after a loss and again months later. When the severity of grief symptoms is crossed with time, four potential bereavement trajectories emerge (see Figure 3.1).

The first, what Bonanno and his colleagues (e.g., Bonanno, 2009) call *common grief*, is characterized by high levels of grief shortly after the loss, followed by a gradual decline in grief-related symptoms over time. In many respects, this is the prototypical form of grief observed in Western cultures. Another potential pattern, *chronic grief*, is characterized by elevated grief symptoms across time. Individuals exhibiting this pattern are highly likely to meet the diagnostic criteria for complicated grief (see Prigerson et al., 2009). Another theoretical pattern is characterized by low levels of symptoms at both time points, a pattern that Bonanno and his colleagues call *resilience*. A final pattern characterizes people who exhibit few

symptoms early on, but show elevated symptoms at a subsequent assessment. Bonanno and his colleagues call this pattern *delayed grief*, which is expected if the relative lack of grief in the early phases of loss is a risk factor for the development of symptoms later on (Bonanno & Field, 2001).

One of Bonanno's important findings is that individuals who express relatively few symptoms of grief shortly after a loss are also likely to express relatively few, rather than more, symptoms later on. That is, the resilient pattern is relatively common in empirical studies, whereas the delayed pattern rarely occurs (e.g., Bonanno et al., 2002). People who show a relative absence of grief 3 months post-loss, for example, are much more likely to continue to show few grief symptoms months down the road.

What are the implications of these findings for Bowlby's ideas on the absence of grief? We believe that these studies convincingly demonstrate that people who are not suffering from extreme symptoms of grief shortly after a loss are unlikely to be suffering from those symptoms at a later point in time. Moreover, we believe that Bonanno's work does a service to the field by demonstrating that when people appear not to be "suffering enough,"

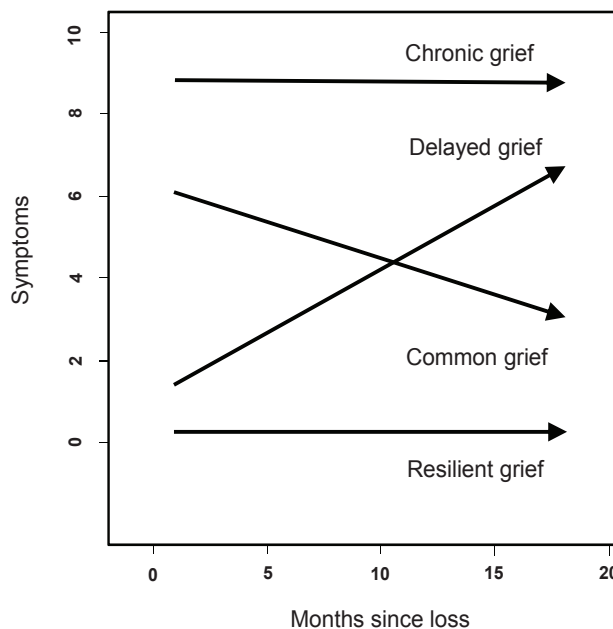

FIGURE 3.1. Prototypical patterns for bereavement. From Fraley and Bonanno (2004). Copyright 2004 by Sage Publications, Inc. Adapted by permission.

according to friends and family, it does not mean that they are grieving “incorrectly.” In fact, one of the key contributions of Bonanno’s work is its demonstration that it is quite common to exhibit resilience following a loss. Yet the norms in Western culture can lead bereaved individuals to wonder whether they are doing something wrong if they are not grieving enough.

Having said this, we should add that some writers have been too quick to dismiss Bowlby’s ideas in light of the finding that the relative absence of grief is a predictor of long-term adaptation. There are two important ideas in Bowlby’s writings that suggest that these dismissals may be premature. First, in Bowlby’s discussion of the absence of grief, he was largely concerned with what we refer to as *off-diagonal* cases. To better explain this idea, consider Figure 3.2, which presents a 2 × 2 table that classifies people with respect to two factors: (1) the expression of grief shortly after a loss (low vs. high) and (2) long-term psychological outcome (negative vs. positive). Based on Bonanno’s research, it seems that there is a moderate negative association between these factors. That is, people who are most visibly distressed by loss are less likely than those who are not to exhibit signs of psychological adjustment later in time (Cell A). Similarly, those who are less visibly distressed by loss are more likely than those who are more visibly distressed to exhibit better psychological adjustment later in time (Cell D).

In his discussion of the absence of grieving, Bowlby was not claiming that there is a positive association between these variables, such that people who fail to express grief shortly after loss will be at greater risk for psychological maladjustment than those who express extreme distress shortly after loss. Indeed, he was aware of the evidence that one of the best predictors of poor outcomes later in time is poor outcomes shortly after loss (Bowlby, 1980, p. 148). Bowlby was calling attention to the fact that there are people on the off-diagonal of Figure 3.2—people who do not report symptoms of grief shortly after a loss but who nonetheless exhibit poor adjustment in the long run (e.g., Cell C). The important message for Bowlby and other clinicians was this: Just because someone is expressing relatively few symptoms of grief shortly after the loss of an attachment figure does not mean they will adapt smoothly to the loss. Some of these individuals may be suppressing the expression of their grief and, if so, there is a chance that those defenses will break down at

some point and reveal more clearly the impact of the loss on the individual’s emotional functioning.

The second point is that Bowlby was concerned primarily with the *absolute* absence of grief rather than with the fact that some people grieve less than others. Bonanno’s focus, in contrast, is individual differences in, or *relative ranks*, with respect to grieving. The individuals who are classified as resilient in Bonanno’s taxonomy are not showing an initial “absence” of grief, absolutely speaking. Instead, relative to others, their grief is less intense and less debilitating. Indeed, Bonanno is careful to note that people who are not grieving strongly are not simply unaffected by the loss; they are simply managing the loss in a way that enables them to move forward in adaptive ways. That is, they seem relatively secure from an attachment-theoretical perspective (Fraley & Bonanno, 2004).

One question that remains is whether people who exhibit Bonanno’s resilient profile are homogenous in their psychological functioning. In the case of young Darwin, for example, it seemed clear to Bowlby that Darwin harbored great pain following the loss of his mother. But Darwin did not feel that he could express those feelings to others, at least not without being reprimanded. This strikes us as a form of absence of grief that is quite different from what might be observed if, in fact, someone was relatively resilient and able to move forward with life tasks without becoming overwhelmed. Similarly, both of these forms of grief seem different from what might result if a person was not deeply attached to the person who was lost.

Thus, our intuition is that people who exhibit a resilient pattern following a loss may represent a mixture of subpopulations. The majority, in fact, may be managing the loss relatively well. They may be deeply affected by it, but are finding meaning in their lives, continuing forward with life goals, and not getting submerged in the painful feelings that can result from loss. But some may not have been given the opportunity to grieve in the way they felt necessary (see Doka, 2008, for an interesting discussion of “disenfranchised” grief). And some who exhibit this pattern may have lost someone who was not a central figure in their lives or in their identities.

Although Bowlby thought that the absence of grief was sometimes a defensive reaction to covert distress, he also noticed that there are exceptions to this pattern. Consider the following quotations from *Loss* (Bowlby, 1980):

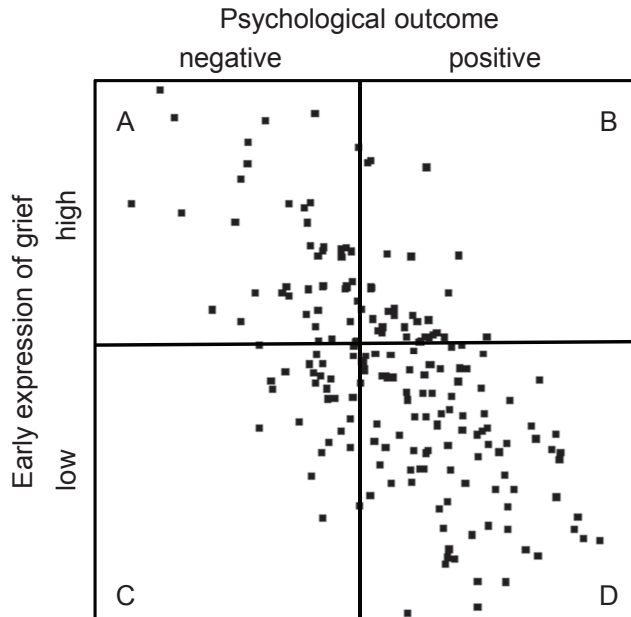

FIGURE 3.2. The consideration of “off-diagonal” cases in discussions of the absence of grief.

Some of those who proclaim their self-sufficiency are in fact relatively immune to loss. (p. 213)

Not everyone [characterized by an assertion of independence of affectional ties] develops a highly organized personality, however. In many the hardness and self-reliance are more brittle and it is from amongst these persons, it seems likely, that a substantial proportion of all those who at some time in their life develop a pathological response to loss are recruited. (p. 225)

Some individuals having this disposition [of compulsive self-reliance] have made such tenuous ties with parents, or a spouse or a child that, when they suffer loss, they are truly little affected by it. (p. 211)

Individuals disposed strongly to assert their self-sufficiency fall on a continuum ranging from those whose proclaimed self-sufficiency rests on a precarious basis to those in whom it is firmly organized. (p. 211)

The more frequently a child is rejected or experiences a separation, moreover, and the more anxious and distressed he becomes the more frequent and painful are the rebuffs he is likely to receive and the thicker therefore will grow his protective shell. In some persons, indeed, the shell becomes so thick that affectional relationships are attenuated to a point at which loss ceases almost to have significance. Immune to mourning they may be; but at what a price! (p. 240)

These quotations reveal two trends in Bowlby’s thinking. They suggest that he thought some people who exhibit an absence of grief are truly unperturbed by loss, or are at least less perturbed than others, because (1) they have never established a close, emotional attachment to their partners in the first place; and/or (2) their defenses have become so “thick,” or highly organized, that it is possible to defensively regulate their emotions fairly effectively.

Research and theory concerning infant–caregiver attachment has generally adhered to the idea that almost all infants become emotionally attached to their primary caregivers. Therefore, following separation or loss, avoidant behavior on the part of infants involves the suppression of *true* feelings of rejection and distress. In adult romantic relationships, however, we may encounter a kind of defensive process that does not normally unfold in the context of infant–caregiver relationships. Specifically, an adult can avoid becoming attached to his or her romantic partner, even in the course of an extended relationship. When the relationship ends, such a person may not experience intense anxiety and sorrow; moreover, few long-term difficulties should be encountered in such a case because the loss is not deeply traumatic.

Recall that Bowlby believed that part of the recovery process entails rearranging one's representations of the world in a way that integrates the reality of the loss with one's implicit assumptions about the world. People vary, however, in the extent to which their assumptions about the world are organized around their relationship partners. When a person is relatively unattached to his or her partner, the relationship will be less important to his or her sense of well-being and security. The partner or the partnership will not be a valued aspect of the self, and the person's memories and goals will not be extensively organized around the partner. The absence of distress in these cases may reflect a true absence of grief and not just a defensive disguise of painful feelings.

We expand on these issues in the next section, where we review some of the recent empirical research on responses to loss and on individual differences in attachment organization. Here, however, we note that Bowlby suggested that the kinds of defensive strategies people use to regulate attachment-related experiences and behavior have not only the potential to be dysfunctional but may also reflect, in some people, a chronic pattern of nonengagement, one that has the potential to blunt their interpersonal experiences and cause pain to their relationship partners and families. This important "side effect" should be added to what Bowlby had in mind when he exclaimed, "At what a price!" In other words, although these individuals may not experience debilitating symptoms of grief at any point following a loss; that is, because of their defensive strategies, such individuals are of clinical interest because their defenses may be preventing them from building relationships that are emotionally and personally meaningful and rewarding for their relationship partners.

Research on Attachment Styles and Reactions to Loss

A key component of Bowlby's theoretical analysis was that the ways in which people mourn, and the degree to which these patterns are adaptive in the long run, can be understood partly in terms of their attachment histories. Specifically, Bowlby (1980) thought that adults with anxious attachment histories (i.e., histories of insecurity, inconsistent care, and persistent frustration of attachment-related needs) would be more likely to exhibit prolonged or chronic grief, whereas individuals for whom attachment-related needs had

been consistently rebuffed or rejected would be more likely to express few overt signs of grief.

In the late 1980s, a number of researchers began to develop taxonomies of individual differences in attachment organization for adults (e.g., Hazan & Shaver, 1987; Main, Kaplan, & Cassidy, 1985). Hazan and Shaver (1987), for example, proposed a three-group taxonomy involving security, avoidance, and anxious-ambivalence, based on the patterns of attachment that had been documented by Ainsworth and her colleagues using the strange situation paradigm (Ainsworth et al., 1978; for a review, see Fraley & Shaver, 2000). When Bowlby's ideas are considered in the context of Hazan and Shaver's three-category model, the theoretical links between attachment organization and grief are clear: Secure individuals should be distressed by the loss of a loved one but find it easier than others to adapt to the loss. Anxious-ambivalent or preoccupied individuals should exhibit a pattern characterized by chronic grief, whereas avoidant individuals should show an apparent absence of overt grief symptoms (see Field & Sundin, 2001; Shaver & Tancredy, 2001; Wayment & Vierthaler, 2002).

Contemporary research on bereavement in adults has begun to examine Bowlby's ideas concerning individual differences (e.g., Mikulincer & Shaver, 2008). There is growing evidence that individuals who are high in attachment-related anxiety are more likely than those who are low in anxiety to have complicated grief reactions (Field & Sundin, 2001; Fraley & Bonanno, 2004; Wayment & Vierthaler, 2002). For example, Field and Sundin (2001) found that anxious attachment, assessed 10 months after the death of a spouse, predicted higher levels of psychological distress 14, 25, and 60 months after the loss. More recently, Meier, Carr, Currier, and Neimeyer (2013) examined prolonged grief symptomology in a sample of 656 bereaved young adults. They found that attachment-related anxiety was associated with grief symptoms, even after they controlled for loss-related circumstances (e.g., relationship to the deceased, violent vs. nonviolent loss). Conceptually similar findings were reported by Waskowic and Chartier (2003), Wayment and Vierthaler (2002), and Wijngaards-de Meij and colleagues (2007).

How do avoidant people fare in response to loss? This particular issue is more challenging to address because theoretical models of avoidance have evolved over time. In the early 1990s, Bartholomew introduced an alternative model of individual differences that makes a critical distinc-

tion between different kinds of avoidant strategies (see Bartholomew & Horowitz, 1991). Specifically, Bartholomew distinguished between fearful-avoidant and dismissing-avoidant attachment patterns. According to Bartholomew, fearfully avoidant adults, while organizing their behavior in a defensive manner, tend to do so as an attempt to quell their insecurities. Because they are explicitly afraid of being hurt or rejected, they avoid opening up to others and try to avoid becoming emotionally invested in them. The avoidant strategies of dismissing individuals, in contrast, appear to be organized around the goal of self-reliance or independence. Although dismissing individuals may avoid opening up to and depending on others, it is because they consciously see little need to forge close emotional bonds with others, not because they consciously fear being hurt. Theoretically, this strategy is motivated by a history of rejection, but consciously it is rooted in a desire to be autonomous and self-reliant.

Importantly, Griffin and Bartholomew (1994) argued that these theoretical “prototypes” can be arrayed along two conceptual dimensions that researchers have come to call *attachment-related anxiety* and *attachment-related avoidance* (see Fraley & Shaver, 2000; Mikulincer & Shaver, 2007). This first dimension captures variation in the degree to which people are vigilantly attuned to attachment-related concerns (Fraley & Shaver, 2000). A highly anxious person, for example, may worry that his or her attachment figure is unresponsive, whereas a less anxious person may feel relatively secure about attachment-related matters. The second dimension captures variation in people’s tendencies to use avoidant versus proximity-seeking strategies to regulate attachment-related behavior, thought, and feeling. People on the high end of this dimension tend to withdraw from intimacy in close relationships, whereas people on the low end of this dimension are more comfortable opening up to others and relying on others as a safe haven and secure base (Fraley & Shaver, 2000).

The classic Hazan and Shaver categories, as well as Bartholomew’s four theoretical prototypes, can be viewed as linear combinations of these two dimensions (see Griffin & Bartholomew, 1994). For example, a prototypical fearful individual is relatively attentive to attachment-related concerns (i.e., is high on the anxiety dimension) and typically employs avoidant strategies to regulate his or her feelings and behavior (i.e., is high on the avoidance dimension). By contrast, a proto-

typically dismissive individual also employs avoidant strategies but is less attentive to or downplays attachment-related concerns (i.e., is low on the anxiety dimension). A prototypically secure individual is low on both of these dimensions.

One of the valuable features of this two-dimensional model is that it distinguishes different kinds of defensive patterns. The classic Hazan and Shaver conception of avoidance implied that avoidance stems from conscious insecurities, thereby conflating dismissing-avoidance with fearful-avoidance (see Fraley & Shaver, 2000). However, once the distinction between different forms of avoidance is recognized, it can be seen that the association between these forms of avoidance and grief reactions may be more nuanced.

Theoretically, the two-dimensional model implies that attachment-related anxiety is the primary driver of complicated and severe grief. This hypothesis is based on the assumption that the control systems underlying attachment-related vigilance, which are tapped by measures of the anxiety dimension, may produce maladaptive grief responses (see Fraley & Shaver, 2000). Theoretically, highly anxious people are more vigilant and insecure regarding the psychological accessibility and availability of their loved ones. Thus, when their loved one is missing, they should not only experience distress but that distress should also be triggered more easily by day-to-day reminders (both physical and psychological) of the loved one’s absence. Over a period of time, the repeated activation of these stressful emotions, coupled with the failure of attachment behavior to reunite the person with his or her loved one, may heighten feelings of distress, hopelessness, and despair.

This two-dimensional model suggests that avoidance, by itself, may not lead to difficulties adjusting to a loss. Fraley and colleagues (1998), for example, argued that avoidant strategies of emotion regulation (e.g., withdrawing from situations that make one feel vulnerable) can be just as effective as proximity-seeking strategies (e.g., turning to others for support or comfort) in regulating attachment-related distress. According to Fraley and colleagues, avoidant individuals sometimes appear vulnerable because researchers do not always distinguish between fearful-avoidance and dismissing-avoidance, thereby conflating attachment-related anxiety and avoidance. Once the distinction is made between different patterns of avoidance, it is reasonable to expect some avoidant individuals (i.e., those who are fearfully avoidant) to have difficulty adjusting to loss because they are highly anxious with respect

to attachment concerns, but we might expect other avoidant individuals (i.e., those who are dismissingly avoidant) to have less difficulty adjusting to loss because they are not as anxious with respect to attachment concerns.

What does the empirical research indicate? Relatively few bereavement studies have attempted to assess attachment-related anxiety and avoidance independently. Among those that have, however, the evidence is mixed. Fraley and Bonanno (2004) studied a sample of 59 bereaved individuals, assessing attachment style shortly after the loss and examining symptoms of grief, depression, and PTSD at 4 and 18 months post-loss. Replicating previous findings (e.g., Field & Sundin, 2001; Wayment & Vierthaler, 2002), they found that attachment-related anxiety predicted elevated levels of depression, grief, and PTSD across time. But they also found that individual differences in attachment-related avoidance were not related to negative outcomes. In the context of Bartholomew's model, then, this implies that adjustment was most challenging for avoidant people who were fearfully avoidant. But those who were dismissingly avoidant showed patterns of adaption that were comparable to those who were secure. This implies that defensive strategies were not effective among fearfully avoidant individuals, but may have been effective among dismissingly avoidant individuals.

In a more recent study, Jerga, Shaver, and Wilkinson (2011) examined self-report data from 368 adults who completed an online survey measuring their attachment style, relationship characteristics, loss circumstances, and grief symptoms. Consistent with other findings regarding anxiety, they found that attachment-related anxiety was associated with prolonged grief symptoms. They also found, however, that people who were generally more avoidant were more likely to report long-term difficulties in adjusting to loss. When considered in the context of Bartholomew's model, this implies that the avoidant people who experienced the most severe distress were fearfully avoidant. Dismissing-avoidant individuals, by comparison, experienced fewer disruptions in functioning (but were not as resilient as those who were secure). Similar findings were reported by Boelen and Klugist (2011), who found that both anxiety and avoidance were correlated concurrently with complicated grief symptoms in a sample of 438 bereaved individuals.

Mancini, Robinaugh Shear, and Bonanno (2009) found that marital adjustment may mod-

erate the association between avoidance and complicated grief in a sample of individuals who had lost their spouses. They found a three-way interaction among attachment-related anxiety, avoidance, and marital adjustment, indicating that dismissing individuals had low levels of grief symptoms if they reported high marital functioning. However, among dismissing individuals who reported low marital functioning, grief symptoms were as high as those of fearful and preoccupied (anxious but not avoidant) individuals.

In their important study, Meier and colleagues (2013) compared a subgroup of individuals who had experienced a violent loss with a control group that was not bereaved. They found that the general health of the nonbereaved individuals was better than that of the bereaved ones, but more importantly, that avoidance was negatively correlated with health in the bereaved group. This suggests that especially stressful or traumatic events might undermine the utility of avoidant strategies that in other circumstances might function relatively effectively (see Mikulincer & Shaver, 2008, for an in-depth discussion of this point). Similar findings were reported by Fraley, Fazzari, Bonanno, and Dekel (2006), who studied stress and coping in a sample of individuals who survived the World Trade Center attacks in 2001. Fraley and colleagues found that highly avoidant individuals had elevated levels of PTSD and depressive symptoms compared to secure individuals. Again, this context was an extremely traumatic one and may have revealed some vulnerabilities that may not be evident under less threatening circumstances. (For further evidence that cognitive and emotional loads can render avoidant defenses unsuccessful, see Berant, Mikulincer, & Shaver, 2008; Mikulincer, Dolev, & Shaver, 2004.)

What are the implications of these findings for Bowlby's ideas about attachment organization and reactions to loss? First, these findings suggest that people who are relatively secure adapt to loss with the fewest complications. They exhibit symptom patterns that overlap with both the common grief and resilient patterns reviewed previously (e.g., Bonanno, 2009). Second, the data consistently indicate that people who are relatively high in attachment-related anxiety are at greater risk of experiencing severe symptoms of grief, depression, and anxiety—the kinds of indicators that are found in complicated grief in recent diagnostic systems. Third, these data, combined with contemporary models of individual differences in attachment organization, lead to some important nuances in

the way we understand avoidance and loss. On the one hand, some forms of avoidance are linked to difficulties in adjustment because of their overlap with anxiety. That is, fearfully avoidant individuals, despite their avoidant tendencies, are likely to experience high levels of dysfunction following loss. But those who are relatively dismissing are not necessarily likely to experience severe emotional disruptions. The evidence concerning whether dismissing individuals function at levels comparable to secure individuals is not yet entirely clear, but, in either case, it seems safe to suggest that avoidance, in and of itself, is not an unambiguous predictor of disruption following loss.

Continuing Bonds: A Controversy Concerning Detachment and Resolution

A dramatic challenge to Bowlby's account of loss appeared in *Continuing Bonds: New Understandings of Grief* (Klass et al., 1996). The authors of that anthology claimed that the modernist emphasis on extreme individualism and mechanistic science mistakenly led Freud and Bowlby to view mourning as a biological, rigidly sequenced process with a fixed healthy endpoint: *decathexis* or *detachment*, defined by Klass and colleagues as complete severance of the emotional bond to a lost attachment figure. In the first edition of this chapter (Fraley & Shaver, 1999), we examined the evidence and rationale for this "postmodern" position and found it wanting—partly because it unfairly caricatured Bowlby's views, and partly because it ignored the possibility of unresolved grief associated with fearful or disorganized attachment. Nevertheless, we credited some of the book's insights and showed how they might be incorporated into attachment theory. We carried this discussion forward in our chapter in the 2008 second edition of this volume.

Since that last edition, the discussion of *Continuing Bonds* in the bereavement literature has waned to some extent. Thus, our goals here are to bring the issue to the attention of new readers and briefly highlight some recent research that speaks to the conditions under which continuing bonds with the deceased can be beneficial.

What Did Bowlby Say about Continuing Bonds?

Some writers have claimed that Bowlby advocated an abrupt and complete detachment from a lost at-

tachment figure. Bowlby (1980), however, reacted against that recommendation. Instead, he argued that the grief reactions that many clinicians apparently viewed as immature or pathological—searching, yearning, and sometimes expressing anger or ambivalence toward the lost attachment figure—are normal aspects of the functioning of the attachment system. It was part of Bowlby's general approach to attachment phenomena to be sympathetic to people of any age, and in any circumstances, whose attachment behavioral system was activated by distress or by unavailability or loss of an attachment figure.

Even Freud, at least in his personal correspondence, did not agree with the position that subsequent writers attributed to him. In our view, the notion of decathexis from mental representations of a lost attachment figure, when stripped of its outdated theoretical language (concerning the investment and disinvestment of psychic energy), refers to a commonly experienced emotional reaction when one suddenly remembers a deceased attachment figure and realizes once again that he or she is gone. This often happens when one has a glancing thought or memory of the deceased person and is jolted by the realization that the thought or related expectation is no longer appropriate. This can occur scores or hundreds of times over many weeks or months and is a normal part of coming to terms with a loss that is not yet fully represented in all of one's unconscious and preconscious memories. As elements of "internal working models" of the lost attachment figure are called up unexpectedly (by situations or associations), altered to acknowledge the loved one's death, and forgotten again as one returns to current activities and concerns, the emotional charge associated with them typically decreases—partly by virtue of habituation and desensitization, partly by virtue of being reorganized into more realistic, updated working models (Shaver & Tancredy, 2001). But this does not mean that the bereaved person's attachment to the lost figure is erased from memory; far from it.

Some of the misunderstandings concerning Bowlby's position might be due to his use of the term *detachment*, which was originally coined to describe a defensive reaction to the return of a temporarily absent attachment figure. When infants are separated from their attachment figures, they protest before eventually exhibiting sadness. Eventually they seem to recover and begin to explore their environments with renewed interest; they seem once again to be interested

in other people. However, if an absent attachment figure returns, Bowlby (1969/1982) noted that many children respond with coolness and an absence of attachment behavior, as if they are punishing the attachment figures for abandoning them or are unsure how to organize their conflicting desires to seek comfort and express anger. Bowlby emphasized that this defensive response is best described as “apparent” detachment because once the children reaccept their attachment figure’s care, they are particularly clingy and hypervigilant, not wanting to let the figure out of sight.

In contrast, when discussing bereavement, Bowlby used the term *reorganization* rather than *detachment*. It was not his belief that, as part of the process of adapting to loss, a person needs to detach from his or her loved one. Indeed, for Bowlby, part of the process of reorganization involved finding ways to integrate the loved one—his or her legacy, memory, and continued psychological presence—into one’s identity, plans, and life. The following quotations from Bowlby (1980) are illuminating in this respect:

There is no reason to regard any of these experiences as either unusual or unfavourable, rather the contrary. For example, in regard to the Boston widows Glick, [Weiss, and Parkes] (1974) report: “Often the widow’s progress toward recovery was facilitated by inner conversations with her husband’s presence. . . . This continued sense of attachment was not incompatible with increasing capacity for independent action” (p. 154). . . . [It seems likely that for many widows and widowers it is precisely because they are willing for their feelings of attachment to the dead spouse to persist that their sense of identity is preserved and they become able to reorganize their lives along lines they find meaningful. (p. 98; emphasis added)

[A secure] person . . . is likely to possess a representational model of attachment figure(s) as being available, responsive and helpful and a complementary model of himself as at least a potentially lovable and valuable person. . . . On being confronted with the loss of someone close to him such a person will not be spared grief; on the contrary he may grieve deeply. . . . [But] he is likely to be spared those experiences which lead mourning to become unbearable or unproductive or both. . . . Since he will not be afraid of intense and unmet desires for love from the person lost, he will let himself be swept by pangs of grief; and tearful expression of yearning and distress will come naturally. During the months and years that follow he will probably be able to organize life afresh, *fortified perhaps by an abiding sense of the lost person’s continuing and benevolent presence.* (pp. 242–243; emphasis added)

Subsequent Writings on the Construct of Continuing Bonds

The continuing bonds book, which was based more on qualitative than quantitative data, stimulated a flurry of more quantitative studies, many of which were reviewed by Boerner and Heckhausen (2003). They concluded, in line with our analysis (Fralely & Shaver, 1999), that “Different types of connections [with the deceased] may be more or less adaptive” (p. 211). They also emphasized that when such connections were obtained in correlational studies, it was unclear which variable—grief severity or continuing bonds—was cause and which was effect, or what third factor might have caused the two variables to be related.

Subsequent studies (e.g., Field & Friedrichs, 2004; Field, Gal-Oz, & Bonanno, 2003) obtained results inconsistent with some of the earlier ones and also failed to discern causal relationships among key variables. In a review of this literature, M. Stroebe and Schut (2005) concluded that it was impossible to tell whether continuing bonds were generally beneficial or detrimental when coping with bereavement. In most studies, continuing bonds (at least as measured) were associated with grief severity, not with resolution. But this fact seemed partially attributable to content overlap in measures of grief severity and continuing bonds (Schut, Stroebe, Boelen, & Zijerveld, 2006). In fact, most operationalizations of the continuing bonds construct seemed inadvertently to make continuing bonds a part of grieving. To make matters more confusing, Lalande and Bonanno (2007) found that the relation between continuing bonds and grief severity, assessed over time, differs between persons in the United States and China.

Our earlier suggestion (Fralely & Shaver, 1999) that continuing bonds can take either secure or insecure forms, and in particular can be part of “unresolved” or “disorganized” attachment, has been most fully developed by Field (2006), who points out that there is a difference between, on the one hand, thinking positively about a deceased attachment figure’s admirable and loving qualities and incorporating some of this figure’s positive qualities and goals into oneself, and, on the other hand, being haunted by the person’s sudden (imagined) appearance or being confused about whether the person is or is not still available in the physical world. Viewed from this perspective, which is based on Main’s (1991) conception of unresolved grief, the empirical studies conducted so far do not seem adequate to resolve arguments about such bonds. A coded interview, based

on insights from research with the AAI, might be more productive. The goal would be to determine how a person represents, relates to, and talks about (coherently or incoherently) a particular deceased attachment figure (see Hesse, Chapter 26, this volume, for details).

Our conclusions are similar regarding therapeutic interventions based on the continuing bonds construct. Whereas many psychotherapists were apparently taught in the past to help bereaved clients deattach and detach from mental representations of deceased attachment figures, many are now being taught to help bereaved clients continue their bonds with lost loved ones (e.g., Neimeyer, 2012). In light of attachment theory and research, it would make more sense to help each person articulate his or her experiences and ideas about the loss, and move toward models of the lost attachment figure and the relationship that are maximally compatible with maintaining a secure stance toward the future. In cases in which a person's memories and continuing bonds are positive, there is no reason to alter them (and perhaps no reason for them to be a focus of psychotherapy; Bonanno, 2004). In cases in which a person's emotions and mental representations seem deeply conflicted, painful, disorganized, and incoherent, therapeutic interventions should be focused on more than continuing bonds per se (some examples can be found in an article by Malkinson, Rubin, & Witzum, 2006).

The Cognitive Attachment Model of Bereavement

Maccallum and Bryant (2013) have recently proposed a cognitive attachment model (CAM) of prolonged grief. The model is explicitly designed to account for why some individuals experience symptoms of prolonged grief following the loss of a loved one. The model is partially rooted in attachment theory, but it also integrates contemporary models emphasizing self-identity and autobiographical memory: for example, Shear and Shair's (2005) biobehavioral model; Boelen, van den Hout, and van den Bout's (2006) cognitive-behavioral model; and Stroebe and Schut's (1999) dual process model.

According to Maccallum and Bryant (2013), the primary task in bereavement is "the revision of self-identity to incorporate the reality of the loss and enable the development of new goals, life roles, and attachments that are independent of the deceased" (p. 719). This process is facili-

tated, according to the CAM, when people are able to activate, pursue, and develop goals that are not dependent on a sense of self or identity that is rooted in the deceased. Maccallum and Bryant (2013, p. 720) write that "recalling memories of the deceased, even positive memories, would make salient the discrepancy between desired goals (e.g., reunion with the deceased) and reality, triggering loss-related memories and yearning."

In this framework, a person's identity is conceptualized as varying along a continuum ranging from merged to independent. A *merged identity* is one in which the bereaved person's identity is constructed around or entwined with the deceased. The person's sense of self, his or her goals, and his or her roles are interwoven with those of the deceased. An *independent identity*, in contrast, is one in which core aspects of the self are not based exclusively on the deceased. This is not to imply that the person construes him- or herself as being fully autonomous or distinct from the deceased individual, but that he or she possesses self-elements that are not exclusively grounded in the deceased.

According to this framework, individuals with a merged self-identity are at greater risk for developing complicated grief symptoms because the discrepancy between personal goals and the post-loss situation is frequently made salient. This in turn has the potential to influence the way in which autobiographical memory processes play out, leading to the preferential retrieval of memories involving the lost individual, appraisals that generate stress, and emotion regulation strategies that reinforce those maladaptive appraisals and perpetuate grief. Indeed, research suggests that individuals experiencing complicated grief are more likely to provide self-defining memories that involve the deceased (e.g., Maccallum & Bryant, 2008). Moreover, Boelen, Keijsers, and van den Hout (2012) found that self-concept clarity was dramatically reduced following loss and that symptoms of grief were more pronounced among those who experienced larger changes in self-concept clarity.

Maccallum and Bryant (2008) propose that anxious attachment may predispose people to develop merged self-identities, which in turn can affect autobiographical memory processes in ways that make the loss more salient and make adaptation more challenging. They also suggest that anxious attachment functions as a moderator of some of these pathways, although those ideas are not fully fleshed out.

One valuable feature of the CAM is that it brings together many core ideas that have been

discussed throughout this chapter. For example, it highlights the role that continuing bonds may play in coping with loss, and it helps to clarify that the extent to which a person's identity is organized around the deceased may be one of the key predictors of both the intensity of the grief and the kind of challenges that must be faced as part of the recovery process. One way in which we think the CAM could be usefully expanded in the future is by disaggregating the merged versus independent identity dimension. In the CAM framework, a merged identity is one in which the person's sense of self is tightly connected to the lost individual. In our reading of Maccallum and Bryant's work, it is not always clear whether this dimension combines (1) the extent to which the lost person is a valued element of one's identity and (2) the extent to which the person's identity is rooted in other domains. To appreciate the distinction, it might be helpful to consider an economic metaphor. A person can invest all of his or her money in one company. Alternatively, a person can diversify his or her investments, placing some in real estate, some in tech stocks, and so on. Even within a diverse portfolio, however, a person can choose whether to invest a large or small portion of assets in one particular area. There is potential variation, then, in how (1) diverse the portfolio is and (2) what proportion of a person's assets are invested in any one domain.

In the case of loss, there can be variability in the extent to which a person is emotionally invested in the lost individual. Some people's identities are firmly grounded in their relationship, whereas other people's identities are more independent. But with this difference held constant, some people have a more diverse portfolio of goals, responsibilities, and competencies. In other words, if we take the two extremes of Maccallum and Bryant's (2008) self-identity dimension (i.e., merged and independent) and split those, it is possible to form a 2×2 table in which people vary in (1) the extent to which their identity is merged with that of the lost individual (e.g., high vs. low) and (2) the extent to which their identity is diversified and contains elements that are distinct from their relationship with the lost individual (e.g., high vs. low). It seems to us that the amount of distress that a person experiences following loss might vary largely as a function of the emotional investment the person has in the lost relationship, but that the ease or difficulty with which the person adapts to the loss will vary more as a function of whether his or her identity is also organized

around goals and tasks that are not integral to the lost relationship.

We find this distinction helpful in considering an attachment perspective because one of the hallmarks of having a secure attachment is that the bond enables the individual to explore the world in a more confident and autonomous manner. As a result, a person with a secure base is likely to develop a number of relationships and competencies that, while facilitated by the secure attachment bond, are not entwined with or dependent on that particular attachment relationship. Importantly, this conceptualization may help reconcile some of the apparent discrepancies between attachment theory on one hand, and Bonanno's research on resilience on the other. When oscillating between a loss-focused mindset and a restoration-focused mind-set (Stroebe & Schut, 1999), it might be most beneficial for a bereaved person to have in place a set of relationships, responsibilities, and plans that have meaning and significance that are independent of the lost person.

Summary and Conclusion

The first time the full significance of [my father, John Bowlby's] work struck me was during a family walk . . . just after his paper on "The nature of the child's tie to his mother" was first published [in 1958]. He said to me, "You know how distressed small children get if they're lost and can't find their mother and how they keep searching? Well, I suspect it's the same feeling that adults have when a loved one dies, they keep on searching too. I think it's the same instinct that starts in infancy and evolves throughout life as people grow up, and becomes part of adult love." I remember thinking, well, if you're right, you're on to something really big!

—RICHARD BOWLBY (2005, pp. vi–vii)

From a combination of attachment theory and numerous clinical case studies, Bowlby (1980) developed a conception of loss, grief, and mourning that remains the deepest and most comprehensive available. His theory is recognized as one of the major explanations of bereavement, and it has generated an enormous amount of research on reactions to loss and individual differences in the way people respond to and adapt to loss. Not surprisingly, Bowlby's theory has also generated criticism and controversy. In this chapter, we have considered some of the main criticisms of the theory. In each case, we considered the possibility that critics have mischaracterized Bowlby's views in an effort to supersede them. But we have

also acknowledged that data collected and reported long after Bowlby's death make it clearer that many people weather losses without becoming disorganized, depressed, or vulnerable to later breakdown; that positive emotion plays a role in resilience following loss; and that the stages Bowlby inferred from studies of young children's separations from and reunions with their parents may not apply directly or without modification to the course of normal grieving.

The field of bereavement studies has made several advances over what existed in Bowlby's era. There are beginning to be prospective longitudinal studies, which allow us to see how prebereavement experiences and mental health affect postbereavement reactions. A clearer distinction is emerging between normal grief and complicated or prolonged grief (the latter is likely to be a consequence, in part, of preexisting anxious attachment). There is a more explicit recognition of continuing bonds, and that those bonds can be either adaptive or maladaptive. The clinical application of the new and old insights will require considerable judgment and training because there is no one-size-fits-all form of therapy that will work or be helpful for every bereaved individual.

Bowlby was not able to answer every important question about grief and mourning. Nevertheless, having reconsidered his work in light of what came before and what has come since, we are humbled by his ability to incorporate so much of the available evidence while keeping an eye on a coherent, comprehensive, and deep theory of human attachment and loss. His work will continue to inform researchers and clinicians interested in bereavement.

Note

1. Bowlby (1980) also discussed "compulsive caregiving" as a disordered form of mourning. Because of space limitations and the relative lack of research examining this pattern, we do not discuss it further in this chapter.

Chapter 4

The Internal Working Model Construct in Light of Contemporary Neuroimaging Research

Inge Bretherton
Kristine A. Munholland

The notion that brains do in fact provide more or less elaborate models that can be made to conduct, as it were, small-scale experiments within the head is one that appeals to anyone concerned to understand the complexities of behavior and especially human behavior. . . . In order to understand human behavior it is difficult to do without such a hypothesis—which squares, of course, with such introspective knowledge of our own mental processes as we have.

—JOHN BOWLBY (1969, pp. 80–81)

In formulating attachment theory (1969/1982, 1973, 1980, 1988) Bowlby maintained that an individual's mental health from the cradle to the grave is intimately tied to relationships with attachment figures who afford emotional support and physical protection. He additionally claimed that the security-enhancing quality of these relationships turns not only on attachment partners' momentary behavior toward one another but also on the translation of their habitual interaction patterns into relationship representations—or, as he called them, *internal working models* (IWMs), a term he did not regard as purely metaphorical (M. D. S. Ainsworth, personal communication, n.d.). IWMs, in Bowlby's view, help both members of an attachment dyad, whether parent and child, or adult couple, to anticipate, interpret, and guide reciprocal interactions.

Bowlby discovered the IWM construct in the writings of an eminent scientist interested in

the neural basis of animal memory, J. Z. Young (1964), while rethinking what he considered to be scientifically outdated explanations of the psychoanalytic “internal world.” The originator of the IWM construct, however, was the innovative cognitive psychologist, Kenneth Craik (1943). Unfortunately, Craik's work was cut short by his early death.

Although Bowlby (1969/1982, p. 80) occasionally used other, more static descriptions for mental representation such as “cognitive map” or “image,” he favored IWM because that term connotes a dynamic representational system that allows humans to imagine (or internally simulate) habitually experienced sequential patterns of social interaction. More explicitly than Craik (1943), Bowlby maintained that in order to make plans for achieving desired goals, humans must acquire not only an IWM of their environment, but also a working knowledge of their own behav-

ioral skills and potentialities in that environment (which he initially called an “organismic model”). Note that whereas Bowlby (1973, 1980, 1988) emphasized the role of IWMs in attachment relationships, his initial notion of representation as IWM-building included interactions with the physical, as well as the social, environment and was limited neither to attachment relationships nor to other social relationships (Bowlby, 1969/1982). He considered emotional appraisals to be an integral aspect of working models.

Despite the centrality of the IWM construct in Bowlby’s thinking about representation, he never developed a systematic overall account of the formation, development, function, and intergenerational transmission of IWMs. His views on these topics are hence scattered across the three volumes of his seminal trilogy *Attachment and Loss* (1969/1982, 1973, 1980) and his final book on attachment, *A Secure Base* (1988). In an attempt to capture the essence of Bowlby’s IWM-related proposals, we included a large selection of verbatim quotes from his works in our 2008 chapter of this handbook. In this revised chapter, we begin with a much briefer summary of Bowlby’s IWM tenets (keeping close to his own wording and providing page numbers for easy reference), and then discuss their fit with related developmental research on event memory. Our primary focus, however, is on IWM-relevant neuroimaging research that has proliferated in the last 20 years. We believe that Bowlby would have incorporated findings from these studies into his writings had they been available to him. We conclude with reflections on ways in which neuroimaging research can affirm, expand, and clarify our thinking about working models in attachment relationships.

Bowlby’s Major Postulates Regarding IWMs

1. Whereas IWMs play an important role in human attachment relationships, Bowlby’s IWM construct is restricted neither to humans nor to relationship representations. As Bowlby (1969/1982, p. 48) stressed: “Members of all but the most primitive phyla are possessed of equipment that enables them to organize such information as they have about the world into schemata or maps.” IWMs, in his view, derive from an organism’s selective processing of interactions with the physical and so-

cial environment, but the complexity and type of IWMs that an organism can build depends on and is limited by the particular organism’s perceptual and effector equipment.

2. Organisms with more adequate working models can make more accurate predictions and organisms whose models are more comprehensive can make predictions in a greater number of situations (Bowlby, 1969/1982, p. 81). Making accurate predictions improves the likelihood of the organisms’ survival and eventual reproduction.

3. In humans, the function of working models is to transmit, store, and manipulate information regarding behavioral choices for achieving the set-goals of behavioral systems (Bowlby, 1969/1982, p. 80), including but not limited to the attachment system, and to aid in the evaluation of alternative courses of action by means of *internal simulation* (Bowlby, 1988, pp. 130, 165).

4. In humans, IWMs include selective appraisals that are often, but not necessarily, experienced as conscious feelings or, as Bowlby preferred, “felt.” Thus, input representing features of the environment and the self is appraised in terms of value (good, bad) and categorized in terms of potential actions based on behavioral choices made previously (1969/1982, p. 112). Individuals who are aware of these prior appraisals can use them to monitor their own current states, urges, and situations. Their facial expressions or postures, moreover, can transmit valuable information regarding these appraisals to companions.

5. By allowing an individual to profit from past experiences, rather than having to react *de novo* to momentary influences and perturbations, IWMs ensure a certain degree of continuity in an individual’s interpretation of and interaction with the social and physical world.

6. However, to be of use in novel situations, it must be possible to extend IWMs imaginatively to potential realities, not merely to apply them to similar recurrent events (1969/1982, p. 81).

7. A key feature *within* a person’s working model of the world is who his or her attachment figures are, where they may be found, and how they are likely to respond. Likewise, a key feature in a person’s working models of the self is whether he or she feels accepted by attachment figures and is confident that they will respond to bids for support. “On these complementary IWMs of self with attachment figures depends an individual’s confi-

dence that attachment figures, in general, will be readily available—most of the time, occasionally, or almost never” and whether he will approach the world with confidence when faced with alarming situations, either by tackling them effectively or seeking support (see Bowlby, 1973, p. 203). Said differently, IWMs of self with attachment figures “increasingly become a property of the child himself” (Bowlby, 1988, p. 129).

8. To function adequately, infants’ embryonic working models of self and attachment figure(s) must be updated in step with their developing communicative, social, and cognitive abilities. The same holds for a parent’s working models of the developing child and self as attachment figure. Despite the time lag that is inevitably associated with IWM updating, under normal circumstances the “currently operative models continue to be reasonably good *simulations* of himself and his parents in interaction” (Bowlby, 1988, p. 130, emphasis added). More radical updating may, however, be called for as a consequence of family transitions, accidents, chronic illness, or loss (Bowlby, 1969/1982, pp. 82, 348).

8. Although IWM-building begins *before* the onset of speech, language acquisition allows children to draw on and learn from the working models of others (Bowlby, 1969/1982, p. 83). Parents transmit to the child the images they have of the child “not only by how each treats him, but by what each says to him” (Bowlby, 1988, p. 130). There are circumstances, however, under which parents may exert pressure on the child to “adopt and confirm a parent’s false models—of self, of child and of their relationships” (1973, p. 322).

9. Young children’s growing competence in perspective taking enables them to develop a degree of insight into their parents’ feelings and motives, hence allowing them to influence their parents’ independent goals. This transforms the child–parent relationship into a partnership (Bowlby, 1969/1982, p. 268).

10. Infant–caregiver relationship patterns worked out in the first 12 months tend to persist at least for the next few years because the IWMs of two people are in play. Given that each member of the pair expects the other to behave in a certain way and tends to try to evoke from the other the behavior he or she expects, reciprocal expectations tend to be confirmed, thus increasing the

stability of their relationship patterns and IWMs (Bowlby, 1969/1982, p. 347).

11. According to Bowlby, “many of the mental processes of which we are most keenly conscious are processes concerned with the building of models, with revising and extending them, checking them for internal consistency or drawing on them for making a novel plan to reach a set-goal. Although it is certainly not necessary for all such processes always to be conscious, it is probably necessary for some of them to be so sometimes” (Bowlby, 1969/1982, pp. 82–83).

12. When—in analogy to a physical skill—cognitive and action components of IWMs become highly ingrained or overlearned, they are applied automatically and without conscious awareness. When IWMs are well adapted, this is an advantage, but when automated IWMs are not well adapted, and parental or internal (superego) rules forbid their reappraisal, revising IWMs becomes an arduous task that may be undertaken only slowly or not at all (Bowlby, 1980, pp. 54–56).

13. Much psychopathology can be attributed to fully or partially out-of-date IWMs that are fraught with inconsistencies and confusions because defensive processes (e.g., denial, self-deception, distortion, and misattribution) obstruct adaptive IWM revisions (Bowlby, 1969/1982, p. 80). Under some circumstances, such defensive processes lead individuals to invert the attachment relationship and construct an IWM of self as caregiver of a helpless or rejecting attachment figure, or else individuals may become morbidly preoccupied with relationship-related emotional pain (Bowlby, 1980, p. 68).

14. Although Bowlby (1973, p. 208) saw adult personality “as a product of an individual’s interaction with key figures, especially of his interactions with attachment figures, during his years of immaturity, nowhere in his attachment trilogy (1969/1982, 1973, 1980) did he envisage that a child might construct qualitatively different IWMs in relation to different attachment figures. After Main and Weston (1981), among others, reported such differences in many families, Bowlby (1988, pp. 128–129) acknowledged that little is known about the relative influence on personality development of the child’s relationship with father and mother, that different facets of personality might be differentially influenced by mother and father,

and that male and female children might be differentially affected. He then speculated that, during the early years, the model of self-interacting-with-mother may be most influential because, in most cultures, the mother is likely to be the child's principal caregiver.

15. The term *internalization* as applied by Bowlby (1988, p. 129) did not refer to the process of forming relationship-specific attachment IWMs, but to the process whereby relationship-specific IWM patterns increasingly become a "property of the child himself." He proposed that these internalized patterns or some derivative thereof were likely to be imposed on new relationships, sometimes "despite the absence of fit" (Bowlby, 1988, pp. 127, 170).

IWMs in Light of Developmental Research on Event Representation

When Bowlby (1969/1982) incorporated the IWM construct into attachment theory, the notion of representation as working model building and revision was unheard of in the academic literature on infant and adult memory, cognition, emotion, and language. Aside from Piaget's (1951, 1952) theory of assimilation and accommodation in the context of sensorimotor schemas and emergent representations, there was little empirical evidence with which Bowlby could support his IWM hypotheses.

Only in the late 1970s did new insights and empirical work on scripts in story understanding, conducted by Schank and Abelson (1977), and research on young children's developing event representations, by Nelson and Gruende (1981), offer empirical evidence in line with Bowlby's notion that humans can mentally simulate interpersonal transaction patterns with attachment figures (Bretherton, 1985, pp. 31–32). Nelson's (1996) revised conceptualization of experiential event memory made the fit with Bowlby even clearer.

For Nelson (1996) as well as Bowlby (1969/1982, 1980), the everyday function of representation is to guide actions in the present and anticipate future events/interactions in light of what has generally happened in the past. Events, in this context, are defined as "whole scenes unfolding over time that involve people and/or other animates acting over time and in particular places" (Nelson, 2005, p. 360). Whereas Nel-

son had initially assumed that infants' and toddlers' recall ability was limited to generic events or scripts, she retracted that view when research showed that even 16-month-olds can demonstrate their memory for unique events they had experienced in a laboratory by *reenacting them* in the same context weeks to months later (see Bauer & Wewerka, 1995). Following Donald's (1993) terminology, Nelson called this reenactive type of early remembering "mimetic," but nevertheless maintained that young children's world models are derived from their generalized event representations (GERs). GERs, in her view, develop when each new instance of a recurring event overwrites memories of the previous one.

Nelson (1996) treated generic event memory as distinct from the episodic and semantic memory systems, as proposed by the eminent memory theorist Tulving (1972), whose ideas subsequently influenced Bowlby (1980). Tulving defined episodic memories as temporally dated, autobiographical episodes or events ("I remember that . . ."), but regarded semantic memories as undated and unlocalized *factual* knowledge ("I know that . . ."). Although GERs are not by necessity undated or unlocalized (i.e., "I remember" can also apply to them), Tulving subsumed generic events into his definition of the semantic system. Nelson argued, more plausibly in our view, that GERs are the *source* from which general knowledge categories are created. Thus, children might learn to group an item into a general "food" category because it can fill the same "slot" in a generic event or script, such as "lunch at the day care center." Nelson further suggested that GERs can provide a framework for organizing autobiographical memories of unique events, a view close to that subsequently adopted by Tulving (2002). Finally, Nelson explained that GERs are not to be confused with procedural (skill) memory which, as defined by Sherry and Schacter (1987), operates outside awareness. Event memory, she noted, "is a form of representation that involves a degree of conscious awareness" (Nelson, 1996, p. 62).

Around age 2, many toddlers take tentative steps toward translating unique and generic non-verbal/mimetic memories into verbal narratives to be shared with others, particularly if their efforts are encouraged by supportive and sensitive caregivers who expand on their children's contributions through affirmations, questions, and evaluative language (e.g., Fivush & Vasudeva, 2002; Laible & Thompson, 2000; Newcombe & Reese,

2004). Concurrently, they acquire a rudimentary ability to translate *others'* verbal narratives back into their own meaningful event representations, although fuller mastery of these communicative/representational processes extends over the preschool years and beyond (Nelson, 1996). A fascinating account of a young child's solitary verbal rehearsal of daily routines and unique happenings before falling asleep was published by Nelson in 1989.

Relationship Scripts

Because young children's capacity for generating verbal event representations was initially examined in the context of emotionally neutral scripts, some attachment researchers objected to the use of this term in relation to IWMs. They maintained that the script notion could not apply to attachment relationships, which are never affectively neutral. However, Nelson's GER construct can easily be extended to include affects and intentions (Bretherton, 1990). Moreover, whereas event schemas as defined by Nelson would allow classes of people (e.g., caregivers in general) to fill the agent and recipient "slots" in a GER, there is no reason why a child should not construct generic relationship-specific representations of, say, "self with father" that are restricted to this particular relationship.

However, if conceptualized as a mere collection of GERs, an IWM of self with a specific other would be unworkable. A better approach would be to regard working models as an organized, multilayered, partially hierarchical network or web of interrelated GERs with different levels of generality (Bretherton, 1985, 1990; Bretherton & Munholland, 2008). In such a network, habitual, experience-near, relationship-specific scenarios would serve as inputs to higher-order general categories. At an experience-near level, relationship-specific attachment memories in infancy would be non-verbal, based on experiential GERs of the way a particular mother cuddled, comforted, and interacted with her child. These GERs could then serve, along with other mother-infant scenarios, as the basis of a more general but still relationship-specific IWM (e.g., expressed verbally as "When I feel bad/sad, Mom helps me feel better"). Such a mother-specific "secure base script" (a term coined by Waters & Waters, 2006) represents basic trust in not only the specific parent's ability to provide emotional support and protection, but also her perceived willingness and availability to

do so. Bowlby (1980, p. 62) sometimes conceptualized working models at this general scriptlike level, that is, as "generalizations of mother, father, and self." However, at other times, he (Bowlby, 1988, p. 128) used a more experience-near description, referring to a child's model "of mother and her ways of communicating and behaving towards him, and a comparable model of his father, together with the complementary models of himself." In our view, these levels work together. Without access to underlying experience-near GERs (as in Bowlby, 1988), trust in attachment figures could neither come into being or be sustained—whether in infancy or later. Trait adjectives such as *trustworthy* or *loving* are but stand-ins for highly general event categories that are meaningful only because of underlying experience-near GERs (see also Waters, Crowell, Elliott, Corcoran, & Treboux, 2002).

The question whether general expectations about others, especially close others, derive from experiences with several attachment and other key figures (as Bowlby suggested in 1973), or primarily from a child's IWMs of self with his or her *principal* attachment figure (as Bowlby surmised in 1988) has not been definitively answered. In partial support of combined influences, Main and Weston (1981) showed that toddlers deemed secure both with mother and father in separate Strange Situations showed greater readiness to engage with a friendly stranger than infants deemed insecure with one parent and not the other. Lowest scores were given to infants with two insecure attachments. Likewise, Van IJzendoorn, Sagi, and Lambermon (1992) showed that children with secure relationships to father, mother, and child care provider in infancy had greater ego resilience as kindergartners. At variance with these findings, Main, Kaplan, and Cassidy (1985) and Grossmann, Grossmann, and Kindler (2005), as well as others, reported that infant attachment classifications to mother, but not father, predicted the quality of representational attachment measures in early childhood and at school entry (assessed with separation pictures). There is as yet no firm consensus on when and how children develop and apply generalized expectations in new relationships and whether these expectations are more predictable from primary or aggregated attachment classifications. We still await an exhaustive meta-analysis of results from longitudinal studies that include relationships with multiple attachment figures (see Howes & Spieker, Chapter 15, this volume, for discussion of multiple attachment figures).

The IWM Construct in Light of Neuroimaging Studies

Not only can children as young as 3 years of age provide rudimentary verbal descriptions of sequentially ordered generic events, as shown by Nelson and Gruendel (1981), even more complex interpersonal event representations are possible at this age if children are permitted to combine verbal with enactive or mimetic narration by using family figures and small props to create attachment- and other family-related stories (Bretherton, Ridgeway, & Cassidy, 1990; Oppenheim, Emde, & Warren, 1997). But what are the brain processes that underlie these developing abilities? Do they justify Bowlby's claim that the human brain constructs mental models in a more than metaphoric sense, and do emerging neuroimaging discoveries line up with Bowlby's views and the event memory literature?

Partial answers to these questions from neuroimaging research have revealed that Bowlby's notions about "a working model in the brain" were remarkably prescient. A rapidly growing number of studies, only a small selection of which can be reviewed and discussed here, have consistently demonstrated links between perception/representation and brain structure/functioning that are congruent with Bowlby's IWM notion. Moreover, as memory theorist Barsalou (2009) has repeatedly explained, these findings also accord with contemporary approaches to cognition, emotion, and event memory according to which representations are contextually situated, grounded in experience, and embodied (see also Damasio, 1999; Decety & Grèzes, 2006; Glenberg, 1997). Instead of assuming that representations consist of amodal symbols (e.g., logical propositions, data structures, and procedures as advocated by Pylyshyn, 1973), neuroimaging studies reveal that mental models rely on the same brain sites that subserve perception (e.g., vision, audition, touch), action (e.g., movement), proprioception (balance), and interoception (e.g., visceral, emotional, and cognitive states).

Admittedly, the most commonly used neuroimaging methods are not yet as precise as one might wish. For example, the two methods for assessing increases of local blood flow in specific brain regions (positron emission tomography [PET] and functional magnetic resonance imaging [fMRI]) have less than ideal temporal and spatial resolution. Transcranial magnetic stimulation (TMS), although useful for temporarily and

reversibly inactivating or hyperactivating specific cortical sites, cannot reach cortical areas buried in cerebral fissures or sulci; and event-related potentials (ERPs), capable of assessing the precise timing of cortical responses, are less exact than desirable regarding the location of these responses. New methods for revealing neural interconnections (magnetic resonance diffusion tractography) are promising, although researchers cannot always discern the functions of these connections, and case studies of single-cell recordings performed before or during brain surgery can test only a limited number of neurons. In addition, deficits following so-called focal brain injuries often involve more than the region of interest (for additional discussion of technical and measurement issues related to this topic, see Sarter, Berntson, & Cacioppo, 1996). Finally, developmental neuroimaging studies are as yet few and far between. Nevertheless, many insights obtained with these brain imaging methods are giving new meaning to and expanding upon Bowlby's (1969/1982, 1973, 1980) IWM notions.

IWMs Enabled by the Organization of Modal and Multimodal Cortical Sites

To be capable of simulating future events based on past experiences with people and objects, IWMs must retain configural aspects of these events in their physical and social context. An ever-increasing number of neuroimaging studies suggests that this is achieved, in the first instance, by the orderly conveyance of signals from the peripheral body and sensory organs to specialized primary motor, extero-, and interoceptive cortical sites, after preprocessing in various subcortical way stations. These cortical sites hence reflect the layout of the body (musculoskeletal, somatosensory, and visceral) and the structure of its exteroceptive organs (e.g., retinotopic for vision, audiotopic for hearing).¹

Note that cortical body maps include not only the well-known primary sensory and motor "homunculi" familiar from textbook illustrations, but a considerable number of auxiliary, somatotopically or topographically organized, secondary and tertiary sites that analyze, sharpen, and integrate signals from the primary maps into meaningful perceptions and motor commands for goal-directed actions. At least three body-reflective motor maps in each frontal lobe (primary, premo-

tor, and supplementary motor) harbor increasingly complex neural prescriptions or schemas for coordinated actions (Fernandino & Iacoboni, 2010). More than two somatosensory body maps are aligned alongside each other in the parietal lobes just behind the central fissure, specializing in skin, deep muscle, and joint sensations. Finally, hidden behind the Sylvian fissure that delimits the frontal from the temporal lobes, the insulae process interoceptive (evaluative) information about the current physiological/visceral condition of the body.

Before the advent of PET and fMRI methods, neural activity in cortical fissures and sulci could not be adequately probed, and the insula was hence largely inaccessible to study. It is now known that the *posterior* part of the insula receives input from all parts of the autonomic nervous system and engenders interoceptive sensations of pain, temperature, itch, sensual/libidinal touch; muscular, visceral, and vestibular sensations; and vasomotor activity, hunger, thirst, and “air hunger.” In the insula’s *anterior* portion, these sensory-discriminative visceral signals are rerepresented together with their positive and negative affective qualities, indicating the current state of the physical “me” (Craig, 2009; see also Damasio, 1999), findings that are consistent with Bowlby’s contention that emotional appraisal processes are a vital aspect of IWMs. The insula has somatotopic organization, at least with respect to painful temperature sensations (Brooks, Zambreanu, Godinez, Craig, & Tracey, 2005) as well as muscle and cutaneous pain (Henderson, Gandevia, & Macefield, 2007). Electrical stimulation in the insula can elicit pain experiences in specific body locations (Mazzola, Isnard, Peyron, & Maugière, 2012).

In the occipital lobes, five or more retinotopically organized sites process different aspects of vision (e.g., visual area 4 processes color and visual area 5 processes motion). Beyond these general purpose sites, the more specialized fusiform face area (FFA; in the inferior occipitotemporal lobes) responds selectively to familiar faces, particularly their unique featural configurations (see reviews by Kanwisher & Yovel, 2006). Patients with focused lesions in the FFA can recognize neither the faces of familiar persons nor their own reflections in a mirror (prosopagnosia; Damasio, 1999).

Adjacent to the FFA is the extrastriate body area (EBA; *extrastriate* means outside the striate or striped primary visual cortex). The EBA captures static and moving images of human—and to

a lesser extent animal—body forms, but not faces. Subregions within the EBA respond to viewing specific body parts, such as hands (Downing, Jiang, Shuman, & Kanwisher, 2001). According to Astafiev, Stanley, Shulman, and Corbetta (2004), EBA neurons are also somatotopically activated during an individual’s own body movements. TMS of this area disrupts the meaningful perception of nonfacial body parts (Urgesi, Berlucchi, & Aglioti, 2004).

The primary auditory cortices in the superior temporal gyrus are tonotopically organized, in line with the pitch-sensitive organization of the cochlea and are supplemented by surrounding secondary (belt) and tertiary (parabelt) sites, with many subdivisions whose distinct functions are not yet well understood but that are believed to specialize in rhythm and melody recognition in speech and music (Kaas & Hackett, 2000).

In sum, peripheral neurons transmit signals indicating the where and what of actions, skin and joint sensations, vision, audition, proprioception, and autonomic functioning to corresponding primary somatotopic and topographic cortical sites, where they are further processed. They are thence transmitted to secondary and tertiary areas before they can be experienced as meaningful. Damage to these auxiliary cortical processing sites results in various *agnosias* (or inability to comprehend the meaning of what is seen, touched, or heard) even when the primary motor and perceptual sites are intact. That there are specialized areas underpinning the perception of faces and bodies points to their importance in relating to and understanding others.

Multimodal Integration

Experience and IWMs are multimodal and hence require the integration of unimodal activation patterns. One somatotopically organized area subserving such integration is the superior temporal sulcus (STS). The STS is recruited when study participants view motions of head, body, and limbs, including eye gaze direction, facial expressions, purposeful movement of lips and mouth during speech, and walking (see review by Haxby, Hoffman, & Gobbini, 2000). A developing ability to detect and understand aspects of biological motion has been empirically documented in infants as young as 4 to 6 months of age (Fox & McDaniel, 1982). In adults, TMS of the STS temporarily disrupts the ability to perceive biological movements in terms of meaningful actions.

Another important multimodal site is located near the temporoparietal junction (TPJ; where the temporal and parietal lobes join). It integrates multisensory (visual, auditory, skin, vestibular, and insular) input. Lesions at this location, especially in the right TPJ, can disrupt the sense that one's body is one's own (self-location) and can engender out-of-body experiences, such as seeing oneself floating above one's body, as well as other illusions regarding agency or perspective (Blanke & Arzy, 2005).

Multimodal integration of limb, head, and body movements in visual (retinotopic) space, spatial navigation, spatial imagery, mental rearrangement/rotation of objects, and a host of other integrative functions, including perspective taking, appear to be supported by the medial and lateral parietal cortices, but their organization in humans is still not well understood.

Affordance-Related Multimodal Integration

The notion that perception serves action was already implied in Lewin's (1933) proposal that humans from infancy onward construe their psychological environment or "life space" in terms of the actions it invites, repels, permits, or prohibits in relation to current goals and competencies (known as *Aufforderungscharakter*, sometimes inappropriately translated as "valence"). Gibson (1977), using the English term *affordance*, subsequently showed that humans interpret aspects of the perceptual world in terms of the specific actions they afford.

Consistent with the notion of affordance, fMRI studies have shown that people who view manipulable objects register these objects' potential uses at the neural level. For example, when participants look at tools that require the use of hands, neurons fire not only in visual areas but also in the "hand" location of the supplementary motor area and in somatotopic cerebellar sites (Grèzes & Decety, 2001; see also Martin, Wiggs, Ungerleider, & Haxby, 1996). Likewise, mere pictures of appetizing food engage sites involved in evaluation of the actual taste and reward value of food (Simons, Martin, & Barsalou, 2005), a reason why admiring still-life paintings in an art museum can lead to feelings of hunger.

Social Observation–Action Matching

An effect with enormous social implications for IWM construction was serendipitously discovered

in a study of monkeys by Rizzolatti, Fadiga, Gallese, and Fogassi (1996). Using microelectrodes to record the activity of single neurons in the premotor cortices of awake monkeys, these authors noticed that a subset of cells in a monkey's premotor cortex, dubbed *mirror neurons*, displayed the very same discharge pattern (1) when the monkey spontaneously performed a specific goal-directed hand action (e.g., picking up a peanut or tearing paper) and (2) when it merely observed another monkey doing so, even if part of the observed action had to be inferred from sound alone.

Probing the possible mirroring activity of single neurons in living human brains is possible only under extraordinary circumstances (e.g., exploration of cortical layout prior to epilepsy- or tumor-related surgery). However, the much earlier finding that human newborns are already able to imitate mouth opening, tongue protrusion, lip pursing, finger movements, and even some facial expressions (e.g., Meltzoff & Moore, 1977) suggested that mirror systems might be found in humans, too.

In one of the many subsequent fMRI studies confirming this hypothesis in adults, video clips of *other* individuals performing specific mouth, hand, and foot movements activated the mouth, hand, and foot areas in participants' *own* premotor map, while simultaneously triggering corresponding parietal neurons that capture the spatial aspects of body movements (Buccino et al., 2001). In a review of the now voluminous mirror neuron literature, Rizzolatti and Sinigaglia (2010) concluded that mirror neurons are activated when people observe others' goal-directed (intentional) actions but not when they view mere body displacements. They contend that mirror neurons hence allow individuals to understand others experientially or "from the inside." Note, however, that this propensity is affected by learning. For example, expert piano players, but not novices, exhibit strong cortical premotor responses while watching a soundless videotape of another expert player at the keyboard. This effect would presumably also apply to social interactions, and hence to social IWM construction (Bangert et al., 2006).

At least in humans, neural mirror systems extend beyond action to emotion. In an fMRI study by Carr, Iacoboni, Dubeau, Mazziotta, and Lenzi (2003), participants' imitation of happy, sad, angry, surprised, disgusted, and fearful emotional facial expressions registered in the same neural sites as when they viewed another person perform these expressions (the face area of participants'

premotor and presupplementary motor maps, a subdivision in Broca's area, and the mouth area of the STS). Interoceptive appraisal sites (the anterior insula and amygdala) were also engaged. Results for each separate emotion were not assessed in this study.

Regarding specific emotions, Wicker and colleagues (2003) found that participants' anterior insula responded not only when they sniffed a foul-smelling substance themselves but when they looked at video clips of others' disgust expressions. The authors' interpretation of this finding is captured in the pithy title of their article: "Both of Us Disgusted in My Insula." In another fMRI study, participants' anterior insulae were activated by experiencing pain and witnessing others' facial pain expressions (Botvinick et al., 2005).

Distinguishing Self from Other

If one's own actions and emotions recruit the same modal and multimodal cortical sites as observation of others' corresponding actions and emotion expressions, neural processes must exist that enable individuals to *distinguish* self from other. Ruby and Decety (2004) addressed this issue in a PET study by asking participants to imagine how *they* would feel and how their *mothers* would feel in three neutral and three emotional situations. In addition to the expected activations common to both conditions, the authors noted responses in the right somatosensory cortex that occurred exclusively when participants considered their own feelings. In contrast, the multimodal TPJ lit up only when participants imagined their mothers' feelings and thoughts. This suggested that, in addition to locating the self within the body, as noted earlier, the TPJ also plays a role in distinguishing feelings of self from feelings of others.

With respect to pain and self–other differentiation, the anterior insula responds to pain when it is directly administered to participants and when they observe other individuals in pain, whereas the posterior insula and somatosensory (SII) cortices are activated only when painful stimuli are administered to the self (Mazzola, Faillenot, Baral, Maugière, & Peyron, 2012).

Remembering and Imagining

So far we have discussed neural responses to ongoing actions/emotions in self and others. However, of crucial importance for an understanding

of working models "in the brain," it turns out that these very same modal and multimodal cortical sites also subserve *remembering* or *imagining* one's own or others' actions, feelings, or situations. For example, neurons in the STS respond not only when individuals perceive the meaning of others' biological motion but also when they imagine *themselves* as protagonists in a story (Vogeley et al., 2001), solve false-belief tasks, and consider moral dilemmas (see comprehensive review of social cognitive neuroscience studies by Frith & Frith, 2006). Other studies revealed strong TPJ activations when participants responded to stories involving others' mental states and beliefs (Saxe & Kanwisher, 2003). In short, direct experiences and mental simulations appear to rely on the same modal and multimodal brain sites, a topic to which we return in the section on memory.

Summary

Mental model building, we propose, begins with the transduction of peripheral body signals into neural motor, exteroceptive, and interoceptive neural firing patterns. That is, incoming signals from the periphery are conveyed in orderly fashion to specialized cortical areas via subcortical way stations. These somatotopically and topographically organized brain regions extract modal meanings in stages. Processed modal signals are then combined and coordinated into multimodal activation patterns that generate conscious unified motor and sensory images imbued with positive and negative emotional feelings of self, other, and self-with-other, relying on processes that are imitative/replicative (although not in the strict literal sense) and at the same time analytic/constructive.

These processes are imitative/replicative because the spatial and temporal structure of somatotopically and topographically organized modal and multimodal neural activation patterns are preserved and can be neurally reinstated when events are remembered and can even be generated *de novo* when imagining novel events. Put forth as a hypothesis by Damasio (1999) and others, the reinstatement notions have since been multiply confirmed (e.g., Naselaris, Olman, Stansbury, Ugurbil, & Gallant, 2015; Nyberg, Habib, McIntosh, & Tulving, 2000; Wheeler, Petersen, & Buckner, 2000). To be clear, we are not making the naive proposal that the brain contains pictures, but that neural patterns that give rise to ongoing experience can be partially reinstated in

the service of planning, appraising, and thinking (Nadel & Peterson, 2013).

Brain processes are also analytic and integrative. As already noted, sensory and motor signals are not just relayed from the periphery to the cortex, but undergo considerable pre-processing in subcortical way-stations before they arrive at their primary cortical destinations. They are then further analyzed in secondary and tertiary modal cortices that extract and sharpen increasingly specialized meanings, including features promoting social interaction (e.g., facial configurations) before being integrated in multimodal regions such as the STS or TPJ.

Regarding the phenomenon of *social* action–observation matching, it appears that in the course of evolution, a capacity for shared subjectivity or experiential understanding of others' behavior and feelings became possible via dual use of various modal and multimodal somatotopic and topographic cortical sites. That this capacity has its beginnings in early infancy is consistent with the previously cited evidence for neonatal imitation and early perception of biological motion, as well as research on early intersubjectivity (Trevarthen & Hubley, 1978), the emergence around 9–12 months of a capacity for joint attention (Bruner, 1975), and mastery of intersubjective gestural communication (Bates, Camaioni, & Volterra, 1974; Bretherton & Bates, 1979).

We do not yet understand the processes whereby activation patterns, separately generated in various modal and multimodal cortical sites, are amalgamated into one unified experience or translated into IWMs of multimodal experience and interactions. Time-locked neural activation has been suggested (e.g., Damasio, 1989) as one possibility, but the unity of experience might also be supported by the many documented interconnections among modal areas (such as bidirectional links between motor, auditory, and somatosensory cortices; see Mazzola, Faillenot, et al., 2012). In addition, neuroimaging studies offer emerging insights into how the motor, exteroceptive, and interoceptive/evaluative sites we have described contribute to further processing in cortical regions responsible for the appraisal and selection of alternative courses of action, the topic we consider next.

IWMs and Behavioral Choice

A major function of IWMs, according to Bowlby (1969/1982), is to generate plans for attaining

desired goals (including but not limited to attachment system set-goals), and to evaluate their potential effectiveness for attaining adaptive outcomes. In this section we review neuroimaging studies that shed light on the proposed involvement of IWMs, particularly their evaluative aspects, in influencing behavioral choice. Relevant research relates mostly to adults and only rarely to attachment–caregiving processes; it nevertheless demonstrates important phenomena regarding IWM-guided goal-directed behavior.

In the developmental literature, executive functions such as planning, goal-directed problem solving, and working memory are generally attributed to the prefrontal cortex (PFC) as a whole. The PFC region comprises that portion of the frontal lobes not occupied by primary and supplementary motor sites and the attention-regulating (oculomotor) frontal eye fields. It is slow to develop, reaching full maturity only in adolescence (Fuster, 2001) and early adulthood (Sowell, Thompson, Holmes, Jernigan, & Toga, 1999).

In contrast to developmental psychologists, neuroimaging researchers have focused on three or four identified major subdivisions of the PFC: the orbitofrontal cortex (OFC; situated behind the orbits for the eyes); the ventromedial prefrontal cortex (VMPFC; between the two hemispheres); and the dorsolateral prefrontal cortex (DLPFC; on the upper and outer side of the prefrontal lobes). For good reasons that will become apparent, some investigators (e.g., Amodio & Frith, 2006; Fuster, 2001) include the anterior cingulate cortex (ACC) in the VMPFC. The cingulate cortex with anterior and posterior portions is a medial structure that encircles the corpus callosum like a cinch, or collar.

Research has shown that dense connections within each PFC subdivision are complemented by systematic links of the subdivisions to each other, suggesting that they have both differentiated and collaborative functions. In addition, each subdivision has distinct reciprocal connections to various somatosensory, interoceptive, and multimodal cortical sites, as well as to subcortical reward nuclei (see reviews by Botvinick, 2008; Fuster, 2001; Miller & Cohen, 2001). Given these complex arrangements, Fuster (2001) cautioned that the workings of the PFC as an executive region cannot be fully understood without considering each of the subdivisions, their interactions, and their communication with modal sites and neural processing hubs across the whole fronto-temporal-parietal network. Further advances in research are

required to implement these recommendations, but useful insights with bearings on IWMs and their uses can nevertheless be gleaned from studies that reveal the OFC (and to some extent, the anterior insula) as priority-setting regions whose signals are processed in the anterior cingulate cortex (ACC) for regulating emotional appraisal-guided behavioral choices.

The Orbitofrontal Cortex

Early researchers held that the OFC's sole function was cognitive, to inhibit highly practiced, automated responses that conflicted with the effective execution of a task. However, both neuroimaging and lesion studies have revealed that the human OFC plays a much more complex role than was once assumed. Patients with OFC-focused injuries tend to undergo extensive personality changes; exhibit impulsive, instinctually disinhibited behavior and coarse humor; and show disregard for social and moral principles. They make counterproductive, highly risky decisions in their day-to-day social and attachment relationships, and employ maladaptive strategies in neuroimaging studies involving experimental gambling tasks (Damasio, 1999). Whereas such patients do well on IQ tests and can verbally explain beneficial choices that they *could* or *should* make, they find themselves unable to act on these constructive alternatives while executing the task in the MRI scanner. In addition, there is limited evidence that infants with this kind of prefrontal damage are even more severely afflicted. Not only do they fail to express (and seemingly fail to experience) social emotions of sympathy, embarrassment, or guilt, they are also unable to develop an understanding of social rules and to recognize rule violations. It appears that in such cases, the brain is not developmentally adaptable enough to make up for the damage (Anderson, Bechara, Damasio, Tranel, & Damasio, 1999).

Given the empirically confirmed contribution of an intact OFC to constructive decision making and social relationships, and given its location in the prefrontal (supposedly executive) region of the brain, it is somewhat surprising that the OFC has no direct links to motor cortices. Rather, OFC functions appear to be *sensory-evaluative*, by linking diverse inputs from several primary and auxiliary *sensory* cortices with positive and negative affective qualities (Rolls, 1996). Examples are the pleasant or unpleasant flavor of food (Rolls & Grabenhorst, 2008), the size of expected monetary rewards and losses, and—especially important for

interpersonal relationships and as shown in several fMRI studies reviewed below—differential OFC activations to the faces of loved ones and to faces of fair versus unfair companions. The OFC also generates flexible responses to sudden changes in others' positive or negative emotional expressions.

Nitschke and colleagues (2004) showed, for example, that mothers exhibited much stronger OFC activations to never-before-seen facial photos of their own infants as contrasted with faces of unfamiliar infants. Viewing their own infants, moreover, was associated with significantly more positive self-reported maternal mood. Strong, preferential maternal OFC activations, interpreted by the authors as evidence of maternal love, were also seen in a study in which mothers were confronted with a much more stringent comparison of their own versus *liked, familiar* children (Bartels & Zeki, 2004). Strathearn, Li, Fonagy, and Montague (2008, p. 49) commented that preferential engagement of maternal cortical (OFC) and subcortical reward-processing areas when viewing their own infants' *smiling* faces attested to “the reward value or salience of the infant's face to the mother, which may in turn relate to maternal sensitivity or conversely, child neglect.” We suspect that if it were easier to conduct neuroimaging studies with infants, preferential activations to maternal faces, indicative of attachment, could also be demonstrated.

Differential OFC responses are evident as well after participants experience positive or negative social interactions with previously unfamiliar companions, as revealed in a two-phase experiment by Singer, Kiebel, Winson, Dolan, and Frith (2004). In Phase I, participants played an Internet game with fair and unfair coplayers (actually, computer programs simulating such coplayers whose purported facial photos were taped to the monitor). In the subsequent, neuroimaging phase, said to be unrelated, participants were asked to identify the gender of a collection of facial photos, including the purported coplayers. Faces of the *prosocial* coplayers evoked significantly stronger positive OFC responses than other faces in the collection and were subsequently rated as better liked than their unfair counterparts, suggesting that differential OFC responses were prompted by conscious evaluations of the coplayers' behavior in Phase I.

The OFC also responds during so-called reversal-learning experiments when a rapid evaluative switch is required because a previously rewarded choice is suddenly no longer effective or is punished (e.g., when a chosen face no lon-

ger smiles, but frowns; see Kringelbach & Rolls, 2003). Patients with OFC lesions lack the capacity to respond flexibly to rapidly changing reward contingencies.

OFC appraisals of reward and punishment (Rolls, 1996), and with respect to pain, affective pain signals from the insula (Medford & Critchley, 2010) influence ACC functions of monitoring and guiding behavioral choices that we discuss next after briefly considering related proposals by Bowlby.

The Anterior Cingulate Cortex

In a largely ignored chapter on appraising and feeling, Bowlby (1969/1982, p. 105) emphasized the importance of emotional appraisals in making choices among alternative means for reaching a goal (attachment related or otherwise). The processes he described are uncannily relevant to current accounts of the ACC's function and include monitoring progress toward a goal, registering its successful attainment, and taking account of outcomes and consequences for learning. Whereas Bowlby (1980, pp. 53–54) saw routine IWM-guided behavior as being based on ingrained habits that may no longer be consciously accessible, he believed that conscious evaluation was required for “juxtaposing information of varying kinds,” “preparing an array of alternative plans and sub-plans, then evaluating them, thus making possible high-level decisions.” These ideas square quite well with current neuroimaging studies according to which the guidance of *habitual* choices is relegated to subcortical control, whereas ACC involvement is called on for reward-related behavioral guidance in the not infrequent instances when several possible behavioral choices conflict.

Until quite recently, the ACC was regarded as a paleomammalian limbic–emotional structure (as proposed by MacLean, 1973). However, consistent with an executive role, anatomical evidence has revealed that the anterior midsegment of the human cingulate cortex (henceforth the aMCC, also known as the dorsal ACC) is best regarded as a motor specialization of neocortex, containing spindle neurons for corticocortical communication found only in apes and humans (Allman, Hakeem, Erwin, Nimchinsky, & Hof, 2001). Relatedly, monkey and human studies have shown that the aMCC contains two somatotopically organized motor sites with efferent and afferent links to all primary and subsidiary motor

cortices, as well as the spinal cord (Paus, 2001). Moreover, suggesting a social-communicative role, “facial” neurons within the head region of these aMCC motor maps send signals to the subcortical facial nucleus that controls muscles of the upper face involved in expressing negative emotions and cognitive confusion (Shackman et al., 2011).

In line with the anatomical findings, an executive decision-making or -fostering function of the aMCC has been demonstrated in surprisingly diverse situations that, at first glance, seem to have little in common (e.g., resolving cognitive conflict, as in Stroop tasks; selecting optimal strategies in games involving gains and losses; solving moral dilemmas; and responses to pain). In a comprehensive meta-analysis Shackman and colleagues (2011, p. 161) confirmed closely overlapping aMCC activations during diverse tasks calling for cognitive problem solving, or effective avoidance of pain and negative emotions/outcomes. They concluded that what these tasks shared was the “need to determine optimal courses of action in the face of uncertainty, that is, to exert control.” Their analyses showed that aMCC activation is heightened by action–outcome uncertainty, and by having to select adaptive responses appropriate to the type of problem or threat encountered (we suggest that this *could* include protective and attachment behaviors, but relevant studies do not yet exist).

Single-neuron studies of monkeys and humans provide some insight into various steps of appraisal-based behavioral decisions. Some aMCC cells are triggered in anticipation of increases or reductions in expected rewards, whereas others warn of or signal erroneous choices for future error correction (Bush et al., 2002). With respect to pain, while probing cells in awake patients before partial ACC ablation, Hutchison, Davis, Lozano, Tasker, and Dostrovsky (1999) detected neurons that fired *prospectively* as a hot or sharp implement approached the patients' hand, while others were triggered *vicariously* or *empathically* as a syringe touched the experimenter's hand. The authors suggest that nociceptive-specific neurons in the ACC may mediate diverse responses, such as alerting and orienting to the potentially threatening stimulus, evaluating and anticipating the threat and executing an appropriate escape response, as well as learning and memory to avoid future unpleasant encounters. Undercutting the notion that this region is *primary* for the “suffering aspects” of pain, research has shown that whereas electrical stimulation of the insula elicits pain ex-

periences (Mazzola, Isnard, Peyron, & Maugière, 2012), direct stimulation of the aMCC does not. Rather, it evokes nonspecific urges “to act,” “to overcome a challenge,” or “to figure your way out of something” consistent with an appraisal-guided executive role (Parvizi, Rangarajan, Shirer, Desai, & Greicius, 2013).

Few human aMCC studies have been directly informed by attachment theory and research, and in some that *were*, overt behavioral choices were not asked for because the primary aim was to compare experienced pain with vicarious/empathic pain or distress. However, in a neuroimaging study of maternal responses to infant crying, Lorberbaum and colleagues (2002) found not only the expected vicarious/empathic neural activations in mothers' aMCC, but also reported that some mothers mentioned urges to help the crying infant. In a study of romantic couples, self-described as truly, deeply, and madly in love, Bartels and Zeki (2000) noted preferential insula and aMCC activations when participants viewed a loved partner's versus a best friend's facial photo. They also found that these responses covaried with stronger self-reported feelings of love and sexual arousal vis-à-vis the partner. During this task, Bartels and Zeki detected hippocampal activations (traditionally linked to memory) that may have been related to recalling interactions with the partner while viewing his or her image. However, the authors did not further discuss the possible significance of their hippocampus findings.

With respect to fMRI studies in which participants observe pain suffered by unfamiliar others, the default response was vicarious activation of the same aMCC locations that are triggered by self-experienced pain (see review and meta-analysis by Lamm, Decety, & Singer, 2011). However, participants' empathic aMCC pain responses were much reduced when the same experiment was performed after they were treated unfairly during a game with previously unfamiliar coplayers. During a subsequent purportedly unrelated task, participants rated unfair coplayers as substantially less liked than fair coplayers while viewing a collection of photos that included these players (Singer et al., 2006). We suspect that participants experienced a lesser behavioral urge to intervene on behalf of the unfair individuals (male participants admitted to a desire for exacting revenge). What is of interest here is not the expectable effects of another's unfairness, but that the participants' appraisal-related deci-

sion processes could, to some extent, be tracked by aMCC modulation.

Additional fMRI and ERP studies reviewed by Lavin and colleagues (2013) documented that hostile prior social interaction with an individual not only lowered the normal intensity of participants' empathic aMCC activations when that individual suffered pain but made task errors or lost expected rewards. Other studies reported that group membership (favoring ingroup members) affected the intensity with which pain and error empathy registered in participants' aMCC. Hence, a simple dichotomy between relationship-specific and general IWMs is likely to be too simplistic. Lavin and colleagues concluded that the aMCC is an integrative executive site for human social decision making, social outcome monitoring, and empathy.

Summary

Strong preferential OFC activations when participants view faces of significant others (infant, child, or adult) lead us to infer that their relationship-specific IWMs have invested these individuals with strong positive value (i.e., feelings of affection and love). Even experimentally induced liking and disliking of previously unfamiliar individuals registers differentially in the OFC.

Evaluative signals from the OFC and insula influence emotion-guided aMCC behavioral monitoring and choice processes. These are manifest when an infant's distress elicits a mother's urge to intervene and when expected empathic aMCC activations vis-à-vis unfair companions are down-regulated. This and other aMCC research underscores the alerting and informative role that positive and negative emotions play in monitoring and guiding behavioral choices in social relationships (Damasio, 2010). Such processes are also likely to be involved in the construction of relationship-specific and general IWMs, their revision, and their consolidation.

Given that the aMCC communicates not only with the OFC and anterior insula but also with other prefrontal, motor, parietal, and medial temporal sites, as well as with subcortical regions, much remains to be understood about its role of emotional guidance in behavioral choice within this larger network. It is particularly puzzling that the influence of memory (let alone IWMs) is almost never mentioned in aMCC neuroimaging studies, not only because remembered emotional

experiences inform behavioral decisions but also because the aMCC and OFC are known to receive input from the hippocampus, which is known to be involved in memory processing (Aggleton, 2012). In the next section we focus on neuroimaging research that suggests new approaches to memory processes relevant to IWM construction and use.

Memory Research and the Prospective–Imagining Brain

As noted earlier, Bowlby's (1980) IWM-related theorizing was strongly influenced by Tulving's (1972) proposition that humans possess two distinct declarative (awareness-accessible) memory systems, one termed "episodic" and the other "semantic." Bowlby described *episodic memory* as personally experienced information, stored sequentially in terms of temporally dated episodes and temporospatial relations that retain their perceptual properties. *Semantic memory*, in his view, consisted of generalized propositions about the world, derived either from personal experience or knowledge learned from others. The storage of "images of parents and self" would therefore also be "of at least two distinct types." Memories of specific interactions and conversations would be stored episodically, whereas "generalizations about mother, father, and self, enshrined in what I am terming working models or representational models" would be "stored semantically (in either analogical, propositional, or some combined format)" (for all quotations in this paragraph, see Bowlby, 1980, p. 62).

Bowlby stressed that having two distinct types of memory storage could be problematic if a child's episodic memory of a troubling experience such as sexual abuse was disavowed or denied by a parent who did not wish the child to understand its meaning. Incorporating this idea into his theory of defensive processes, Bowlby proposed that to allay anxiety caused by seeing attachment figures in a bad light, a child in such situations was likely to defensively exclude or repress his or her own episodic memories and retain conscious access only to semantically stored knowledge acquired from parents.

In 2002, 30 years after his initial propositions about two forms of declarative memory, Tulving made it known that his earlier conception of episodic memory (which Bowlby adopted) was now outdated. He redefined episodic memory as a neurocognitive mind/brain system underpin-

ning the *capacity to reexperience or mentally relive* personal events that had occurred in the past at a particular time and place, or to *pre-experience or pre-live* events that might occur in the future. This required a special kind of past and future awareness, dubbed "autonoësis," in contrast to noësis, or the retrieval of factual information from semantic memory. In 2009, Tulving and Szpunar further elaborated (1) that reliving the past or pre-experiencing the future required the stored information to be isomorphic with what is or could be in the world, reminiscent of Bowlby's working model notion; (2) that episodic memory depended on semantic memory with which it shared many, but not all, neural underpinnings; (3) that both episodic and semantic remembering required consciousness and a sense of self; (4) that neither episodic nor semantic remembering depended on language, although language greatly facilitated them; and (5), that auto-noëtic consciousness had evolved because humans with this capacity were better able to predict what might happen in the future and could thus avoid or at least anticipate potentially threatening or otherwise detrimental events. This statement is at partial variance with Bowlby because of Tulving and Szpunar's exclusive focus on episodic (and not semantic) memory in generating predictions.

Retrospective and Prospective Memory

Several years after Tulving put forth the notion of auto-noësis, or past and future episodic time travel, several neuroscience teams almost simultaneously discovered that *envisioning future episodes* activates the very same cortical network as *recalling past personal episodes* (reviewed by Schacter & Addis, 2007). What came to be called the "core network" comprises the medial and prefrontal PFC, the medial temporal lobe (MTL), including the hippocampus, the posterior cingulate cortex, and the medial parietal cortex (also known as "precuneus")—all major integrative hubs (often termed *association areas*). This core network substantially overlaps what Raichle, MacLeod, Snyder, Powers, Gusnard, and Shulman (2001) identified as the "default network." Contrary to expectations, the default network was particularly active between fMRI task-related episodes, when individuals were supposedly resting but were actually daydreaming or mulling over past events (see review by Buckner, Andrews-Hanna, & Schacter, 2008). It is beyond the scope of this chapter to discuss the core

network in detail, or to compare it with the default network, whose functioning is currently undergoing considerable rethinking. We focus instead on componential and combinatorial aspects of memory construction and imagination that emerged from this research and that have considerable implications for elaborating our ideas on IWM construction.

The core network findings led Schacter and Addis (2007) to advance the *constructive episodic simulation hypothesis*, according to which humans can envision plausible future episodes by extracting and then flexibly recombining event components derived from remembered episodes. Schacter and Addis maintained that these components (sometimes called “bits and pieces”) were widely distributed across different brain sites rather than being stored as a “literal copy” in a single location.

In the same year, Hassabis and Maguire (2007) reported that participants also recruited the core network while imagining a *fictitious* event not obviously linked to remembered or predicted personal situations. Focusing particularly on the function of the hippocampus and adjoining sites in the MTL, Hassabis and Maguire hypothesized that *scene construction* was the common underlying process, which they defined as

mentally generating, maintaining and visualizing a complex, coherent scene or event. This is achieved by the retrieval and integration of relevant informational components, stored in their modality-specific areas, the product of which has a coherent spatial context and can then later be manipulated and visualized. (p. 299)

Additional support for this hypothesis came from Hassabis, Kumaran, Vann, and Maguire’s (2007) discovery that people with bilateral hippocampal injuries, long known for their inability to form new episodic memories, also struggled when asked to imagine personal futures. These patients’ descriptions lacked spatial coherence and consisted of isolated fragments rather than connected scenes, again highlighting the role of the hippocampus in retrieving and integrating various event components into a coherent spatial and temporal whole. Related to more complex aspects of IWM construction than discussed so far, these findings and those reviewed below support and broaden Bowlby’s notion that IWMs need to be extendable to novel situations. We also believe these findings to be important for conceptions of IWM-related future planning and defensive processes.

New Views of MTL and Hippocampal Functions

Inklings that the hippocampus is indispensable for forming *new* episodic and semantic memories first emerged from Scoville and Milner’s (1957) case study of the famous patient H. M., whose hippocampus was removed because of uncontrollable epilepsy. This study gave rise to the assumption that the hippocampus played a merely temporary role in consolidating short-term into long-term memories that would then be stored in other (non-specified) cortical sites and be recallable without hippocampal intervention. However, current evidence that the hippocampus also participates in episodic memory retrieval and the construction of future, as well as fictive, episodes calls for a revised conceptions of MTL and hippocampal functions.

Complicating the issue still further were findings that the hippocampal formation is needed for successfully distinguishing among simultaneously displayed, highly similar but not identical complex visual scenes, and that an adjoining MTL site (the perirhinal cortex) enables discrimination among complex objects that share most but not all features (see review by Lee, Yeung, & Barense, 2012). Additionally, Zeidman, Mullally, and Maguire (2014) confirmed that the anterior hippocampus is active during scene perception (assessed with photos of locations, many including people and suggesting action), as well as during imagined scene construction (assessed with two-word cues for locations). In summary, perceiving/understanding, recalling, and imagining scenarios in context appear to rely on multiple uses of the same MTL and hippocampal substrates, although how these processes are differentiated from each other is not yet understood.

Zeidman and colleagues (2014) noted that scene construction, in comparison to scene perception, evoked significantly stronger (temporary) connectivity between the anterior hippocampus and primary visual sites, the dorsolateral PFC, inferior parietal lobe, and the STS. They hence concluded that the anterior hippocampus is involved in building an *internal model* of both perceived and imagined scenes, whereas the posterior hippocampus is activated only by scene perception and analyzes visual-spatial scene features. Relatedly, Bosch, Jehee, Fernández, and Doeller (2014) demonstrated that stimulus-specific, recognizable activation patterns that were evident during scene perception were reinstated in visual areas (V1 to V3) during recall, with tentative confirmation that reinstatement was mediated by the hippocampus.

SUMMARY

Neuroimaging research affirms that the hippocampal formation and surrounding MTL are recruited when humans perceive and simulate (remember and imagine) complex scenarios that, in our view, are important in IWM construction. They offer contextual and spatial frames for the modal, multimodal, and evaluative processes described earlier and provide neural underpinnings for the event representation research discussed earlier. Via hippocampal and MTL signals, neural activations initially evoked by perceiving whole episodes in spatiotemporal context can apparently be reinstated in modal and multimodal areas. This makes it possible to relive/refeel them in memory and even to pre-live/pre-feel or vividly imagine fictive events. However, the mental “editing” involved in *assembling* event components in the service of remembering or producing coherent spatiotemporal scenarios, let alone a life story, can at present only be guessed at (see detailed speculations by Damasio, 2010). Nor is there consistent evidence or explicit discussion of how the experience of reconstructing remembered scenes from “bits and pieces” is neurally different from doing so when constructing imagined future or fictitious scenes. This gap may be filled when we gain a more complete understanding of the function played by the now known, enormously complicated interconnections among MTL and hippocampal subdivisions and by the organization of distinct inputs to and outputs from hippocampal subfields to other cortical sites (Aggleton, 2012).

Semantic Memory/Knowledge, Categorizing, and Summarizing

If semantic memory is synonymous with world knowledge, then its purview is considerably vaster than that of episodic memory (see an up-to-date assessment of current debates in this field by Yee, Chrysikou, & Thompson-Schill, 2013). In this section, we restrict our focus to three IWM-related semantic memory topics: a simulation approach to category formation, various levels of summarizing temporal events, and the grounding of language in simulations.

Simulation and Concepts

Barsalou (2009) regards mental simulation (in contrast to amodal representation) as a basic brain strategy supporting a broad range of memory and

cognitive processes. In one of several studies that take a simulation approach to concept formation, Barsalou and Wiemer-Hastings (2005) asked students to generate thoughts about concrete concepts (*bird, sofa*) and abstract concepts (*truth, freedom*). Rather than coming up with feature lists or dictionary definitions, the students’ responses included considerable contextual information, not only for concrete but also for abstract concepts (e.g., freedom: “people on TV saying whatever they want to be saying”; truth: “when what you are saying is not a lie”). In addition to parts and properties of objects, participants mentioned related behavior, evaluations, goals, and introspections, including beliefs. Introspections were more frequent in descriptions of abstract concepts (*truth*). Participants did not simulate exemplars of concrete and abstract concepts in isolation, but in the context of a variety of summarized and unique situations (how something feels, what can be done with it, in what settings various exemplars of it would be used or experienced, whether or not one likes it/them). Different aspects of the concept were called upon in different simulated contexts (e.g., a chair in a kitchen vs. a dentist’s office), and descriptions drew on both unique and generic/semantic memories.

This is as far as we can take this discussion here. Note, however, that the above mentioned category findings call for a consideration of language in relation to simulation (and hence verbally expressed IWMs), a topic we address after considering summarized events.

Summarized Events

To examine Tulving’s (2002) claim that episodic memories (usually prefaced with “I remember that . . .”) are distinct from memories for generic events (usually prefaced with “I know that . . .”), Barsalou (1988) asked random individuals at his university to participate in a survey at the beginning of the fall semester. The tape-recorded task was to spend 5 minutes recalling summer activities in any order that came to mind. The authors primarily expected recounts of specific events.

Most participants, however, responded with a chronological sequence of several extended events (e.g., a challenging job for 2 months, followed by a trip to Europe and several weeks at home. They then filled in more details with summarized events (“On my days off we always went to the beach”) and specific events (“We went to see a play at the

outdoor theater”), although the latter were mentioned less frequently. Given the 5-minute time limit, participants’ use of longer time frames is not surprising per se. What is noteworthy is the lack of a strict distinction between episodic and semantic remembering, made possible by language labels that permit various levels of temporal summarization.

An even more extended time frame (lifetime periods or “My time in college was stressful”) was reported in a study of autobiographical interviews by Conway, Singer, and Tagini (2004), suggesting that IWMs could be organized within such temporal frames.

The Grounding of Verbal Event Descriptions in Simulations

The category and event summary studies by Barsalou and colleagues raise questions regarding the nature of links between mental simulation and verbally reported IWM-related memories in interviews and clinical contexts. These led Barsalou (2012) to make the following provocative points: (1) Verbal accounts must ultimately be grounded in multimodal mental simulations, and situated categories (as described earlier) are central to processing language structure as expressive of meaning; (2) lexical meanings and simulated, nonverbal concepts are not identical, but have much in common; (3) verbal accounts are too incomplete to be understood without at least some shared situated knowledge; and (4) people construct situation models in the course of attempting to understand texts; hence, reasoning is often difficult if a concrete situation cannot be imagined (Yeh & Barsalou, 2006).

Simulation in Clinical Perspective

Clinically oriented studies relevant to the IWM construct adopted notions of simulation akin to Barsalou’s before neuroimaging studies began to proliferate. We review some of them here because they discuss both advantages and drawbacks rather than focusing primarily on the adaptiveness of past and future episodic thinking. They are helpful because they can shed light on individual differences in IWM construction that are related to mental health and psychopathology.

We begin by discussing the effectiveness of prospective simulations, then consider the phenomenon of overgeneral memory, and lastly pres-

ent findings about defensive processes as related to self-defining autobiographical memories.

Effective Prospective Simulations

Elaborating on propositions by Bowlby (1980), Taylor, Pham, Rivkin, and Armor (1998) posited that simulations have constructive purposes beyond the predictable turns of events. Thus, people may revisit a troubling scenario to pinpoint when and why an interaction went awry, then imaginatively substitute what they might or should have said for use during a future, similar occasion. Or they may relive an accident or near accident in order to reflect on how to exercise greater vigilance when encountering similar situations. Likewise, simulating possible emotional repercussions of an upcoming situation may be helpful in facing a related situation in reality. However, when such simulations take the form of obsessive ruminations without resolution, they are likely to be detrimental to mental health.

Empirical evidence that some types of prospective simulation are more constructive than others emerged from a study by Taylor and colleagues (1998) that distinguished *process* from *outcome* simulations. Engaging in process simulation implies plans that detail the successive steps necessary for reaching a goal (and include seeking instrumental help and engaging in cognitive reappraisal). Such plans also reduce anxiety. Outcome simulations, in contrast, focus on the pleasure or relief on having reached the goal, but they proved less effective because participants failed to reckon with the effort and steps required to actually attain the goal.

Overgeneral Memory and Psychopathology

Relevant to linguistic markers for “state of mind” used in Adult Attachment Interview (AAI) classifications (Hesse, Chapter 26, this volume), clinical research has revealed associations between psychopathology and *overgeneral memory*, defined as retrieving only generic events even when detailed autobiographical memories were specifically requested. The effect held for clinically and subclinically depressed groups, as well as for individuals with unresolved trauma (e.g., sexual and physical abuse in childhood). Overgeneral memory has also been linked to experiencing accidents, war, cancer, and PTSD, and pervades interviews even when clients are not recalling traumatic memories. Overgeneral memory has been explained as truncated memory search for aversive episodes and is associated with

dysfunction in executive control and with rumination involving global, undifferentiated self-representations (see studies cited by Williams, 2006).

Self-Defining Memories and Defense

What is remembered long-term and reasons why, are topics that have been relatively neglected by neuroimaging researchers who often employ shorter delays (minutes, hours, or days, but not years) between a new experience and related episodic remembering. Focusing on long-term remembering, Conway and colleagues (2004) stressed that many autobiographical memories and even much semantic knowledge will be semiforgotten or irretrievably lost if not periodically retrieved. They pointed out that the comparatively few episodic memories that *are* retained in the very long term tend to be appraised as self-defining and for this reason become integrated with a person's autobiographical knowledge base (including IMWs of self-in-relationships). Such memories tend to be affectively intense and vivid, associated with long-term goals and identity concerns, and are easily accessed because of frequent rehearsal.

Relating self-defining memories to defensive processes, Conway and colleagues (2004) drew on a wealth of past research and theorizing too voluminous to cite. They proposed that the content of autobiographical memory is affected by tensions between two potentially conflicting goals, termed adaptive correspondence and self-coherence. They claim that adaptive correspondence may suffer when discrepancies between an individual's goal-structure and current behavior or experience pose a threat to self-coherence. In such situations, episodic memories may be distorted in the service of unrealistic self-enhancement and even self-deprecation, or they may be repressed altogether to leave the individual's goal structure (or life story) unchallenged. We suggest that such effects could explain defensive processes in IWM-guided perception, IWM construction, and related behavioral choice.

Noting obvious overlaps between their conception of autobiographical memory and secure-autonomous, dismissing, preoccupied, and unresolved "states of mind with respect to attachment" reflected in the AAI (Main, 1995), Conway and colleagues (2004) described three cases in which AAI status was meaningfully related to performance during a self-defining memory task. However, whether their conclusions hold in the overall study has not yet been reported.

Discussion and Reflections

Let us first acknowledge that in order to place boundaries around the task we set for ourselves in this chapter, we have left aside important domains that are potentially involved in working model construction. These include subcortical appraisal processes that feed into cortically supported simulations; the action of hidden regulators involved in direct limbic-to-limbic mother-infant communication that are described with greater emphasis with respect to animals by Polan and Hofer (Chapter 6, this volume) and with greater emphasis on human infants by Trevarthen and Aitken (2003) and Schore (1994); the potentiation of specific brain systems, including the OFC, by neurohormones such as oxytocin; the effects of stress on the developing hypothalamic-pituitary-adrenal system (e.g., Gunnar, 2003; see also Hane & Fox, Chapter 11, this volume); and emerging insights about genetic and epigenetic influences on social functioning (reviewed in Hofer, 2014; see also Bakermans-Kranenburg & Van IJzendoorn, Chapter 8, this volume).

Recognizing these limitations, we reflect on potential contributions that the simulation approach can make to an expanded understanding of human IWM construction and use. Whereas not all neuroscientists subscribe to the simulation view, support for it has grown so substantially since the last edition of this handbook that only a small selection of findings could be included in this chapter.

Embodiment and Simulation

Mental models that can be made to "work" or conduct simulations must preserve the temporal, spatial, and psychological relation-structure of the experiences they represent, as Craik (1943) proposed and Bowlby (1969/1982) reiterated. Neuroimaging studies have revealed how the human brain conserves configural and relational information as it is transmitted from the body and perceptual organs to cortical regions via subcortical processing stations. These cortical regions are the very ones that also allow us to vividly *reexperience* the past and imagine future and fictive events by reinstating or evoking the appropriate modal and multimodal cortical activations. What is more, many of these sites also enable us to experientially apprehend others' meaningful behavior, sensations, and feelings, not only while inter-

acting with them, but also while thinking about them.

Mental simulation, moreover, can spill over into bodily activations beyond the brain, so that we experience others through our physical and autonomic responses as well. For example, facial or bodily muscles can be covertly yet measurably active when individuals consciously or unconsciously resonate to or mirror the behaviors and emotions of others (Glenberg, 1997). Such effects are usually not assessed in neuroimaging studies because relative immobility (including head restraints) is required to prevent motor interference during scanning. Together with neuroimaging studies, such findings imply that experiences in close relationships are likely to leave their imprint on not only our brains/minds but also our physical being.

The embodiment findings also suggest that questions about detailed memories of childhood loss and abuse experiences, such as those evoked during the AAI, are likely to awaken psychological conflict and negative mood in individuals who have not been able to resolve such experiences (Conway et al., 2004). Steele and Steele (2005) confirmed, for example, that interviewees' negative emotions before responding to the AAI were not predictive of secure–insecure AAI classifications, whereas negative emotions after the interview were. Those with autonomous-secure status felt positive about the opportunity to reflect openly and coherently on important childhood and current relationships, whereas those classified as dismissing and preoccupied felt worse. Unfortunately the requirement to remain as immobile as possible in the scanner makes it exceedingly difficult to conduct AAIs and related interview assessments in conjunction with neuroimaging (for a lone, ingenious clinical study related to this topic, see Buchheim et al., 2012).

Analytic and Constructive Processes: Experience, Memory, and Imagination

IWM building involves a number of depictive/imitative and constructive processes that have hitherto been mostly taken for granted. The somatotopic and topographic layout of cortical modal and multimodal sites enables site-to-site coordination of signals (i.e., coordinated information as to where a specific bodily injury is seen and felt), but this does not fully explain how our brains construct a unified experience. Moreover, multimodally inte-

grated information must be further integrated with value judgments (OFC, insula) and linked to context. The latter seems to require MTL processing and signals to modal cortices that manage to reinstate a semblance of past modal and multimodal cortical activations, and can seemingly also evoke them de novo when individuals imagine or listen to accounts of future and fictive events (hence stories can induce laughter or tears). How such reinstatements are accomplished in detail is still a mystery, but there is ever-increasing evidence that they occur.

Additional issues are raised by findings that the same motor, sensory, and interoceptive appraisal sites are used for experiencing self and others. This means that the seemingly self-evident knowledge that an individual owns his or her own body and feelings, and that these are separate from those of others, cannot be taken for granted, but must be based on neural processes of self–other differentiation that are only beginning to be understood. Another, usually taken-for-granted ability whose brain underpinnings are not fully understood is engaging in mental time travel while remaining aware of the present. Greater knowledge of how these differentiating processes are performed might lead to better insights into how they can go awry during development, and how they can interfere with adequate IWM construction.

Observational and clinical infant research (e.g., Ainsworth, Bell, & Stayton, 1974; Stern, 1985; Trevarthen & Hubley, 1978) revealed decades ago that infants and children develop relationships and relationship-specific IWMs optimally in the context of responsive early communication and care by attachment figures (see also the special issue of *Attachment & Human Development* on maternal sensitivity, edited by Grossmann, Bretherton, Waters, & Grossmann, 2013). Neuroscience findings that link quality of parental care to brain development in infancy have “tangibly” affirmed these long-known observational results, but to date neuroscience research is mostly limited to general evidence for brain growth, appropriate synaptic pruning, and the developmental schedule of myelination. Because neuroimaging research with infants and young children is challenging, we still lack details about the involvement of relationship and other experiences in the early patterning of cortical motor, exteroceptive, and interoceptive sites. Such knowledge would give us some much-needed insight into how infants' and young children's capacities for mental simulations develop at the neural level.

IWMs, Imagination, and Defense

Bowlby's (1988) proposal that attachment IWMs consist of semantically stored summary representations needs rethinking, especially with respect to his account of defensive processes (Bowlby, 1980). We urge that Bowlby's rather tentatively stated ideas on memory and defense not be elevated to the status of dogma (see related statements by Fonagy & Target, 2007). It would be a mistake to neglect potentially useful insights for updating and revising theoretical ideas regarding IWM construction and defensive processes offered by discoveries in the field of neuroscience, as well as by discoveries in the study of emotion, representation, narratives, and language.

Neuroimaging studies suggest that our capacity to imagine plausible futures and fictive events draws on "bits and pieces" of remembered events (although deliberate transformations of whole events could also play a role). We know that the ability to invent a different past from the one we experienced or remember, and to simulate plausible desired and undesired futures (whether plausible or not) begins early with the emergence of simple story enactment in pretend play, continues in daydreaming, and makes art and literature possible, but detailed developmental studies of these abilities and their meaning with respect to attachment IWMs are still lacking given that current efforts in attachment research tend to dwell on measurement improvement and reliability.

The componential aspects of remembering and imagining that have been suggested by neuroimaging studies could shed light on the occurrence of memory errors, misattributions, intrusions, and event fragmentation caused by partial forgetting of event components, whether defensively motivated or not (Schacter et al., 2012). That imagined emotional episodes become more believable with repetition is empirical confirmation of the persuasive power of wishful thinking (Szpunar & Schacter, 2013).

Autobiographical studies show that defensive memory distortions are common when an individual's experiences or conduct pose threats to self-coherence and thus challenge existing goal structures. Such processes could be explored in AAI and other attachment interview texts, although with the proviso that *self-coherence* as defined by Conway and colleagues (2004) refers to individuals' attempts to create a *superficially* consistent life story by distorting construals of the past or present. This definition of coherence differs greatly from

Main's (1995) proposal that coherent AAI accounts are supported by a secure-autonomous state of mind, associated with the ability to acknowledge and *integrate* positive and negative aspects of relationships into a vivid, detailed, believable, and *coherent* narrative (see also Cassidy, 2001).

Finally, although the dictum that an unexamined life is not worth living suggests that reflection on experience is always worthwhile, clinicians caution that prospective simulation can be used both productively and counterproductively.

Simulation and Language

We have presented a view of remembering as simulation that involves neural reinstatement of vivid experiences, without paying much attention to the role of language. As MacWhinney (2005) cogently pointed out, simulation and language work together because they evolved together for many millennia, but language does not seem suited as an ungrounded symbol system on its own.

Whereas words are largely based on arbitrary (amodal) sounds rather than simulations, it is important to acknowledge that this may not always have been so, given the many words that imitate sounds (onomatopoeia) and that iconic gestures frequently accompany oral conversations, with or without the speakers' awareness (McNeill, 2005). We have noticed, for example, that spontaneous depictive or enactive gestures are common during the Parent Attachment Interview. One mother (taking the perspective of her child) tapped herself gently on the cheek while describing the child's affectionate behavior toward her, and another hugged herself in the same context (Bretherton, unpublished research). It might be of interest to examine videotaped AAIs for such embodied meanings, which, if concordant with narration, could be related to a secure-autonomous AAI state of mind.

Concerning the componential and constructive nature of event perception and event memory at the neural level, we suspect that this may have made language as a componential representational and communicative system possible. However, word sequences have to make explicit what simulations can do with mental mimesis. In contrast to mental or physical enactments, language must use explicit devices for expressing temporal, spatial, causal, and personal relations, including tenses to mark past and fu-

ture, spatial words, and implicitly code perspective taking with deictic expressions such as this (near me) and that (near you).

Language, on the other hand, has useful properties that mimesis does not. These allow us to convey “facts” and evaluative attitudes in the same expression (e.g., a father dismissing his mother’s affectionate behavior as “lovey-dovey”). Such meanings would be difficult to impart via enactment alone, although tone of voice, or a throw-away gesture could perhaps express such double meanings. Language also contributes uniquely to category creation by providing “handles” for complex situated categories as described by Barsalou (1988); for summarized experiences within longer and shorter time frames (e.g., infancy, wedding); and for multifaceted, abstract concepts, such as love and truth, that a single simulation can only partially express (Barsalou & Wiemer Hastings, 2005). Language can also provide handles for typologies that are grounded in vast amounts of patterned situated information, as exemplified by AAI and Strange Situation classifications)

Consciousness

Although it is often claimed that IWMs operate mostly at the unconscious level or are exclusively unconscious, this is not quite what Bowlby (1980) stated. In line with the literature on controlled and automatic processing, he pointed out that as interaction patterns become increasingly habitual and ingrained, they also become more automatic and hence less open to conscious control and revision. As previously noted, there is supporting evidence for this distinction at the neural level. The aMCC is no longer recruited when choices become highly habitual.

Attachment researchers often characterize the unconscious or implicit operation of IWMs as *procedural*. We should recognize, however, that this usage differs from implicit motor skill memory for which the term was originally coined. Furthermore, skill memory in people with an intact hippocampus is unconscious/implicit only in some respects. They may not be able to describe precisely how they move their limbs during swimming or dancing, how they produce grammatical sentences, and how they interact with another person, but they can imagine performing these skills, are aware of their skill level, and know that a skill can be improved by observational analysis and deliberate practice.

As Barsalou (2009) and others have pointed out, implicit or unconscious top-down use of mental models during ongoing perception does not imply that explicit aspects of such models thereof cannot be called to mind while reflecting on past or future. Furthermore, while acknowledging the general consensus that an enormous amount of the brain’s processing occurs outside awareness and at subcortical levels, let us not forget that persons who are bereft of a cortex, because of prenatal injury, are also bereft of much human experience (Damasio, 2010). We suggest that the notion of unconscious/unconscious IWMs functioning requires rethinking.

Attachment IWMs: Feelings of Love and Affection

Our analyses here cannot speak to how the brain creates the preferential evaluations that make some figures, whether child, parent, or mate, more important than others, whether in interaction or thought. We know that infant preferences for parental figures begin very early, but how this preference is implemented in the brain and built into IWMs is not fully understood (for suggestions, see Swain et al., 2014). We can point out, however, that with respect to research with adults (parents or partners), the effect of such preferences, once established, is strikingly evident in differential OFC activations by the faces of loved ones, even when compared with familiar, liked others.

In a much-cited statement, Bowlby (1980, p. 40) described preferential valuations inherent in intense feelings of love and affection toward children by parents, toward parents by children, and by romantic partners toward each other:

Many of the most intense emotions arise during the formation, the maintenance, the disruptions, and the renewal of attachment relationships. The formation of a bond is described as falling in love, maintaining a bond as loving someone, and losing a partner as grieving over someone. Similarly threat of loss arouses anxiety and actual loss gives rise to sorrow; while each of these situations is likely to arouse anger. The unchallenged maintenance of a bond is experienced as a source of security and the renewal of a bond as a source of joy.

In the current literature on attachment, however, much emphasis has been given to monadic aspects of attachment, such as describing individuals with a secure-autonomous AAI status as feel-

ing “secure within themselves” (Main, Hesse, & Kaplan, 2005) or explaining a secure stance in the Adult Attachment Projective as reliance on an “internalized secure base” (George & West, 2004). Valuing of attachment relationships has been associated with these monadic aspects, but feelings of love and longing in attachment relationships and inherent in IWMs have been largely neglected. The capacity to experience these feelings and evoke them in memory may have evolved because they fostered familial care seeking and caregiving, and hence survival (also see, in this volume, Zeifman & Hazan, Chapter 20, and Simpson & Belsky, Chapter 5). We suggest that their importance and role in attachment relationships and relationship IWMs deserves much greater attention.

Acknowledgments

We wish to express our gratitude to Rose Addis, Lawrence Barsalou, Martin Conway, Peter Fonagy, Myron Hofer, Claus Lamm, Eleanor McGuire, Laure Mazzola; Katherine Nelson, Lyn Nadel, Tania Singer, Colwyn Trevarthen, and Brian MacWinney for kindly and promptly responding to questions and sharing materials. Any interpretive errors of their or others’ work are, of course, ours. We also thank the editors for their patience and helpful supportive critiques.

Note

1. To avoid confusion we interject here that Damasio (1999, p. 23) used the terms *model of the body in the brain* and *body map* to refer to the moment-to-moment, coordinated, multimodal flow of activation pattern in the various neural sites that (jointly) represent the current state of the body rather than, as we do, referring to the somatotopic layout of various modal and multimodal cortical sites.

PART II

BIOLOGICAL PERSPECTIVES

Chapter 5

Attachment Theory within a Modern Evolutionary Framework

Jeffrey A. Simpson
Jay Belsky

It has often been assumed that animals were in the first place rendered social, and that they feel as a consequence uncomfortable when separated from each other, and comfortable whilst together, but it is a more probable view that these sensations were first developed in order that those animals which would profit by living in society, should be induced to live together, . . . for with those animals which were benefited by living in close association, the individuals which took the greatest pleasure in society would best escape various dangers; whilst those that cared least for their comrades and lived solitary would perish in greater numbers.

—CHARLES DARWIN (1871, Vol. 1, p. 80)

As this quotation indicates, Charles Darwin was an attachment theorist. Although he focused on “society” (instead of significant others) and “comrades” (instead of attachment figures), Darwin was the first scientist to appreciate the full extent to which human social nature is a product of selection pressures. John Bowlby, who not only admired Darwin’s theoretical vision but was one of his biographers (see Bowlby, 1991), spent most of his brilliant career treading the intellectual path that Darwin started paving. Integrating ideas from Darwin’s theory of evolution by natural selection, object relations theory, control systems theory, evolutionary biology, and the fields of ethology and cognitive psychology, Bowlby (1969/1982, 1973, 1980) developed a grand synthesis of social and personality development across the lifespan, which is now known as attachment theory. One

reason why attachment theory is so generative and prominent today is its deep intellectual ties to fundamental principles of evolution.

In many respects, however, attachment theory and its adherents have not kept up with developments in evolutionary biology. In fact, beyond acknowledging that attachment behavior evolved via natural selection to facilitate the survival of infants in the environment of evolutionary adaptiveness (EEA), surprisingly little attachment-related research and writing addresses the importance of either reproduction and reproductive fitness as the target of natural selection or the role of environmental conditions, including parenting, in regulating the development of reproductive strategies. These are critical issues that we address in this chapter.

As we shall see, attachment theory is one of a handful of major middle-level evolutionary theo-

ries. Bowlby's interest in the cognitive, emotional, and behavioral ties that bind humans to one another began with an astute observation. Across all human cultures and most primate species, young and vulnerable infants display a specific sequence of reactions following separation from their stronger, older, and wiser caregivers. Immediately following separation, most infants *protest*, typically crying, screaming, and throwing temper tantrums as they search for their caregivers. Bowlby surmised that vigorous protest during the early phases of caregiver absence is a good initial strategy to promote survival. Intense protests usually draw the attention of caregivers to their infants, who, during evolutionary history, would have been susceptible to injury or predation if left unattended.

If loud and persistent protests fail to retrieve the caregiver, infants enter a second stage, *despair*, during which their movement declines and they fall silent. From an evolutionary standpoint, Bowlby realized that despondency is a good "second" strategy to promote survival. Excessive movement could result in accident or injury, and loud protests combined with movement may draw predators. Thus, if protests fail to retrieve the caregiver, the next best survival strategy would be to avoid actions that might increase the risks of self-inflicted harm or predation.

Bowlby also observed that, after a period of despair, infants who are not reunited with their caregivers enter a third stage: *detachment*. During this phase, the infant begins to resume normal activity without the caregiver, learning to behave in an independent and self-reliant manner. Bowlby (1969/1982) conjectured that the function of detachment is to permit the formation of emotional bonds with new caregivers. He reasoned that emotional ties with previous caregivers must be relinquished before new bonds can be formed. From the standpoint of evolution, detachment allows infants to cast off old emotional ties and begin the process of forming new ones with caregivers who may be willing to provide the attention and resources necessary for survival.

Bowlby believed that the cognitive, emotional, and behavioral reactions that characterize each stage reveal the operation of an innate attachment system. The main reason why the attachment system evolved and remains so deeply ingrained in human nature is that it provided a good solution to one of the most difficult adaptive problems our ancestors faced—how to increase the probability of survival through the most perilous years of social and physical development. Inspired

by Darwin, Bowlby believed that the attachment system was genetically "wired" into many species through directional selection during evolutionary history.

There were, of course, limitations to Bowlby's and other early attachment theorists' understanding and application of evolutionary thinking, many of which Bowlby sought to correct as he developed attachment theory (see Belsky, 1999; Simpson, 1999). One shortcoming was his initial focus on the differential survival of species rather than individuals. Another shortcoming was his focus on the survival function of attachment rather than the implications it has for differential reproduction. To enhance reproductive fitness, individuals must not only survive to reproductive age, but they also must successfully mate and raise children, who then must mate and raise their own children, and so on. Fortunately, as we shall see, some contemporary attachment theorists have shifted attention to how attachment phenomena and processes in childhood are systematically linked to the enactment of different reproductive strategies in adulthood (Belsky, in press; Belsky, Steinberg, & Draper, 1991; Chisholm, 1996, 1999). However, because individuals cannot reproduce without first surviving to reproductive age, Bowlby wisely built the foundation of attachment theory on this vital precursor to ultimate reproductive fitness.

Early attachment theorists also held the erroneous view that most rearing environments in the EEA were benign, resulting in the secure attachment pattern being "species-typical" (e.g., Ainsworth, 1979; Main, 1981). The EEA, however, was not nearly as uniform, resource-rich, or benign as many early attachment theorists envisioned (e.g., Edgerton, 1992), which means that no single attachment pattern should have been primary or species-typical. In fact, as we shall see, the adoption of different attachment patterns (in children) or orientations (in adults) most likely reflect evolved, often unconsciously enacted tactics that probably improved *reproductive fitness* in response to the specific environments in which individuals grew and developed in ancestral times and perhaps still today. Reproductive fitness reflects the extent to which an individual's genes are present in his or her descendants. The concept of inclusive fitness (described below) highlights the important distinction between genes present in direct descendants (i.e., children) and those present in indirect descendants (e.g., grandchildren, nieces, nephews). From an evolutionary standpoint, the

maximization of reproductive or inclusive fitness is the goal of all living organisms, including humans, and thus is the target of natural selection.

Perhaps the biggest impediment to Bowlby's understanding of evolution, however, was the undeveloped state of evolutionary thinking when he began formulating attachment theory in the 1950s and 1960s. The foundation of attachment theory was well established long before several significant "middle-level" theories of evolution—theories that address the major adaptive problems with which humans were confronted during our evolutionary history—were introduced in the 1970s. As a consequence, Bowlby was not privy to much of what is now known as the "modern" evolutionary perspective when he started erecting the tenets of attachment theory. Until recently, few of the modern middle-level evolutionary theories were systematically linked with mainstream attachment theory and research. We hope to facilitate this process.

The overarching goal of this chapter is to place attachment theory in a modern (neo-Darwinian) evolutionary perspective. The chapter had seven sections. The first briefly reviews theoretical developments that have transformed Darwin's (1859, 1871) original theory of natural selection into the modern evolutionary perspective. We also discuss where attachment theory fits within the hierarchy of evolutionary principles and middle-level theories. The second section describes the major adaptive problems that our ancestors had to overcome given the probable nature of the environments they inhabited in the course of the past 100,000 years, focusing on the most stable features of the social EEAs that humans probably inhabited.

The third section addresses how the two major components of attachment theory—the normative component and the individual-difference component—fit within a modern evolutionary view of human behavior. In discussing normative attachment, we briefly review the species-typical course through which attachment bonds develop across the lifespan. Different patterns or styles of attachment are construed as adaptive, ecologically contingent behavioral strategies that should have facilitated reproduction in adulthood given the probable environments that individuals would inhabit as adults.

Section four reveals how another major middle-level theory of evolution—Trivers's (1974) theory of parent-offspring conflict—sheds new light on several attachment-related phenomena,

including how and why parents and children negotiate issues of weaning, parental investment, and the child's eventual independence. In the fifth section, we review and evaluate several attachment/life history models, most of which articulate how and why different attachment patterns in childhood might affect the trajectory of social and personality development, culminating in divergent reproductive strategies in adulthood. In the final two sections, we discuss some unresolved issues and promising new directions for research, and offer concluding comments.

The Place of Attachment Theory in Modern Evolutionary Thinking

Though it remains one of the greatest intellectual accomplishments in the history of science, Darwin's (1859) original theory of evolution was incomplete and imprecise. Darwin's thinking was constrained by several factors. First, his theory predated our understanding of genes and patterns of inheritance. Second, because Darwin did not focus on genes as the principal units on which natural selection operates, he could not explain why some organisms engage in self-sacrificial or nonreproductive behavior. This enigma was not solved until Hamilton (1964) introduced the concept of *inclusive fitness* (i.e., the notion that differential gene replication is what truly drives evolution). Third, Darwin had only a faint understanding of how sexual recombination and genetic mutations provide the variation from which better adaptations and new species are selected. Fourth, he did not fully appreciate the degree to which specific adaptations have both benefits and costs. Similar to many theorists of his time, Darwin focused more on the benefits bestowed by certain adaptations, without fully factoring in their associated costs (Cronin, 1991). Darwin's brilliance, however, allowed him to envision how natural selection might operate *without* the benefits of all this later knowledge.

The Rise of Modern Evolutionary Theories

Few theoretical advances occurred in the evolutionary sciences for more than a century after Darwin published his second landmark book, *The Descent of Man, and Selection in Relation to Sex*, in 1871. This state of affairs changed in the mid-

1960s. With the development of inclusive fitness theory, Hamilton (1964) introduced kin selection. By focusing on the gene rather than the individual organism as the primary unit on which selection operates, Hamilton solved the biggest paradox that Darwin never unraveled, namely, that during the evolutionary struggle for reproductive fitness, some organisms forgo reproduction to assist the reproductive efforts of their biological relatives.

Hamilton solved this riddle by realizing that an individual's total (inclusive) fitness depends on his or her own reproductive output plus the total reproductive output of all kin who share some portion of the individual's genes. If genes are the units on which selection operates, and if individuals can facilitate the reproductive output of their biological relatives, there would be situations in which it would pay to sacrifice one's own reproductive output, including one's life, to facilitate the reproduction of close relatives. Unlike Darwin, Hamilton could calculate the degree to which pairs of individuals are likely to share novel genes. On average, parents share half of their genes with their children, full siblings share half of their genes with each other, grandparents share one-fourth of their genes with their grandchildren, aunts and uncles share one-fourth of their genes with their nieces and nephews, and first cousins share one-eighth of their genes.

Armed with this knowledge, Hamilton confirmed that self-sacrificial behavior could have been selected in situations where the costs of engaging in an act were less than the benefits to be gained times the degree to which individuals were biologically related (i.e., altruistic behavior should occur when $C < Br$, where C = costs, B = benefits, and r = the degree of relatedness; see Simpson, 1999). For example, while it would make sense to sacrifice one's own life to save at least two biological children (each of whom shares 50% of the parent's genes), one would have to save many more nieces or nephews (who carry fewer genes) to achieve the same fitness benefits. Hamilton's intellectual breakthrough marked the dawn of the modern evolutionary perspective. Indeed, inclusive fitness theory is the overarching theory of natural selection from which virtually all middle-level evolutionary theories are derived. Although Hamilton's research was not cited by Bowlby (1969/1982), Bowlby's first major statement on attachment proved to be one of the first middle-level evolutionary theories. In developing attachment theory, Bowlby sought to understand and explain how our ancestors successfully solved

the first major barrier to inclusive fitness—how to survive the perils and dangers of infancy.

Several important theoretical advances followed in the 1970s, many of which were spearheaded by Robert Trivers. In 1971, he introduced the theory of reciprocal altruism, which explains why organisms with inherently "selfish" genes should, at times, behave cooperatively with non-kin. The development of this theory was important for attachment theory given the presumed links between early attachment security—insecurity and the development of empathy and prosocial behavior. Trivers identified some of the specific conditions under which selective reciprocal altruism ought to enhance an individual's inclusive fitness. Axelrod (1984) then demonstrated mathematically how a quid pro quo strategy of helping others (i.e., a tit-for-tat strategy) can evolve and become stable amid other competing strategies.

In 1972, Trivers unveiled the theory of parental investment and sexual selection. According to this theory, different amounts of parental investment in children govern sexual selection, which explains why females and males in many species differ on certain physical attributes (e.g., relative body size) and behavioral characteristics (e.g., aggressiveness). Trivers argued that, in species in which one sex *initially* invests more time, effort, resources, and energy in producing and raising offspring (usually women, in the case of humans), the other sex (usually men) should compete to mate with the higher-investing sex. The intense *intrasexual* competition that results should have produced some of the modal physical, behavioral, and emotional differences witnessed between the sexes. This leads one to wonder whether we should expect similarities or differences in attachments to mothers versus fathers.

In 1974, Trivers introduced the theory of parent-offspring conflict, which explains why parents and their children—individuals who share half their genes and, thus, should be jointly invested in passing them on to future generations—experience conflict: Their individual self-interests are not identical. Because this theory has several fascinating implications for how attachment patterns between children and their caregivers can be understood, it is discussed in greater detail below. For now, though, it is important to recognize that this theoretical precept challenges the common assumption that parents are motivated to be unconditionally devoted to their offspring rather than "strategic allocators" of time, attention, and other resources.

In recent years, life history theory (Charnov, 1993; Kaplan & Gangestad, 2005) has become a unifying perspective within the evolutionary sciences. To leave descendants, individuals must solve multiple problems associated with survival, growth, development, and reproduction across the lifespan. Depending on life circumstances, an individual's time, effort, and energy can be allotted to *somatic effort* (i.e., investing in growth and development of one's own body to facilitate survival enroute to later reproduction) or *reproductive effort* (i.e., funneling effort toward progeny). Reproductive effort has two components: *mating effort* (i.e., locating, courting, and retaining suitable mates) and *parenting effort* (i.e., gestating, giving birth, postnatal child care, and teaching/socialization). Life history theory explains how individuals should best allocate somatic versus reproductive effort given their past, current, and anticipated (future) life circumstances, as well as their health and well-being.

Attachment Theory in the Hierarchy of Evolutionary Theories

Inclusive fitness theory, which encompasses both Darwin's concept of fitness due to one's own reproduction (i.e., direct descendants: children) and Hamilton's notion of fitness due to the reproduction of one's biological relatives (i.e., indirect descendants: grandchildren, nieces, etc.), is the superordinate theory of evolution from which all middle-level evolutionary theories flow. The middle-level theories, which include reciprocal altruism (Trivers, 1971), sexual selection and parental investment (Trivers, 1972), parent-offspring conflict (Trivers, 1974), and attachment (Bowlby 1969/1982), address the specific adaptive problems that humans faced and had to resolve during evolutionary history. Thus, they reside one level below inclusive fitness theory. Because life history theory addresses how individuals should allocate their finite resources across the entire lifespan, it interconnects and integrates the middle-level theories. Each middle-level theory in turn has a small set of basic principles that reside at the next level down (see Simpson, 1999). Most evolutionary hypotheses and predictions are derived from these basic principles.

Sexual selection and parental investment theory, for instance, contains two major principles relevant to mate selection. The theory suggests that the search for mates is governed by the degree to which prospective mates (1) are likely

to be good investors in and providers for future offspring, and (2) have desirable attributes (e.g., physical attractiveness or other mate-attracting features) that could be passed on genetically to offspring (Gangestad & Simpson, 2000). Specific predictions and hypotheses are then derived from each of these principles.

Attachment theory also has two primary theoretical components. The *normative component* of attachment theory makes predictions about relatively universal, stable patterns of behavior, particularly in response to situations in which individuals feel ill, fatigued, afraid, or upset (Bowlby, 1969/1982). The *individual-difference component* offers predictions about the ontogenic origins and developmental sequelae of different patterns or orientations (styles) of attachment, including why each pattern or style should be "adaptive" in certain environments.

Even though each middle-level evolutionary theory addresses a specific set of adaptive problems, many of them have overlapping implications for social behavior. Kin selection theory, for example, also stipulates when conflict should arise between parents and their children; parent-offspring conflict theory specifies when reciprocal altruism should emerge between different sets of pair-bonded parents; and reciprocal altruism theory addresses when men and women might strive to attain status and ascend social hierarchies in groups (Simpson, 1999). In some cases, middle-level theories generate different hypotheses and predictions regarding a given outcome. For some phenomena, therefore, there is no single evolutionary prediction, particularly if competing middle-level theories are involved (Buss, 1995). What is most important to appreciate is that predictions derived from evolutionary theorizing *are* empirically testable.

Stable Features of the Social EEA

In order to understand the context in which the attachment system evolved and the problems it was designed to "solve," one must consider the physical and social environments that humans most likely inhabited during evolutionary history. Although attachment theorists have speculated about what the EEA may have been like (especially the physical EEA; see Bowlby, 1969/1982), less consideration has been given to the *social EEA* (Simpson & Belsky, 2008).

For most of our evolutionary history, humans were hunters and gatherers (Cronk, 1999; Kelly, 1995) who lived in small, cooperative groups (Brewer & Caporael, 2006; Eibl-Eibesfeldt, 1989). Most people within a tribe were biologically related to one another, and strangers were encountered rather infrequently, mainly during intertribal trading, social contact, or war (Wright, 1994). Though people occasionally migrated in and out of their natal groups, most remained in the same tribe their entire lives. Men and women formed long-term pair bonds (Cronk, 1999), but serial monogamy was probably most common (Fisher, 1992). Children were born approximately 4 years apart and were raised with considerable help from extended family and perhaps even non-kin (Wright, 1994); few children were raised exclusively by their biological parents. Humans, in fact, were probably “cooperative breeders” who shared childrearing with their kin (Hrdy, 1999, 2005). Younger children most likely spent considerable time being socialized by older children (Eibl-Eibesfeldt, 1989) if they survived premature death, especially during the first 5 years of life. Both men and women were involved in securing food, with men doing most of the hunting and women doing most of the gathering (Wood & Eagly, 2002). Participation in the daily functioning of small, cooperative groups may in fact have been the predominant survival strategy of early humans (Brewer & Caporael, 2006). These likely features of the social EEA must be considered when conceptualizing attachment theory within an evolutionary framework.

Normative and Individual-Difference Components of Attachment

As mentioned earlier, attachment theory has two primary components: (1) a normative component that explains modal or species-typical patterns and stages of attachment in humans (e.g., “How and why are attachment bonds formed?”), and (2) an individual-difference component that explains deviations from modal or normative patterns and stages (e.g., “How and why do different patterns of attachment exist?”). The attempt to account for both species-typical patterns of behavior and predictable individual differences is a hallmark of nearly all major middle-level evolutionary theories.

Normative Features of Attachment

There are three normative features of attachment that have especially important ties to evolutionary principles (Simpson & Belsky, 2008): the “synchronization” of infant–parent responses/behaviors during the first few months of life, young children’s need to maintain contact with and seek proximity to their caregivers, and the basic stages through which attachment propensities develop.

Synchronized Capabilities

Compared to most other species, human infants are born in an underdeveloped and premature state (Kaplan, Lancaster, & Hurtado, 2000). From the moment of birth, however, human infants are “prepared” to bond with their caregivers (Simpson, 1999), and several ways in which mothers behave—at birth and early in development—seem to operate in *synchrony* with the capabilities and limitations of their infants, facilitating infant–caregiver bonds (Simpson & Belsky, 2008). For example, mothers typically exaggerate their facial expressions, change them more slowly, and maintain visual contact for longer periods of time when interacting with infants than with others (Eibl-Eibesfeldt, 1989). When talking to infants, mothers engage in “motherese” (Fernald, 1985), slowing their speech, accentuating certain syllables, and speaking one octave above normal speech (Grieser & Kuhl, 1988). These patterns of behavior are preferred by most young infants and are well suited to their developing visual and auditory capacities. Systems that operate in a synchronous, lock-and-key fashion between codependent individuals, as those just highlighted do, are often a telltale sign of evolved adaptations.

Contact Maintenance and Proximity Seeking

According to Bowlby (1980), attachment behaviors include actions that promote proximity between children and their attachment figures. Young children engage in three classes of behavior to establish or maintain proximity to their caregivers (Bowlby, 1969/1982). *Signaling behaviors* (e.g., vocalizing, smiling) tend to draw caregivers toward the child, usually for positive interactions. *Aversive behaviors* (e.g., crying, screaming) bring caregivers to children, typically to terminate the aversive reactions. *Active behaviors* (e.g., ap-

proaching, following) move the child toward the caregiver. Though different phenotypically, these behaviors all serve the same evolutionary function—to keep vulnerable infants in close physical proximity to their caregivers, thereby increasing their chances of survival. Since death prior to reproduction was the first major threat to inclusive fitness, Bowlby reasoned that directional selection shaped the attachment system in humans, establishing the foundation of our social nature.

Phases of Development

According to Bowlby (1969/1982), attachment propensities develop through four phases in humans (see also Marvin, Britner, & Russell, Chapter 13, this volume). In the first phase, which takes place between birth and age 2–3 months, infants respond to a wide variety of social stimuli and people without exhibiting strong preferences for one attachment figure. Although Bowlby may have overestimated how open young infants are to contact comfort from multiple caregivers, he was correct in believing that infants are malleable in terms of whom they can and do bond with during the opening months of life. The early openness of the system may have facilitated survival—and may, therefore, have been selected—in a world where the risk of maternal death resulting from delivery and/or its complications was far more common than it is today.

During the second phase, which occurs between age 2–3 months and about 7 months, infants display greater discrimination in social responsiveness. They begin, for instance, to distinguish caregivers and family members from strangers, selectively prefer certain persons, and direct their attachment behaviors toward specific attachment figures. Such discrimination should have helped the infant “reel-in” the caregiver, further facilitating survival (in the service of eventual reproduction), and thus resulting in its selection.

In the third phase, which extends from age 7 months to roughly 3 years, children play a more active role in seeking proximity and initiating social contact. During this phase, they also start developing internal working models (i.e., beliefs, expectancies, and attitudes about relationships based on experiences with attachment figures) of themselves and significant others (Bowlby, 1973). This is also when the three primary “functions” of attachment are first seen in the child’s behavior: *proximity maintenance* (staying near to, and resist-

ing separations from, the attachment figure), *safe haven* (turning to the attachment figure for comfort and support), and *secure base* (using the attachment figure as a base from which to engage in nonattachment behaviors). If children in this phase have prolonged separations from their attachment figures, they experience the three stages of response to separation: protest, despair, and detachment. For reasons outlined earlier, these responses should also have aided and abetted survival and reproduction, thereby leading to their selection.

The fourth phase, which begins around age 3, marks the beginning of behaviors that signal goal-corrected partnerships with attachment figures. Given the further development of their language skills and theory-of-mind capabilities, children start to see the world from the perspective of their interaction partners. This allows them to incorporate the goals, plans, and desires of their partners into their own decision making, which results in the negotiation of joint plans and activities. These unique abilities should also have facilitated the formation and maintenance of pair bonds and, thus, may have been selected by evolutionary processes.

As children move through the toddler years, their desire for physical proximity is gradually replaced by a desire to maintain psychological proximity (i.e., felt security; Sroufe & Waters, 1977). Early in adolescence, overt manifestations of attachment bonds with parents subside, and the three functions of attachment—proximity maintenance, safe haven, and secure base—are gradually transferred from parents to peers and romantic partners as adolescents enter adulthood (Furman & Simon, 1999). During this final stage, the centrality of reproduction as an evolutionary process becomes more obvious and direct instead of indirect (i.e., through enhancing survival).

Individual Differences in Attachment

Although infants are biologically predisposed to form attachment bonds to their caregivers, the type of bonds they form ought to depend on the conditions in which they are raised, as Bowlby (1969/1982) and Ainsworth (1979) proposed. Perceptions of environmental conditions, in turn, should be filtered through evolved psychological mechanisms, including sensation (e.g., physical warmth), perception (e.g., caregiver responsiveness), and representations (e.g., internal working mod-

els). Such psychological mechanisms are typically activated by specific environmental cues, resulting in “optimal” ecologically contingent strategies that evolved to solve specific adaptive problems posed by certain kinds of environments (Buss, 1995; Tooby & Cosmides, 1992).¹

Infants, of course, do not have the cognitive ability to appraise the quality of local environmental conditions, such as whether the environment is safe, plentiful, and rich in resources versus threatening, harsh, and impoverished. However, they *do* have the ability, which is well appreciated by attachment theory, to determine whether caregivers are sensitive, responsive, and attentive to their biological needs. Such information ought to provide clues about the nature and quality of current—and perhaps future—environmental conditions (Belsky, 1997; Chisholm, 1996; Frankenhuis, Gergely, & Watson, 2013). If caregivers in evolutionary history were able to devote the time, effort, and energy necessary to be sensitive, responsive, and attentive to the needs of their children, the local environment was probably safe and sufficiently rich in resources, broadly defined. In contrast, if caregivers were insensitive, nonresponsive, and devoted less attention to their children, the local environment was probably less resource-rich and perhaps even dangerous.

Ainsworth’s Strange Situation is well suited to detect different patterns of attachment because it presents infants with two common cues to danger in the EEA: being left alone, and being left with a stranger. Examining reunions between mothers and their 12- to 18-month-old infants, Ainsworth, Blehar, Waters, and Wall (1978) identified three primary attachment patterns in young children: secure, anxious-ambivalent, and anxious-avoidant. Upon reunion, securely attached children use their caregivers to regulate and attenuate their distress, resuming other activities (e.g., exploration, play) rather quickly after calming down. Anxious-avoidant children retract from their caregivers upon reunion, opting to control and dissipate their negative affect in an independent, self-reliant manner. Anxious-ambivalent children make inconsistent and conflicted attempts to derive comfort and support from their caregivers, intermingling clinginess with outbursts of anger (see Fearon & Belsky, Chapter 14, and Solomon & George, Chapter 18, this volume).

Each attachment pattern reflects a different “strategy” that would have solved adaptive problems posed by different kinds of rearing environments (Belsky, 1997; Chisholm, 1996; Main,

1981). Mothers of securely attached infants tend to be available and responsive to the needs and signals of their infants (Ainsworth et al., 1978; De Wolff & Van IJzendoorn, 1997). Largely because of this, secure children do not have to worry about the availability and responsiveness of their caregivers, which allows them to concentrate on other life tasks.

Anxious-ambivalent children have caregivers who tend to behave inconsistently toward them (Ainsworth et al., 1978), sometimes because of poor or deficient parenting skills (Isabella, Belsky, & von Eye, 1989; Lewis & Feiring, 1989). Among children who are maltreated, anxious-ambivalent children are more likely to have been victims of parental neglect (Youngblade & Belsky, 1989). Thus, the demanding nature of anxious-ambivalent children may reflect an ecologically contingent strategy designed to obtain, retain, or improve greater parental attention and care (Cassidy & Berlin, 1994; Main & Solomon, 1990). For children with such parents, this behavioral strategy would have increased proximity to caregivers, solicited better care, and improved the child’s chances of survival (and eventually reproduction).

Avoidant children usually have caregivers who are cold and rejecting (Ainsworth et al., 1978). Among maltreated children, avoidant children are more likely to have suffered physical or emotional abuse from their parents (Youngblade & Belsky, 1989). The evolutionary origins of avoidance, however, may be more complex and multifaceted than those of anxious-ambivalence. Bowlby (1980) conjectured that avoidance allows infants to disregard cues that might activate the attachment system. If such cues were fully processed, avoidant infants might recognize the true inaccessibility and rejecting demeanor of their primary caregivers, which could be incapacitating.

Two additional evolutionary explanations for avoidance in childhood have been proposed. According to Main (1981), the distant, self-reliant behavior that characterizes avoidant infants enables them to maintain reasonably close proximity to belligerent or overwhelmed caregivers without driving them away. Avoidance, in other words, may have evolved to overcome deficiencies in caregiving provided by highly distressed, hostile, or unmotivated parents. During evolutionary history, this behavioral strategy would have increased the survival of infants who, if they put too many demands on their parents, might have been abandoned. Alternatively, earlier reproduction may

facilitate inclusive fitness in some circumstances, especially in harsh environments with few resources (Trivers, 1985). If maternal rejection was a valid proximal cue of the severity of future environments, avoidant tendencies might motivate children not only to move away from their parents earlier but also to become more opportunistic and risk taking, thereby facilitating survival and early reproduction in arduous environments (Belsky, 1997; Belsky et al., 1991). Moreover, if the stress experienced by insecure children undermined their health, internal bodily signals indicating declining health and increased morbidity or mortality may also have played a role in strategically regulating development (Belsky, 2014; Rickard, Frankenhuis, & Nettle, 2014).

As children enter adolescence, cumulative experiences in relationships are further assimilated into internal working models, which are continuously being updated and revised. These models reflect the degree to which individuals (1) believe they are worthy of love and affection, and (2) view significant others as loving and affectionate (Mikulincer & Shaver, 2007). Unlike in childhood, however, the attachment system in adulthood becomes integrated with the mating and caregiving systems (Shaver, Hazan, & Bradshaw, 1988), making adult attachment orientations (styles) more challenging to interpret than attachment patterns in children.

Attachment Theory and Parent–Offspring Conflict Theory

One middle-level evolutionary theory that has considerable relevance to attachment theory is parent–offspring conflict theory (Trivers, 1974). According to this theory, children (who share 50% of their genes with parents and full siblings) should want greater investment from their parents than their parents have been selected to provide. As a result, parents and offspring have slightly divergent reproductive interests, which result in conflict that peaks during the final stages of weaning. Stated another way, the evolutionary interests of parents and their infants are not perfectly aligned, which means that what is good for the child is not necessarily good for the parent, and vice versa. Unlike many current applications of attachment theory, the modern evolutionary perspective does not romanticize or idealize parent–child relationships.

Parent–Offspring Conflict Theory and Parental Investment

According to Trivers (1972), parental investment involves any actions performed by a parent for his or her offspring that increase the offspring's chances of survival, while reducing the parent's ability to invest in other current or future offspring. The level of investment depends on the costs and benefits associated with a given parental act or behavior. *Costs* are defined as units of forgone reproductive success by other current or future offspring, and *benefits* are defined as units of reproductive success of the current offspring (Trivers, 1974). In humans, acts of investment include allocating time, effort, energy, or resources to children through activities such as feeding, protecting, sheltering, and teaching. The amount of investment that children seek and parents offer should hinge on how both parties view the costs and benefits of different forms of parental investment.

When infants are young and highly dependent on their parents for care and resources, the costs of investment to parents are low and the benefits to infants are high from the reproductive standpoint of each party. During the early stages of childrearing, therefore, the reproductive interests of parents and their offspring coincide reasonably well, but not perfectly. However, as infants grow, consume more resources, and become more self-sufficient, the reproductive interests of parents and offspring diverge. From the parents' perspective, the costs of investment continue to rise over time while the benefits the infant derives from additional investment asymptotes. During this phase, directing investment to new offspring could enhance parents' reproductive success more than continuing to invest in an increasingly autonomous, self-sufficient child. This is the point at which weaning takes place in most cultures.

Given that children share only half of their genes with their parents and full siblings, two of their siblings must survive and successfully reproduce to propagate the infant's genes fully to future generations. Thus, infants should “devalue” the costs of investment incurred by their parents by 50%, expecting twice as many benefits as their parents have been selected to provide. Children and parents, therefore, should experience conflict until, from the perspective of the parent, the cost of parental investment is more than twice the benefit to the infant (or, from the perspective of the child, the cost of parental investment exceeds self-benefit). When this point is reached, the child's

inclusive fitness would be reduced if he or she continued to demand additional investment. Conflict should then subside as the child accepts the diversion of parental investment to other siblings.

Attachment theory does not fully recognize and account for the somewhat different reproductive interests of infants and their caregivers. Instead, scholars often assume that the evolutionary interests of parents and their children are largely equivalent and that, barring significant abnormalities, each child should be of equal “reproductive value” to its parents. Both of these assumptions are questionable. The reproductive value of a child should depend on several factors (Daly & Wilson, 1981; Trivers, 1974), including attributes of (1) the infant (e.g., his or her health, normality), (2) the mother (e.g., her health, age, ability to provide for the infant), (3) the father (e.g., the certainty of his paternity, his resources, his willingness to invest in the infant), (4) the nuclear family (e.g., the number of existing children, their birth spacing, the presence of stepsiblings), and (5) the local environment (e.g., whether or not resources are available to minimize the costs and maximize the benefits of further parental investment). When the costs of investing in a given child are disproportionately high relative to the benefits, parents should display preferential investment in certain children (Daly & Wilson, 1981). In some instances, attachment insecurity might arise from conditions that lower parental investment. Lower levels of investment should be evident in inadequate or poor caregiving behaviors, such as parental inattentiveness, neglect, rejection, abuse, and infanticide in extreme cases.

Cross-cultural research reveals that parental investment is, in fact, lower in families that have at least one biologically unrelated parent; when fathers question their paternity; when infants are ill, weak, or deformed; during periods of famine; when families are poor or lack social support; when mothers are very young; when families have too many children; and when birth spacing is too short (Daly & Wilson, 1988; Hrdy, 1999).

Parental Investment and Attachment

Relatively little is known about whether the conditions that reduce parental investment actually *cause* insecure attachment in children, primarily because it is unethical to employ such experimental interventions. However, strong links have been chronicled between certain contextual factors and

the quality of parental care, which is causally related to attachment security (Fearon & Belsky, Chapter 14, this volume). These factors include parental psychological health and well-being (e.g., Belsky & Jaffee, 2006), quality of marital/romantic partner relations (e.g., Krishnakumar & Buehler, 2000), and social support/connectedness (e.g., Andresen & Telleen, 1992). This research indicates that the greater the well-being, marital quality, and social support, the more sensitive, responsive, stimulating, and less detached (or hostile) the parenting tends to be. These “determinants of parenting” (Belsky, 1984) are also related to attachment security in the expected direction, such that better conditions instill greater security, which fosters better parental well-being (e.g., Atkinson et al., 2000; Jacobson & Frye, 1991). There is even evidence that parenting is the proximate mediator linking these more distal contextual factors with attachment security (e.g., Crittenden, 1985).

Evolutionary Models of Social Development across the Lifespan

Attachment theory addresses social and personality development “from the cradle to the grave” (Bowlby, 1979, p. 129). Most early attachment research, however, investigated certain barriers to inclusive fitness (e.g., problems associated with infant survival) to the relative exclusion of other barriers (e.g., problems associated with mating and reproduction). Even though some early attachment theorists (e.g., Main, 1981) conjectured that different attachment patterns in children might reflect different evolved strategies for promoting survival under certain rearing conditions, childhood attachment patterns were not theoretically tied to the development of different adult romantic attachment styles and mating orientations until the early 1990s, when Belsky and his colleagues (1991) published an influential paper on human social development from an evolutionary/attachment perspective.

Life History Theory

More recent theoretical developments have been guided by life history theory (LHT) (Charnov, 1993). LHT addresses how and why individuals allocate time, energy, and resources to different traits, behaviors, and life tasks when they are faced with tradeoff decisions that could influence their

reproductive fitness (Kaplan & Gangestad, 2005). In particular, LHT models the selection pressures in our ancestral past that should have determined when, and the conditions under which, individuals allocated time, energy, and resources to physical development, growth, reproduction, body repair, or aging.

According to most life history models, individuals can increase their reproductive fitness in two general ways (Parker & Maynard Smith, 1991). First, they can “invest” in traits or attributes that affect the timing of their mortality (i.e., the age at which they die). Second, they can “invest” in traits or attributes that influence the timing of their fertility (i.e., the age and rate at which they reproduce). Many life history traits/attributes, however, have countervailing effects on mortality and fertility (Kaplan & Gangestad, 2005). Traits or attributes that improve fertility through more frequent or more intense mating effort, for example, usually shorten survival, because many of the traits that make people (particularly men) more attractive to the opposite sex compromise the immune system (Grafen, 1990). Moreover, the allocation of energy and resources to growth during development tends to retard fertility when individuals are young, but enhance it once individuals mature sexually (Charnov, 1993). And the allocation of time, energy, and resources needed to ensure that one’s children grow to be strong and healthy typically undermines one’s own future fertility and survival.

Because one “can’t have it all,” individuals must negotiate three fundamental tradeoffs during their lives: (1) whether to invest in present (immediate) reproduction or future (delayed) reproduction; (2) whether to invest in higher quantity or higher quality offspring; and (3) whether to invest in mating effort or parenting effort. The way in which each tradeoff is resolved ought to depend on several factors, including the demands of the local environment (e.g., how taxing it is, the number of pathogens it contains, whether biparental care is required); the health, skills, abilities, and resources available to an individual at that time; the health, skills, abilities, and resources of others (e.g., kin, potential mates, competitors); and so forth.

The Belsky, Steinberg, and Draper Model

Inspired by LHT and earlier research on father absence during childhood (Draper & Harpending, 1982), Belsky and colleagues (1991) developed the first evolution-based and attachment-oriented

lifespan model of human social development. According to this model, the main evolutionary function of early social experience is to “prepare” children for the social and physical environments they are likely to encounter during their lifetime. The model focuses primarily on rate of development (i.e., faster vs. slower) and therefore offspring quantity versus quality tradeoffs. Ellis (2004) has labeled it “psychosocial acceleration theory” even though the theory addresses both slower and faster development. Certain information gleaned from the early environment should allow individuals to adopt an appropriate reproductive strategy—one that, on average, best increases inclusive fitness—in future environments. Hinde (1986), for example, proposed that if maternal rejection is induced by harsh environments in which competition for limited resources is intense, offspring who are aggressive and noncooperative should have higher reproductive fitness as adults than those who do not display these attributes. Conversely, offspring raised in environments with abundant resources could increase their fitness by adopting a more cooperative and communal orientation in adulthood.

The five-stage Belsky and colleagues (1991) model proposes that (1) early contextual factors in and around the family of origin (e.g., level of stress, spousal harmony, financial resources) affect (2) early childrearing experiences (e.g., level of sensitive, supportive, and responsive caregiving). These experiences then affect (3) psychological and behavioral development (e.g., attachment patterns, internal working models) that in turn influence (4) somatic development (i.e., how quickly sexual maturation is reached) and eventually (5) the adoption of specific ways of mating and parenting. These stages are linked sequentially, but earlier stages may statistically interact to predict later outcomes. Early contextual factors in the family of origin, for instance, can interact with early childrearing experiences to forecast the rate of somatic development.

Belsky and colleagues (1991) hypothesized that two developmental trajectories culminate in two reproductive strategies in adulthood (although they could also be opposite ends of a single continuum rather than discrete vs. continuous phenotypes). One strategy entails a short-term, opportunistic orientation toward close relationships, especially with regard to mating and parenting, in which sexual intercourse occurs earlier in life, romantic pair bonds are short-lived and less stable, and parental investment is lower. This orientation is geared to increase the *quantity* of off-

spring. The second strategy entails a long-term, investing orientation toward mating relationships in which sexual intercourse occurs later in life, romantic pair bonds are stronger and more enduring, and parental investment is greater. This orientation maximizes offspring *quality*. A critical and novel prediction derived from this model involving rate of development is that early rearing experiences should influence the timing of puberty. Specifically, sexual maturation should occur earlier for individuals who develop along the “quantity trajectory” than for those who develop along the “quality trajectory.”

A large body of evidence supports the Belsky and colleagues model (for reviews, see Belsky, 2012; Ellis, 2004; Simpson & Belsky, 2008). For example, consistent with nonevolutionary perspectives, greater socioemotional stress in families is associated with more insensitive, harsh, rejecting, inconsistent, and unpredictable parenting practices. Economic hardship (McLoyd, 1990), occupational stress (Bronfenbrenner & Crouter, 1982), marital discord (Belsky, 1981; Emery, 1988), and psychological distress (McLoyd, 1990) are all precursors of more hostile and/or detached parenting styles. Conversely, greater social support and more economic resources facilitate warmer and more sensitive childrearing practices (Lempers, Clark-Lempers, & Simons, 1989), perhaps because less taxed parents are more patient with or tolerant of their young children (Belsky, 1984).

The link between parental sensitivity and the psychological and behavioral development of children is also well established, consistent with both attachment theory and many other theories (e.g., social learning, emotion socialization, life course). During the first year of life, insensitive and unresponsive caregiving predicts the development of insecure attachments (De Wolff & Van IJzendoorn, 1997), which in turn forecasts behavior problems later in development. Insecurely attached 2-year-olds, for instance, are less tolerant of frustration (Matas, Arend, & Sroufe, 1978). Insecurely attached preschoolers are more socially withdrawn (Waters, Wippman, & Sroufe, 1979), less likely to display sympathy to distressed peers (Waters et al., 1979), less willing to interact with friendly adults (Lutkenhaus, Grossmann, & Grossman, 1985), and less well liked by their classmates (LaFreniere & Sroufe, 1985). During elementary school, insecure children have more severe behavior problems, especially aggression and disobedience (Lewis, Fiering, McGuffog, & Jaskir, 1984). According to Belsky and colleagues (1991), these

behaviors are governed by insecure working models, which prepare the child for opportunistic advantage taking and, therefore, noncommunal relationships later in life.

The most novel part of the model concerns what predicts the rate of somatic development. Belsky and colleagues (1991) hypothesized that children exposed to greater socioemotional stress develop insecure attachments, exhibit behavior disorders, and should reach puberty—and thus reproductive capacity—earlier than children without these attributes. According to life history logic (Chisholm, 1993, 1999; Kaplan & Gangestad, 2005), environments in which resources are scarce, relationship ties are tenuous, and mortality risks are elevated should cause more energy and effort to be allocated to rapid physical development, early mating, and short-term romantic pair bonds. This developmental strategy should increase the chances of reproducing before dying (or should have done so in our ancestral past). On the other hand, environments in which resources are plentiful and relationship ties are reciprocal and enduring should lead to effort being channeled to further somatic development, later sexual maturity, delayed mating, and longer-term romantic pair bonds that contribute to greater parental investment. In more benign environments, reproductive fitness could be enhanced by deferring reproduction until (1) individuals have acquired the skills and resources needed to maximize the quality of each offspring, and (2) offspring can benefit from all of the embodied capital that humans need to reproduce successfully.

Several strands of evidence support these predictions (Belsky, 2012). First, greater parent–child warmth, cohesion, and positivity predict delayed pubertal development in both prospective longitudinal studies (Ellis, McFadyen-Ketchum, Dodge, Pettit, & Bates, 1999; Graber, Brooks-Gunn, & Warren, 1995) and retrospective or concurrent ones (Kim, Smith, & Palermi, 1997; Miller & Pasta, 2000). Second, greater parent–child conflict and coercion predict earlier pubertal timing in both prospective longitudinal studies (Ellis & Essex, 2007; Moffitt, Caspi, Belsky, & Silva, 1992) and retrospective or concurrent ones (Kim et al., 1997). Third, the happier and/or less conflict-ridden the parental relationship, the later pubertal maturation occurs in girls, both in prospective longitudinal studies (Ellis et al., 1999; Ellis & Garber, 2000) and in nonprospective ones (Kim et al., 1997). Indeed, early insecure attachment—measured at age 15 months—forecasts earlier age

of menarche and both onset and completion of pubertal development (Belsky, Houts, & Fearon, 2010). These results cannot be easily explained by traditional attachment theory, but they are central to psychosocial acceleration theory. Not all studies have found puberty-related links like those just highlighted. Steinberg (1988), for instance, did not find associations between the amount of family conflict/coercion and pubertal timing in girls. However, family experience–pubertal developmental links consistent with psychosocial acceleration theory have recently emerged in studies that take into account genetic confounding, either via sibling designs (Tithers & Ellis, 2008) or natural experiments (Pesonen et al., 2008).

Almost all of these findings are based on studies involving girls. Although it was once thought that this gender disparity could be attributable to the greater difficulty of measuring puberty in males, this fact does not seem to explain these sex differences. New theorizing by James, Ellis, Schlomer, and Garber (2012) has noted that the early versus later reproduction tradeoff central to Belsky and colleagues' (1991) original theorizing is more pressing for females, whereas that between somatic development and reproduction is more pressing for males, who must engage in considerable intrasexual competition for mates. Recent empirical work by this team provides evidence consistent with this important insight (James et al., 2012).

Evidence relevant to the final stages of the Belsky and colleagues (1991) model (i.e., the mating strategies individuals adopt in adulthood) comes from two sources: (1) research linking adult attachment styles to mating and romantic relationship functioning, and (2) research bridging adult attachment and parenting practices. Individuals who report being more securely attached to romantic partners are less likely to have promiscuous sexual attitudes or engage in extrapair sex (Brennan & Shaver, 1995); are more likely to desire only one sexual partner over a 30-year period (Miller & Fishkin, 1997); and, if female, have sexual intercourse at a later age than their insecure counterparts (Bogaert & Sadava, 2002). Securely attached adults also have more satisfying romantic relationships (J. A. Feeney, Chapter 21, this volume), display less negative affect and more constructive conflict resolution tactics when interacting with romantic partners (Simpson, Rholes, & Phillips, 1996), and engage in more self-disclosure and are more responsive to self-disclosures by partners (Mikulincer & Nachshon, 1991). Consequently, secure adults are

also less likely to divorce or separate (J. A. Feeney, Chapter 21, this volume), have longer lasting romantic relationships (Hazan & Shaver, 1987), and report greater commitment to and trust in their dating partners (Simpson, 1990) and spouses (Fuller & Fincham, 1995).

These findings, although consistent with Belsky and colleagues' (1991) original model, are limited due to their cross-sectional nature and their focus on romantic (rather than childhood) attachment assessments. Recent longitudinal research using data from the Minnesota Longitudinal Study of Risk and Adaptation has provided even more direct support for the model (see Simpson, Collins, & Salvatore, 2011). Simpson, Collins, Tran, and Haydon (2007), for example, have documented links between attachment security (assessed in the Strange Situation at 12 months) and how individuals experience and express conflict with their romantic partners 20 years later. Specifically, individuals classified as insecure at age 1 tend to experience and express relatively more negative emotions in their romantic relationships in their early 20s, and this effect appears to be mediated through their lower social competence in grade school and their less secure same-sex friendships at age 16.

Supporting the Belsky and colleagues (1991) model, adult attachment is also associated with differential expectations about children and parenting even before individuals have children. Rholes, Simpson, Blakely, Lanigan, and Allen (1997), for instance, found that insecurely attached college students anticipate being more easily aggravated by their young children if/when they become parents, expect to be more strict disciplinarians, believe they will express less warmth toward their children, and are less confident about their ability to relate well to them. In addition, avoidant college students believe they will derive less satisfaction from caring for their young children and express less interest in having them. Once they have children, avoidant parents report feeling less emotionally close to their first newborn child as soon as 2 weeks after birth (Wilson, Rholes, Simpson, & Tran, 2007), and avoidant mothers are less emotionally supportive of their preschooler children, adopting a detached, controlling, or instrumentally focused mode of relating to them (Crowell & Feldman, 1991; Rholes, Simpson, & Blakely, 1995). (For a review of studies of self-reported adult attachment patterns and parenting characteristics, see Jones, Cassidy, & Shaver, 2015.)

Furthermore, mothers classified as secure on the Adult Attachment Interview (AAI) (who in many cases received greater warmth and contingent care from their own parents) are more sensitive to and supportive of the needs of their children (Hesse, 2008, Chapter 26, this volume; Van IJzendoorn, 1995). For example, attachment security is linked with greater warmth and more appropriate structuring of learning tasks by fathers and mothers (Adam, Gunnar, & Tanaka, 2004), greater emotional support in various situations (Crowell & Feldman, 1991), less negativity (Slade, Belsky, Aber, & Phelps, 1999), and greater awareness of the child's needs (Das Eiden, Teti, & Corns, 1995).

The Chisholm Model

Chisholm (1993, 1996) extended Belsky and colleagues' (1991) thinking by proposing a slightly revised and expanded model of alternative reproductive strategies, one that focuses on the immediate versus delayed reproduction life history tradeoff. This work advanced our thinking in three significant ways. First, it drew attention to local mortality rates as being the critical cues that humans monitor to regulate their rate of development and, ultimately, their reproductive strategies. After all, high mortality rates ought to have been a direct barometer of the difficulty of local environments, and they should have been associated with poorer caregiving in the EEA. According to Chisholm (1993, 1996), parental indifference or insensitivity—being a valid cue of local mortality rates—would have motivated children to develop avoidant working models and behaviors that should have increased fitness in such arduous environments. Low mortality rates, which should have signaled more hospitable environments, should have been associated with better and more attentive caregiving. Sensitive parenting, in other words, should have conveyed to children that premature death was less likely, resulting in secure working models and behaviors that enhanced fitness in benign environments.

Consistent with Chisholm's theorizing is evidence connecting adverse life conditions with expectations regarding longevity and the timing of reproduction later in life (Nettle, 2010; Nettle & Cockerill, 2010). For example, as life expectancy declines in a local area, the probability of women reproducing by age 30 increases (Wilson & Daly, 1997), and teen mothers who expect to die at a younger age are more likely to become mothers

at an earlier age (Johns, 2003). Such findings are consistent with Geronimus's (1996) "weathering hypothesis," which states that early birth is a strategic response to the rapid decline in health among women, especially poor women, in their 30s and 40s. This underscores the value of treating local mortality rates as a powerful cue in the development of alternative reproductive strategies.

Besides highlighting the importance of local mortality rates, Chisholm (1999) also called attention to *time preference*—the tendency to discount the future by favoring smaller, immediate rewards over larger, delayed ones—as the psychological mechanism linking early rearing experiences with the timing of future mating and parenting behavior. Individuals raised in harsh or unpredictable (i.e., insecurity-inducing) environments, in which waiting for rewards could result in leaving no descendants, ought to prefer immediate payoffs, even if delayed ones might be significantly better (Wilson & Daly, 2005).

Chisholm's (1996) third major contribution was his identification of two parent-based threats to the survival and growth of children in the EEA—parents' *inability* and *unwillingness* to invest in offspring—to which children should have evolved to detect and respond. Thus, the secure attachment pattern is a facultative adaptation to parents' ability and willingness to provide high investment, as reflected in their warm/sensitive caregiving. The avoidant attachment pattern, in contrast, is an adaptation to parents' unwillingness to invest (regardless of their ability), reflected in their cold/rejecting caregiving. Finally, the anxious-ambivalent pattern is an adaptation to parents' inability to invest, reflected in their inconsistent/unpredictable caregiving.

The Belsky and colleagues and Chisholm models have both played important roles in getting scholars to think more deeply about how and especially *why* early experiences shape subsequent development, something that many developmental psychologists have simply taken for granted. Both models, however, have been expanded and further refined by the infusion of additional evolutionary considerations. First, neither model addresses all of the factors that, from an evolutionary standpoint, should govern the adoption of specific reproductive strategies in adulthood. Mate selection is contingent on a multitude of factors, ranging from a potential mate's genetic quality to his or her ability to accrue and share resources, to his or her capacity to impart knowledge and information to offspring (Gangestad & Simpson, 2000).

In addition, psychosocial acceleration theory, as originally conceptualized, was not sufficiently sensitive to the different roles that men and women assume in reproduction (Buss & Schmitt, 1993; Geary, 2005). This inspired James and colleagues (2012) and Del Giudice (2009) to develop sex-differentiated models that accentuate the different life history tradeoffs that females and males must negotiate. For females, the critical tradeoff is between early and later reproduction; for males, it is between growth and reproduction. Despite these limitations, the Belsky and colleagues and Chisholm models represent important advances in our understanding of attachment and social development across the lifespan.

The Del Giudice Model

Del Giudice (2009) has developed a model that incorporates sex differences within an explicitly attachment/evolutionary framework and, in so doing, extends psychosocial acceleration theory in some novel ways. Recent cross-cultural research indicates that boys are more likely to be avoidantly attached in middle childhood, whereas girls tend to be anxious (reviewed in Del Giudice, 2009; for an alternative view, see Van IJzendoorn & Bakermans-Kranenburg, 2010). Del Giudice argues that sex differences in attachment patterns in middle childhood might have adaptive significance for both children and adults because they reflect the enactment of sex-specific life history strategies. Consistent with Belsky and colleagues (1991), early psychosocial stress and insecure attachment patterns are viewed as cues of heightened environmental risk, which shift development toward reproductive strategies that facilitate current reproduction over later reproduction and emphasize mating effort over parenting effort. In line with well-established sex differences between mating and parenting effort (Geary, 2005), insecure males typically enact avoidant strategies, whereas insecure females enact anxious ones, both of which increase subsequent investment from kin and mates. (Females ought to become avoidant, however, when environmental risks become high.)

The most novel part of the model is the proposal that sex differences in attachment should emerge in middle childhood—for reproductive-fitness-related reasons—rather than occurring earlier in development, which is the focus of psychosocial acceleration theory. Indeed, adrenarche (the early stages of sexual maturation) is theorized

to be a “developmental switch-point,” reorganizing attachment during middle childhood, which then has several important implications for ties between attachment patterns and sexual development across the lifespan. Specifically, at the start of middle childhood, insecure children’s attachment patterns become sex-biased, shunting reproductive strategies down sex-optimal developmental pathways. Because attachment security versus insecurity early in childhood is a good barometer of local ecological risk, it has been retained by evolution as a stable, prototype-like behavioral trait (Fraleigh, 2002). These early strategies, however, are disposable phenotypes that can be modified later in development if they no longer match the environmental demands to which the developing child is exposed. This is important, Del Giudice (2009) claims, because avoidant and anxious attachment patterns have different adaptive value for boys and girls with regard to competition in same-sex peer groups in middle childhood.

According to Del Giudice (2009), the strongest selection pressure on attachment patterns in middle childhood should come from intrasexual competition within peer groups when children start competing with others for status, attention, and resources. Negotiations within these groups should be particularly challenging for insecurely attached children, who can no longer count on their nuclear family members to buffer them from all the inherent stress and failures. The avoidant behavioral pattern, which is characterized by heightened aggression, excessive self-reliance, and inflated self-esteem, is used more effectively by males to attain higher status and popularity in middle childhood peer groups (Benenson, 2014). Girls, in contrast, shift to anxious patterns that help them utilize “tend-and-befriend” tactics (Taylor et al., 2000), which are more effective at promoting ascension and success within their social groups.

Successful social strategies, of course, do not always involve competitive status seeking. If environmental conditions are safe/predictable, and monogamy and high paternal investment define the local mating system, low-risk, cooperative strategies ought to maximize males’ long-term fitness better, with less male avoidance (i.e., greater security) resulting in less male–male competition and lower conflicts of interest between mothers and fathers.

Maternal and paternal attachment might also differentially affect the behavioral strategies that children adopt in middle childhood. Mater-

nal and paternal investments are differentially responsive to extrinsic risk (Quinlan, 2007), which could alter children's life history strategies in novel ways. The level of paternal investment, for instance, often contains more diagnostic information about the amount of male–male competition, polygyny, and paternal involvement within the local environment, which could shape children's levels of competitiveness and risk taking (especially in boys), as well as the adoption of avoidant versus anxious attachment patterns (particularly in girls). Future research needs to test these hypotheses and determine whether genotypic variability also affects the regulation of these life history-related traits.

The Ellis Model

Whereas psychosocial acceleration theory called attention to family dynamics, including marital and parent–child relational experiences in regulating the development of reproductive strategies (Belsky et al., 1991), Ellis and colleagues (1999; Ellis & Garber, 2000) drew upon Draper and Harpending's (1982) focus on father absence and Trivers's (1972) parental investment theory to hypothesize that fathers have a special role in the development of girls' reproductive strategies. Belsky and colleagues (1991) viewed early father absence as a marker of stress in the family of origin and appreciated the influence of the quality of both mothering and fathering. Ellis (2004), on the other hand, suggests that father absence or stepfather presence is a particularly salient, evolutionarily privileged cue of paternal investment that signals low, unpredictable, or changing levels of paternal investment in families.

Father absence does, in fact, predict accelerated pubertal development among girls, both in prospective studies in which girls are followed from childhood into adolescence (e.g., Campbell & Udry, 1995; Ellis & Garber, 2000; Ellis et al., 1999) and in retrospective studies of adults (e.g., Doughty & Rodgers, 2000; Hoier, 2003; Quinlan, 2003). Similar effects, however, have not been found in African American samples (e.g., Campbell & Udry, 1995; Rowe, 2000). In addition, research does not always find greater predictive power of fathering or the father–child relationship over mothering and the mother–child relationship (e.g., Ellis, Shirtcliff, Boyce, Dearthoff, & Essex, 2011). All too often, evidence of father effects on pubertal development comes from studies that

do not include measures of mothers (see Belsky, 2012).

Nevertheless, research does indicate that the earlier father absence occurs in a child's life (especially within the first 5 years), the more strongly it predicts the speed of female pubertal development (e.g., Ellis & Garber, 2000; Quinlan, 2003). Stepfather presence may also affect pubertal timing, perhaps accounting for some of the father absence effects (Ellis, 2004). Supporting this view, greater conflict between the mother and stepfather combined with earlier stepfather presence in the home is especially influential in accelerating pubertal development in girls (Ellis & Garber, 2000). Consistent with Belsky and colleagues' (1991) emphasis on the quality of parent–child relationships, Ellis and colleagues (1999) also found that girls' pubertal development is delayed the more time fathers spend caring for their daughters during the first 5 years of life and the more fathers have positive/affectionate interactions with their daughters at age 5.

Thus, there are good theoretical and even empirical grounds for *not* treating mothers and fathers as interchangeable agents of influence in understanding how childhood experiences shape reproductive strategies. Greater attention should be paid to the presence of biologically unrelated male figures in the home during development and to the differential influence of maternal and paternal investment (i.e., quality of parenting).

The Hazan–Zeifman and Kirkpatrick Models

Scholars have also attempted to explain the nature and strength of adult romantic pair bonds from a life history/attachment perspective. Hazan and Zeifman (1999; Zeifman & Hazan, 2008), for example, propose that adult romantic relationships are an instantiation of attachment relationships formed earlier in life. They point out many similarities between childhood attachment to caregivers and adult attachment to close peers and romantic partners (also see Shaver et al., 1988). Both infants and adults, for example, display similar reactions to separation from or loss of their attachment figures. In addition, people value qualities in prospective mates that parallel those they valued in their caregivers, and children and adults behave similarly when seeking close contact, physical intimacy, and affection from their attachment figures. Parent–child and adult–adult attach-

ment relationships also pass through a similar set of developmental stages.

Hazan and Zeifman (1999) suggest that the primary evolutionary function of secure attachment in adult relationships is to increase the likelihood of stable and enduring pair bonds so mates can provide better mutual support (see also Zeifman & Hazan, Chapter 20, this volume). Pair bonding, therefore, is conjectured to enhance the reproductive fitness of both parents and their offspring. Adult mating strategies are, in fact, related to the pair-bond status of one's parents, with father absence and greater marital discord in the family of origin predicting earlier sexual maturation, short-term mating strategies in adulthood, and less stable marriages (Belsky, 1999). Children who have more pair-bonded parents, by comparison, should adopt long-term mating strategies and emphasize quality rather than quantity of investment when they have their own children (Hazan & Zeifman, 1999). (See the earlier evidence linking positive marital and partner relationships with more supportive parenting and greater likelihood of having secure offspring.) More strongly pair-bonded partners should also contribute to their own reproductive success by providing each other with greater support, which is associated with better long-term physical and mental health and more regular ovulation patterns (Zeifman & Hazan, 1997).

Partially in response to this model, Kirkpatrick (1998) claims that adult attachment styles evolved to enhance reproductive fitness based on early childhood experiences, but he questions whether security and protection are the *primary* functions of adult attachment. Instead, Kirkpatrick suggests that components of the caregiving system (e.g., love) may have been co-opted during evolutionary history to cement romantic pair bonds in adulthood, and that—similar to the views of Belsky and colleagues and Chisholm—adult attachment styles primarily reflect evolved reproductive strategies.

One of the principal life history tradeoffs involves allocating time and energy to mating effort versus parenting effort. Kirkpatrick (1998) argues that it was not always adaptive or advantageous for women and men to enact long-term, monogamous mating strategies (see also Gangestad & Simpson, 2000). Consequently, adult attachment styles may be a “mechanism” for choosing the best mating strategy given the nature of one's early childhood experiences and the quality of early parental investment. Individuals who receive consistently sensitive and responsive parenting should develop

secure working models, resulting in the adoption of long-term, committed mating strategies. These individuals should also develop greater trust and intimacy in their relationships (Simpson, 1990) and should fall in love with partners who have higher mate value (Hazan & Shaver, 1987), which they do. Avoidant individuals, in contrast, should have less committed relationships, pursue short-term mating strategies, and have more unrestricted sociosexual orientations, which they do (Simpson, Wilson, & Winterheld, 2004). And anxious persons should desire and want to pursue long-term mating strategies, yet their strong desire to be attractive to and merge with their romantic partners ought to result in short-term sexual relationships that are unstable (Kirkpatrick, 1998). Given these findings, Kirkpatrick (1998) believes that features of the caregiving system—especially love operating as a “commitment device” (Fletcher, Simpson, Campbell, & Overall, 2015; Frank, 1988)—could have been co-opted to bind and stabilize long-term romantic pair bonds.

Conceptualizing the Early Developmental Environment

According to life history thinking, the quality of the environment early in life can exert long-lasting effects on psychosocial development, including the development of specific mating and parenting strategies in both males and females, and different rates of pubertal timing in females. In conceptualizing the early rearing environment, Ainsworth and her colleagues (1978) have identified sensitive responsiveness as a key factor regulating the development of secure versus insecure attachment patterns. Moreover, Chisholm (1996, 1999) has suggested that because parenting quality is a good barometer of local mortality rates, it serves as a powerful, evolved cue that shapes the development of secure versus insecure attachment patterns and, therefore, the development of slow versus fast reproductive strategies in adulthood.

These observations become especially interesting in light of a recent cross-species analysis by Ellis, Figueredo, Brumbach, and Schlomer (2009), who examined the environmental factors that regulate the development of different reproductive strategies in assorted species and made a critical distinction between exposure to harsh versus exposure to unpredictable environments early in life. Security, of course, emanates from warm, sensitive,

and consistently responsive caregiving, whereas insecurity stems from cold, insensitive, and inconsistent (or unpredictable) caregiving.

From a cross-species perspective, *harshness* refers to age-specific rates of morbidity–mortality in the local environment. In Western societies, harshness is indexed by socioeconomic status (SES), given that lower levels of SES are linearly related to nearly all forms of morbidity and mortality (Ellis et al., 2009). And, of course, such distal contextual conditions are associated with harsher, less supportive, and less responsive parenting (McLoyd, 1998). The harsher and poorer the environment, the higher the rate of morbidity (e.g., illness, injury) and mortality (death) at every age in a society. *Unpredictability* refers to stochastic changes (fluctuations) in the harshness of environmental conditions across time and may therefore incorporate inconsistent or unpredictable parenting. Unpredictability is signaled by important changes in the ecology of the family that directly affect parents and/or their children, such as frequent changes in the job status of parents, residential changes, and parental transitions such as divorce and remarriage (see Belsky, Schlomer, & Ellis, 2012; Simpson, Griskevicius, Kuo, Sung, & Collins, 2012). Although a great deal of research by developmentalists studying attachment has unwittingly blended the two dimensions—especially at the proximate level when operationalizing sensitive parenting—Ellis and colleagues' (2009) model suggests that harshness and unpredictability might have independent effects on life history-relevant behaviors in young adulthood. However, this model does not delineate when each form of stress ought to forecast specific life history traits in adolescence or adulthood, and it does not speak to the origins of attachment security.

To date, only a few prospective longitudinal studies have tested the effects of environmental unpredictability and harshness in childhood on later behavior in direct response to Ellis and colleagues' (2009) theorizing. Brumbach, Figueredo, and Ellis (2009) found that exposure to both greater environmental unpredictability and harshness measured in adolescence independently predicted faster life history strategies in adolescence, such as engaging in more deviant social behavior. Belsky and colleagues (2012) observed that being raised in more unpredictable environments during the first 5 years of life forecasted having more sexual partners by age 15, both directly and as mediated by maternal depressive symptoms and maternal sensitivity (which were also assessed during childhood). Simpson and colleagues (2012)

reported that individuals exposed to less predictable environments between ages 0 and 5 displayed a faster life history strategy at age 23, having more sexual partners, engaging in more aggressive and delinquent behaviors, and being associated with criminal activities. Exposure to either harsh environments or experiencing unpredictability in later childhood (ages 6–16), however, did not predict these outcomes. Viewed together, these findings indicate that unpredictable childhood environments exert unique effects on risky behavior later in life, consistent with adopting a faster life history strategy, and there may be a developmentally sensitive window for assessing unpredictability. They also raise intriguing questions about whether one can distinguish harsh versus warm parenting from consistent/predictable versus inconsistent/unpredictable parenting when examining the interactional origins of attachment patterns.

A recent longitudinal study has investigated the effects of early unpredictability on parenting 30 years later. Using data from the Minnesota Longitudinal Study of Risk and Adaptation, Szepeswol, Simpson, Griskevicius, and Raby (2015) found that for males, exposure to greater unpredictability during the first 5 years of life forecasts less parental involvement/investment and less supportive parenting behavior in men who have children. These effects, however, were mediated through the quality of care that mothers gave their male children and the attachment representations of childhood that these males harbored in adulthood. Specifically, males (but not females) exposed to greater unpredictability during the first 5 years of life had mothers who were rated by observers as providing less sensitive care/support (i.e., less predictable warmth) between years 0 and 5, which in turn predicted them having more insecure attachment representations at age 26 (assessed by the AAI). Age 26 AAI insecurity, in turn, forecasted less observer-rated parental involvement/investment as well as less supportive behavior in adulthood. This evidence is important because it links unpredictability to actual parenting behavior, which is a critical component of Belsky and colleagues' (1991) original model.

Unresolved Issues, Promising Directions, and Conclusions

We have covered only a few of the several unresolved issues and promising directions for future

research. Two of the most perplexing questions center on why maternal sensitivity accounts for only a portion of the variance in children's attachment status and why the intergenerational transmission of attachment patterns is not stronger than it is (Van IJzendoorn & Bakermans-Kranenburg, 1997). LHT might be able to provide solutions to these puzzles.

Applying evolutionary bet-hedging logic, Belsky (1997; Belsky & Pluess, 2009) and Boyce and Ellis (2005; Ellis, Boyce, Belsky, Bakermans-Kranenburg, & Van IJzendoorn, 2011) have theorized that children should differ in their susceptibility to parental influence. Belsky and his colleagues suggest that differential susceptibility could be adaptive for parents, children, and their siblings if a parent's attempt to "prepare" his or her children for the future environment is mistaken due to the inherent unpredictability of future conditions. This would explain why, from an evolutionary standpoint, differential susceptibility to parental influence is witnessed within families. It would also explain why intergenerational transmission effects are weaker than expected. There is even more evidence, both observational and experimental, that children vary in their susceptibility to parenting and other influences (Belsky & Pluess, 2009, 2013). Most notable is discovery of a recent gene \times environment interaction by Manuck, Craig, Flory, Halder, and Ferrell (2011), which indicates that the theory-distinguishing prediction of psychosocial acceleration theory—that exposure to an adverse rearing environment predicts earlier sexual maturation—holds for girls who carry one version of estrogen receptor genes but not another. Given that most attachment-related research is still not informed by a differential-susceptibility perspective, past research may have both under- and overestimated certain effects of rearing experiences on attachment outcomes—underestimated for those individuals who are more susceptible, and overestimated for those who are less susceptible.

If the early rearing environment regulates the development of reproductive strategies, which now seems likely, we need to determine exactly *how* certain environmental cues actually shape attachment patterns and reproductive strategies. Frankenhuis and Panchanathan (2011) have proposed that among those who are more susceptible to environmental regulation, the timing of "commitment" to a particular course of development (e.g., secure attachment, slower physical development) may depend on the clarity of the contextual

cues. When cues are clear and consistent, a "reading" of them may lead to earlier commitment, but when they are less clear or when more time is required to decipher the environmental "tea leaves," individuals may defer commitment to one developmental pathway versus another. Attachment and developmental theorists should contemplate the implications of this possibility. Might some children who appear insecure early in life but then develop secure representations have experienced less consistent sensitive caregiving cues and, therefore, required more time before "committing" to such a developmental pathway? If so, could this explain why the presumed developmental antecedents of early attachment patterns are neither as strong nor as reliable as attachment theorists initially expected?

Time also comes into play when one considers the intergenerational transmission of attachment. To date, transmission has been assumed to be a single-generation process (e.g., a mother's attachment status shapes her child's attachment status via her parenting), with little consideration of the possible impact of grandparents, great-grandparents, and so forth. The evolutionary concept of intergenerational phenotypic inertia (Kuzawa, 2005), however, suggests that some forms of influence may endure across multiple generations, even when the most proximate generational experiences are at odds with the modal family trajectory. In particular, this model proposes that individuals should place greater diagnostic weight on conditions that have endured over multiple generations (e.g., repeated insecurity) rather than just the preceding one (e.g., one case of security), especially when the latter is inconsistent with the former. One might wonder whether an exclusive focus on the immediately preceding generation accounts in part for the intergenerational "transmission gap" that Van IJzendoorn (1995) identified.

This raises another set of issues. Although evolutionary forces should have shaped developmental trajectories, organisms also evolved to respond adaptively to rapid changes in local environments. The field of behavioral ecology, in fact, models such adaptive behaviors (see Gangestad & Simpson, 2007). In addition, the strategic pluralism model (Gangestad & Simpson, 2000) proposes that human females evolved to base mating decisions (including decisions about parenting qualities in mates) on two dimensions—the extent to which prospective mates display evidence of (1) viability (i.e., good health or other desirable mate-attracting attributes that could be passed

on genetically to offspring) and (2) investment potential (in both the romantic relationship and any resulting offspring). In pathogen-prevalent environments, women should place more weight on men's viability attributes, so the "good genes" of such mates might be passed on to their children. In environments that demand heavy investment in children or biparental care, women should place greater importance on men's investment potential to enhance the likelihood of offspring survival. Given their different life experiences, adults who have different attachment histories and styles may evaluate, calibrate, or apply each mate dimension somewhat differently. This returns us to the mate value of relationship partners. Avoidant women, for instance, may expect and require less paternal investment in light of their independence and self-reliance and, given their mistrust of others, they may want less. Anxious women, in contrast, may expect and demand greater investment given their chronic concerns about relationship loss and abandonment.

Epigenetics research may also advance our understanding of intergenerational attachment issues. Animal research has shown that maternal grooming of newborn female rat pups does not just calibrate pups' stress-response system when they are adults and raise their own offspring; through nongenetic mechanisms, such care also influences the development of the *grand-offspring* of the original grooming mother (Cameron et al., 2005). These findings are important because they partially explain the attachment-mothering intergenerational cycle, in that rearing experiences stimulate gene action, which launches a cascade of developmental processes and outcomes leading to different reproductive strategies in adulthood, which are then transmitted intergenerationally by nongenetic means. This evidence raises further intriguing questions about possible gene \times environment interactions; indeed, work by Caspi and colleagues (2002) supports differential susceptibility to parental influence by showing that the impact of rearing effects (e.g., child maltreatment) on the development of opportunistic, antisocial behavior varies depending on genotype. What remains unclear, however, is whether individuals who possess genetic "vulnerabilities" succumb to environmental risks, or whether early rearing experiences activate certain genes that then facilitate opportunistic, antisocial behavior.

Finally, like all too many developmental scientists who lack foundational knowledge about evolutionary theory, virtually all thinking and

writing to date about attachment (and even the development of reproductive strategies) has presumed that malleable children have their development regulated primarily by their rearing experiences. Yet as Trivers (1974) pointed out more than four decades ago, the fact that parents and children share on average only 50% of their genes means that their biological interests are not isomorphic, and they are therefore bound to experience conflicts of interest (see also Schlomer, Del Giudice, & Ellis, 2011). Del Giudice (2012) has noted that this may explain why children—even highly malleable ones—do not simply "take instructions" from their parents. What are the implications of this observation for understanding the development of attachment patterns specifically and for developmental plasticity more generally?

In conclusion, attachment theory is an evolutionary theory of human social behavior "from the cradle to the grave" (Bowlby, 1979, p. 129). Although the theory's initial ties to evolution focused on how the normative and individual-difference components of attachment should have promoted infant survival, recent work has revealed how attachment patterns across the lifespan—including adult romantic attachment styles—may have evolved to increase reproductive fitness. These theoretical advances are important for several reasons. Until recently, attachment theorists have not addressed *why* early developmental experiences should be systematically related to later life outcomes, *why* intergenerational transmission of attachment should exist, or *why* maternal sensitivity should shape attachment security in children. Traditionally, attachment theorists and researchers have focused on *how* these processes work. Recent applications of LHT *within* attachment theory have rectified this deficiency, directing attention to questions of both ultimate *and* proximate causation. These theoretical advances are also important because they suggest that adult attachment styles might *not* be inconsequential evolutionary "artifacts" of the attachment system in children. According to life history accounts, the attachment system in young children should have facilitated survival and development through the perilous years of early childhood, not just psychological health and well-being. In adulthood, the attachment system may further enhance inclusive fitness via the adoption of environmentally contingent, alternative reproductive strategies, not just satisfaction and happiness in close relationships.

In the future, attachment scholars need to anchor more of their thinking and research within a modern evolutionary framework. As Dobzhansky (1973) once exclaimed, “Nothing in biology makes sense except in the light of evolution” (p. 125). The same claim applies to much of psychology in general, and to much of developmental and social psychology in particular. We strongly advocate treading the intellectual path first paved by Darwin and extended by Bowlby and other modern evolutionary theorists. Various middle-level evolutionary theories—especially parent–offspring conflict theory, parental investment and sexual selection theory, and a life-history framework—have a tremendous amount to offer scholars interested in attachment phenomena across the lifespan. Significant future advances in attachment theory and research are likely to rest on the successful and complete integration of attachment theory into a modern evolutionary perspective.

Note

1. The term *strategy* refers to a set of coevolved anatomical, physiological, psychological, and/or behavioral traits designed by natural selection to increase inclusive fitness. It does *not* imply foresight, conscious awareness, or premeditation. The term *optimal* does *not* imply that natural selection produces a single, perfect phenotype. *Optimal strategies* are sets of coevolved traits that tend to increase inclusive fitness in specific environments given various tradeoffs.

Chapter 6

Psychobiological Origins of Infant Attachment and Its Role in Development

H. Jonathan Polan
Myron A. Hofer

John Bowlby (1969/1982) was the first to give the psychological concept of human attachment a strong base in evolutionary theory. He was convinced that early attachment is evidence of a previously unrecognized motivational system present in both mammals and birds, which had been selected during evolution for the survival value of the protection it afforded offspring through the emotional bond that develops between infant and mother. The strong tendency for young to stay close to their mothers, and their apparent emotional distress upon separation, was the core behavioral indicator of what Bowlby viewed as a basic instinct organized according to the principle of goal-corrected feedback—a concept borrowed from engineering, which had proved useful in understanding physiological adaptation and homeostasis.

With the discovery of qualitatively different patterns of attachment in children and of mental representations in mothers (Bowlby's "internal working models"), attachment research moved quickly in these new directions, as if the nature of the "bond" and the separation response were well understood. But for many behavioral scientists studying early development experimentally, evidence from their research did not fit Bowlby's concept of a *unitary* attachment system at work within

the mother–infant interaction. Instead, they found a number of relatively independent systems organized to carry out functions such as searching, following, orienting, early learning and memory, thermoregulation, vocalizing, and other early expressions of affect, each with its own organizing principles. In addition, Bowlby's concepts did not lend themselves easily to laboratory research with animals, and, occasionally, seemed to lead to a frustrating form of circular reasoning. For example, an infant's attachment bond was inferred from the infant's response to separation (Bowlby, 1973), which itself was explained as a consequence of disruption of the attachment bond.

Evolutionary principles give us a conceptual common ground that can be shared by neuroscience, psychology, and psychoanalysis, providing answers to questions about how the human mind and brain have come into being and why they have their present form. The historical nature of both development and evolution bridges the gap between the "reductionist" emphasis of the molecular/cellular neurosciences and the "holistic" emphasis on the meaning of events that is the central focus of psychoanalytically oriented clinicians. Early human development traverses a series of levels of scale and organization—from the multicellular interactions of the embryo to the inte-

grated systems and behavior of the fetus, to the emerging cognitive and affective capacities of the child. The biological, behavioral, and psychological processes at work at those levels of organization seem very different. But the new properties that emerge at each level arise from the combined operation of simpler processes taking place at the previous level. Understanding those transitions, and the emergence of new properties at higher levels, is one of the central issues for research in early human development, as well as for attempts to integrate neuroscience, psychology, and psychoanalysis.

In the second edition of this handbook, Simpson and Belsky (2008) extended the evolutionary theoretical approach, begun by Bowlby, to the possible long-term developmental effects of early attachment patterns and the transmission of these patterns across generations. They described the contribution of different developmental attachment patterns for enhancing reproductive fitness, as well as simple survival in the next generation. For example, a secure attachment pattern may prepare offspring best in a predictable, secure environment in which prolonged parental investment in offspring is possible; however, the insecure patterns may be more adaptive in chaotic, dangerous, and depriving environments in which fearful responses maximize short-term survival and early sexual maturation maximizes the number of offspring produced.

New discoveries regarding the genetic mechanisms of early development over the past decade have provided the basis for an integration of the fields of evolutionary and developmental biology (for a review, see Carroll, 2005). Development can now be viewed as a major source of potentially adaptive variation for selection to act upon in the course of evolution. We have learned that genes are not only instruments of inheritance in evolution but also targets of molecular signals originating both within the organism and in the environment outside it. These signals regulate development. Rapid progress in understanding these molecular genetic mechanisms has revealed an unexpected potential for plasticity, which can enable a relatively few evolutionarily conserved cellular processes to be linked together by differential gene expression into a variety of adaptive patterns that respond to environmental changes, as well as to genetic mutations. The resulting plasticity allows a variety of developmental pathways, evident in both behavior and physiology, to be generated from the same genome. This discovery of the cen-

tral role for the regulation of gene expression in development and novel epigenetic mechanisms mediating this regulation have at last provided a specific locus and mechanism for the frustratingly vague and much-debated concept of gene-environment interaction (see Bakermans-Kranenberg & Van IJzendoorn, Chapter 8, this volume).

These advances in our understanding of both development and evolution have given us a new way to understand the psychological constructs and life history consequences of early attachment. In this chapter, we outline how the strategy of uncovering the component processes underlying the psychological constructs that have been proposed in the study of early human attachment, and the perspective of evolutionary developmental biology, offer new and potentially useful ways of thinking about attachment and, from this, creating new ways to help patients.

The term *early attachment* has a number of different meanings in the psychological literature. In its most general sense, it refers to a set of behaviors we observe in infants, and to the feelings and thought processes (conscious and/or unconscious) we suppose infants to have, based on our own experiences and the psychological concepts we ourselves have formed as individual human beings or learned from others. Within this range of usage of the word *attachment*, several different schools of thought have emerged—some within psychoanalysis and others within different schools of psychodynamic psychotherapy. Common to all, however, are three themes: (1) some sort of emotional tie or bond that is inferred to develop in an infant for its caretaker, which allows the infant to identify its own mother and keeps the infant physically close; (2) a series of physiological and behavioral responses to separation that constitute the infant's emotional reaction to interruption of that bond; and (3) the existence of different patterns and qualities of interaction between infants and mothers that have important long-term effects on the infant's subsequent development, and that lead to a repetition of particular patterns of mothering by daughters in the next generation. These three central concepts of attachment theory have been extremely useful clinically, but they leave a number of observations unexplained and questions unanswered, as we explain below.

We use recent psychobiological research to provide answers to questions left open by attachment theory, and we organize the answers by the three concepts just outlined. The answers emerging from our laboratory research with animals, and

from research by others, have tended to support clinical observations, but they have also extended them in unexpected ways. We cannot settle questions of human nature by studying other animals, but we can generate new hypotheses, concepts, and ways of thinking that ultimately may apply to our clinical work with patients.

Development of the Bond

Exclusive, or preferential, orienting toward and proximity seeking by offspring toward their mothers are defining behaviors of filial attachment, requiring offspring to recognize their mothers and distinguish between maternal and nonmaternal stimuli. Although rat pups cannot see or hear until at least postnatal day (PND) 11, their sense of smell is competent at birth. Rat pups begin discriminating familiar from unfamiliar odors immediately after birth based on learning *in utero* (Hepper, 1987) and postnatally (Gregory & Pfaff, 1971; Johanson, Turkewitz, & Hamburgh, 1980; Nyakas & Endroczi, 1970). We asked whether pups could also discriminate *among the familiar odors* in their environment—specifically, their mothers and their home shavings. That ability would be evidence of *filial* attraction, not simply a nonspecific orientation toward *any* familiar cues, and its onset would mark an important developmental milestone for the infant.

In a two-choice test chamber, pups as young as 4–5 days old crawled closer to their mothers' odor than to that of their home nest shavings. Furthermore, pups increased maternal preference after overnight isolation, demonstrating early development of a motivational component. As little as 0.5°C of additional warmth on the mothers' side of the test chamber caused even 2-day-olds to express a preference for maternal odor over that of equally familiar home nest shavings (Polan & Hofer, 1998). Thus, preference for the odor of mothers over home shavings is acquired between PNDs 1 and 2.

We and others found some rather surprising reinforcers of the early olfactory learning that support the emergence of maternal preference behavior. Classical olfactory conditioning during the first 9 PNDs involves reinforcers that neither satisfy an obvious physiological need state nor are themselves attractive (Sullivan, Hofer, & Brake, 1986). Examples include pinching the tail, vigorous repetitive stroking with a soft brush (Sulli-

van & Hall, 1988), and mild foot shock (Camp & Rudy, 1988). Each of these artificial reinforcers appears to imitate something that a mother typically does to her pups. When she returns to the nest after foraging, she often steps on the pups, picks them up with her teeth, carries them, and licks them vigorously before replacing them in the litter pile. Tail pinching may mimic being stepped on, and stroking may mimic being licked; perhaps mild shock mimics the sensation of teeth gripping the skin when the mother transports her pups. What these and the other primary reinforcers in neonates (even milk ingestion) have in common is that they are vigorously behaviorally arousing to pups.

Thus, a wide variety of stimuli that mimic specific maternal behaviors toward the pups, and all that vigorously activate pups, support the learning of a preference for a novel odor with which they are paired (reviewed in Sullivan & Hall, 1988; Wilson & Sullivan, 1994). Norepinephrine plays a key role in mediating this activation-dependent associative preference learning during a sensitive period extending through the first postnatal week and a half (see next section).

What advantage might there be in newborn rats' predisposition to learn approach responses to a wide range of unconditioned stimuli—some of which are noxious? This ability was likely selected in evolution precisely because it enables pups to learn from the widest range of maternal interactions and cues, learning about their mother each time she reenters the nest up to 20 times a day. By stepping on, retrieving, licking, crouching over, and providing milk to them, the mother powerfully conditions an attraction in her pups to her own odor and tactile cues. This approach conditioning substantiates Bowlby's (1969/1982) positing of an imprinting-like basis for the formation of mammalian attachment. By activating stimuli during the 9-day sensitive period, and beyond that for cues originally conditioned during the sensitive period (Sullivan, 1996), it is the *functional equivalent* of imprinting in an altricial mammalian species.

Preference behavior, essentially a choice of the direction of movement on a horizontal surface, though profoundly revealing as a model of filial attachment, greatly oversimplifies the full repertoire of maternally directed orienting behaviors (MDOBs) we observed in the nest. A rat pup is born into a three-dimensional "sandwich" world, consisting of the substrate of its nest materials beneath it and the canopy of its mother's belly looming above as she hovers over the litter.

In this environment, the newborn pup must (1) burrow under the mother's abdominal surface and (2) orient and maintain itself in relation to her ventrum, so that (3) contact with her body will permit heat transfer, protection, nipple grasp, and access to ongoing maternal cues that regulate the pup's endocrinological, physiological, and behavioral processes. In this world, the mother's body is both the *source* of stimuli to which the pups are responding and the *superstructure* upon which the pups organize their responses in three dimensions.

To determine precisely what maternal stimuli guided these complex pup behaviors, we modeled the mother's ventral body surface with overhead "roof" surfaces featuring increasingly dam-like tactile and olfactory cues. Under even the least mother-like roof, a wire mesh, pups became aroused, crawled, turned supine onto their backs, and audibly barked. Once supine, some pups planted their feet against the overlying mesh and crawled on their backs. Thus, an overhead mesh roof evokes behaviors that appear identical in form to those we observed in the nest, by which pups orient toward and seek proximity to the maternal ventrum. Under roof surfaces that featured increasingly mother-like cues, 2- to 3-day-olds engaged in correspondingly higher frequencies of the behaviors (Polan & Hofer, 1999a), showing that early maternally directed proximity-seeking behaviors are not simple reflexes stimulated by nonspecific inputs, but are graded responses to specific maternal features.

We next asked whether these behaviors might respond to changes in the pups' motivational state. Operationally, we asked how a period of acute overnight deprivation might affect the expression of the maternally directed orienting and proximity-seeking behaviors. We found that maternal deprivation significantly *enhanced* responding to sufficiently mother-like surfaces but did not affect behavior in the absence of maternal stimuli. Therefore, motivation specifically modulates maternally directed orienting behaviors, but not undirected behaviors performed in isolation.

Finally, to understand how early in development the entire repertoire of behaviors is present and when they come under the sensory guidance of maternal features, we tested newborn pups that were deprived just before and after their very first nursing bout. After the first nursing experience, the behaviors were already subject to sensory guidance by maternal features, whereas before any nursing occurred, pups performed the behaviors vigorously but independently of the type of stimu-

lus encountered (Polan, Milano, Eljuga, & Hofer, 2002). Thus, the first experience of nursing organizes an important transition in the control of these orienting behaviors from reflex-like action patterns to responsiveness to specific maternal features.

New Views of Sensitive Periods

Since the original descriptions of avian imprinting by Lorenz and Tinbergen, the concept of sensitive periods has occupied attachment researchers with a view toward pinpointing the sources and mechanisms of psychopathology and devising preventions. Mammalian sensitive periods were thought to be confined to *precocial* species such as sheep, whose grazing in open terrain requires the infant's attachment bond to be literally "up and running" within hours after birth. The identification of maternal licking and grooming in rats as the stimulus that promotes long-term programming of the hypothalamic-pituitary-adrenocortical (HPA) axis led to discovery of an apparent sensitive period in the development of attachment in an *altricial* mammal. *Handling*, or brief daily maternal separation during infancy, which promotes extra maternal licking and grooming upon reunion, causes permanent down-regulation of the HPA axis and a high tolerance for stress in adulthood. To be effective, handling has to be initiated within the first postnatal week (Meaney & Aitken, 1985).

This sensitive period for HPA axis programming by maternal behavior coincides with a sensitive period for early olfactory learning, which also depends on maternal behavior, as described earlier. Olfactory preference learning is our best current model for how learned preferences for maternal cues begin to establish mother-seeking attachment behaviors in the infant. The sensitive period for this kind of learning extends through PND 9. Learning of maternal odor cues depends on behavioral stimulation, which serves as the unconditioned stimulus (US) that is paired with the odor. Up through PND 9, all sufficiently arousing stimuli—whether presumed pleasant ones, such as stroking with a soft brush (mimicking the mother's licking), or aversive ones, such as a tail pinch or foot shock that mimic maternal rough handling—cause pups to seek proximity with and prefer the odor with which they are paired (Camp & Rudy, 1988; Sullivan et al., 1986). During this sensitive period, it is difficult to condition *avoidance* behav-

ior to an odor paired with any exteroceptive US. This strong predominance of preference learning over avoidance learning can be seen as an evolutionarily determined developmental adaptation that serves an infant's need to form a bond to its mother.

Abruptly at PND 10, however, the behavior learned from odor–shock pairings reverses direction to become the more adult-like response, avoidance, and stroking no longer conditions proximity seeking or preference for a new odor. Sullivan, Landers, Yeaman, and Wilson (2000) determined a special brain mechanism for preference learning during this pre-PND 10 sensitive period: an overactive locus ceruleus, a midbrain nucleus that mediates arousal, releasing large amounts of the neuromodulator norepinephrine at its synapses in the olfactory bulb. When stroking is paired with a new odor, the olfactory signals reaching the bulb converging with the norepinephrinergic signals from the midbrain are transduced into a new response pattern—approach behavior—when the odor is next encountered. This simple learning circuit omits brain regions involved in adult learning, in particular the amygdala, which later is crucial in fear conditioning. During the sensitive period for olfactory preference learning, the amygdala is kept “offline” even during aversive stimulation (Moriceau & Sullivan, 2005). This special early learning process, which strongly favors preference learning and inhibits avoidance learning, may well be the basis by which infant mammals, from puppies to humans, form strong attachments to even abusive caregivers (Scott, 1963).

Although the amygdala is kept “offline” from the olfactory learning circuit, it is hardly inactive during the sensitive period. Rather, it initiates the long-term processes of HPA axis programming by maternal licking and grooming. Adult animals that, as infants, experienced high levels of licking and grooming have a “toned-down” stress axis, which has an attenuated “on” switch in the form of decreased secretion of corticotropin-releasing hormone by the hypothalamus, and an augmented “off” switch in the form of extra corticosterone receptors in the hippocampus. The amygdala is the first brain locus to register added daily maternal care. By PND 6, after just 4 days of augmented maternal care, the amygdala's central nucleus increases production of corticotropin-releasing factor, which induces the production of the stress hormone corticosterone, and, by PND 9, decreases the expression of glucocorticoid receptors (GRs) (Fenoglio, Brunson, Avishai-Eliner,

Chen, & Baram, 2004), which detect corticosterone in the brain and provide feedback to reduce its production. These changes occur long before the permanent increase in GR expression in the hippocampus, and, although transient, may be part of the cascade of events that establishes the permanent changes in HPA axis regulation in the hypothalamus and hippocampus. These early changes in elements of the corticosterone response system in the amygdala also have a surprising immediate influence on the circuits for olfactory learning. An early boost in corticosterone levels hastens the end of the sensitive period, turning off preference learning and ushering in precocious avoidance learning (Moriceau, Wilson, Levine, & Sullivan, 2006).

Thus, the period from birth through PND 9 harbors at least two sensitive periods: one for the emergence of the attachment relationship itself, which equips the pup to survive the immediately demanding transition to postnatal life; and another that, in a sense, is banked for the pup's later benefit, the emotional tuning of its adult life, as a legacy of its rearing, but that under emergency conditions even alters the duration of the first sensitive period, as we describe below. Through evolution's conservative economy of form and function, the pup's nervous system is equipped to generate both kinds of behavioral plasticity from the same maternal care behaviors, licking and grooming.

Sullivan's group recently found a “transitional sensitive period,” immediately following the sensitive period, lasting from PND 10 to PND 15 (Sevelinges et al., 2011), during which odor–shock conditioning can produce either a more adult-like fear/avoidance response or a preference/approach response typical of the sensitive period. Remarkably, the mother's presence acts as a “switch” between these two forms of learning during this transitional sensitive period. When the mother (or just her odor) is present, the amygdala disengages, resulting in preference/approach learning, just as in the sensitive period, but when the mother is absent, the amygdala is engaged by the odor–shock conditioning, resulting in a more adult-like fear/avoidance response. Thus, during the transitional sensitive period, the mother provides the pup with a “social buffer,” blocking the new amygdala-dependent stress-induced fear/avoidance learning when the pups are with her (Bisaz & Sullivan, 2012).

The mechanism of action of this maternal switch is the mother's regulation of the pups' own production of the stress hormone corticosterone.

Her presence suppresses the pups' stress-induced corticosterone secretion, which limits the amount of corticosterone reaching, and activating, the amygdala (Moriceau & Sullivan, 2006). A quiescent amygdala permits odor–shock conditioning to continue to produce the approach/preference learning typical of younger pups. In essence, the transitional sensitive period is a window prior to weaning and the pups' emergence from the nest, during which maternal presence and stress interact to pivot the direction of pups' new learning from approach to avoidance, or vice versa. Thus, this interval can be seen as an adaptive shaper of how pups will face weaning and emergence from the nest: If a stressful environment pressures the mother to be absent from the nest for long stretches, perhaps due to poor foraging conditions, pups will acquire more fear/avoidance responses to novel experiences, equipping them for harsh conditions outside the postweaning nest.

Taking these insights a step further, Sullivan's group is using the odor–shock conditioning paradigm to model the formation of attachment despite maternal abuse. As discussed earlier, the conditioned odor cue (conditioned stimulus [CS]) that has been paired with shock functions as a maternal odor; that is, pups prefer it to the odor of familiar clean bedding and are stimulated by it to attach to the mother's nipples even after her natural odor has been removed. And, this odor's potency as an attachment cue is retained even after the sensitive period ends (Sullivan et al., 2000). For comparison, to model attachment to nonabusive maternal care, other pups were conditioned by pairing an odor with soft brush strokes, mimicking typical maternal licking and grooming behaviors. Both conditioning treatments were performed on PND 8, and the results were tested by exposure to the CS, or to the natural maternal odor, the next day (Raineke, Moriceau, & Sullivan, 2010).

When tested under *nonstressful* conditions, both groups of pups showed equally strong attachment behaviors and brain activity patterns. Specifically, brain activity was the expected sensitive period response to conditioned odors: robust olfactory bulb engagement in response to either the CS or the natural maternal odor, and no activation of the amygdala to either odor (Raineke et al., 2010). But when tested under physiological stress induced by administering exogenous corticosterone, the two groups' responses diverged dramatically. The odor–shock (abuse model) pups' attachment behaviors toward the conditioned odor were nearly erased, while the odor–stroke (typical care model) pups' attachment behaviors toward the odor were

fully intact. Moreover, the odor–shock pups had altered brain responses to the conditioned odor (i.e., strong activation of the amygdala), while odor–stroke pups did not (Raineke et al., 2010).

A more naturalistic model of maternal abuse validated these findings: From PND 3 to PND 8, litters were reared with a dam that was stressed by being given insufficient bedding material to make an adequate nest. Such a dam gives less maternal care and more rough handling; possibly as a result, her pups have high circulating levels of corticosterone, show reduced attachment behaviors toward her, and react to her odor with amygdala activation (Raineke et al., 2010). Both models show that an attachment that forms despite abusive maternal behavior functions normally under benign environmental conditions, but, under stress, undergoes behavioral breakdown and altered neural function, even during the sensitive period. These events may mark the earliest psychobiological manifestations of the vulnerability to later psychopathology that emerge from maternal maltreatment as development proceeds, as we now discuss.

Sensitive Period Seeds of Psychopathology

Since maltreatment in nature is unlikely to be confined to a sensitive period, Sullivan's group exposed pups to odor–shock conditioning beginning in the sensitive period (at PND 8) and continuing into the transitional sensitive period (through PND 12). They found that the fear/avoidance learning that would be expected at PND 13 is blocked, even in the mother's absence. Instead, the odor preference response learned in the sensitive period persists into the transitional sensitive period (Moriceau, Raineke, Holman, Holman, & Sullivan, 2009). Under these conditions, corticosterone secretion and amygdala activity during the transitional sensitive period are suppressed to the low levels of sensitive period pups (Moriceau et al., 2009). The conditioned odor, having acquired a mother-like valence during the sensitive period, continues to mimic the mother's influence as a social buffer in the transitional sensitive period.

Such pups develop later behavioral abnormalities that resemble psychiatric symptoms that often affect abused children later in life. Pups reared with either kind of maternal maltreatment—daily odor–shock or insufficient bedding—showed deficits in social behavior with another pup as early as the preweaning period (PND 20), and a depres-

sion-like behavior, increased immobility on the Porsolt forced swim test, occurred in adolescence (Rainekei, Cortés, Beinoue, & Sullivan, 2012). Elegant immunohistochemical and pharmacological assessments demonstrated that excess activation of the amygdala during the forced swim test was the cause of this depression-like behavior in these maltreated adolescents (Rainekei et al., 2012).

This depressive predisposition of maltreated pups persists into adulthood when another symptom appears, lack of preference for a sweet drink versus water, which can be interpreted as anhedonia (Sevelinges et al., 2011). Amygdala dysfunction is again implicated as the neural basis of these behaviors. Strikingly, however, there is an apparent paradox embedded in the adult outcome. When the odor that was associated with shock in infancy was supplied during the adult behavioral and neural tests, all results normalized (Sevelinges et al., 2011). Moreover, this odor continued to elicit a preference response in the adults (Sevelinges et al., 2011), and when the adults were reconditioned by pairing this odor with shock, the resulting fear response and amygdala activation were attenuated (Sevelinges et al., 2007). Moreover, these adults had infant-like olfactory bulb activation when compared to adults that had never experienced the odor–shock pairing in infancy (Moriceau et al., 2009). Thus, early maternal maltreatment is a double-edged sword: One edge induces adult depression, whereas the other provides a safety signal in the adult that blunts new fear learning and relieves the depressive behaviors (Sevelinges et al., 2011). It is as if the adult offspring holds the abusive mother in its long-term memory as an ambivalent object, mirroring how she was originally experienced in infancy. And in blunting the fear associated with dangers encountered in adulthood, the remembered maternal odor could predispose the adult to repeat the abuse of the early attachment. This parallels the phenomenon of revictimization—the higher probability that adults who have been abused as children will be abused in adulthood (Messman-Moore & Long, 2003)—and suggests that the rat or mouse models could reveal mechanisms underlying this important clinical phenomenon.

Responses to Separation

Behavioral systems that maintain an infant in close proximity to the mother and promote physical attachment to the nipple do not fulfill our

criteria for a fully developed attachment system. Another essential component is a particular set of responses to maternal separation. In fact, Bowlby's attachment theory was developed to explain the separation responses that became all too evident during the societal devastations of World War II (Bowlby, 1969/1982). It was maternal separation that revealed the existence of a deeper layer of processes beneath the apparently simple interactions of mother and infant. The behavioral and physiological responses of the infant to separation, in Bowlby's conception, were consequences of the danger inherent in the "disruption" of an "affectional bond" that had been formed as part of an integrated psychophysiological organization that Bowlby called "the attachment behavioural system." More recent research, however, has revealed a network of simple behavioral and biological processes underlying these psychological constructs that we use to define and understand early human social relationships.

Experiments in our laboratory have shown that infant rats have complex and lasting responses to maternal separation, similar to those of primates, and that these responses occur in a number of different physiological and behavioral systems. We found that the slower developing components (Bowlby's "despair" phase) were *not* an integrated psychophysiological response, as had been supposed, but were the results of a novel mechanism (reviewed in Hofer, 1994). As separation continued, each individual system of the infant rat responded to the loss of one or another of the components of the infant's previous interactions with its mother. Providing one of these components to a separated pup (e.g., maternal warmth) maintained the level of brain biogenic amine function underlying the pup's general activity level, but it had no effect on other systems. For example, the pup's cardiac rate continued to fall, regardless of whether supplemental heat was provided. The heart rate, normally maintained by sympathetic autonomic tone, was found to be regulated by provision of milk to neural receptors in the lining of the pup's stomach. With loss of the maternal milk supply, sympathetic tone fell and cardiac rate was reduced by 40% in 12–18 hours.

By studying a number of additional systems, such as those controlling sleep–wake states, activity level, sucking patterns, exploratory behavior and isolation calling, we found different components of the mother–infant interaction (e.g., olfaction, taste, touch, warmth, and texture) that either up-regulated or down-regulated each of these functions. We therefore concluded that in

maternal separation, all of these regulatory components of the mother–infant interaction are withdrawn at once. This widespread loss creates a pattern of increases, as well as decreases, in the levels of function of the infant's systems depending on whether the particular system had been up- or down-regulated previously by specific components of mother–infant interactions. We called these *hidden regulators* because they were not evident from simply observing the ongoing mother–infant relationship.

One of the best-known responses to maternal separation is the infant's separation cry, a behavior that occurs in a wide variety of species, including humans. In the rat, this call is in the ultrasonic range. Pharmacological studies by Susan Carden in our laboratory and by a number of others showed that the ultrasonic vocalization (USV) response to isolation is attenuated or blocked in a dose-dependent manner by clinically effective anxiolytic drugs that act at benzodiazepine and serotonin receptors (reviewed in Hofer, 1996). Conversely, USV rates are increased by compounds known to be anxiogenic in humans.

This evidence strongly suggests that separation produces an early affective state in rat pups that is expressed by the rate of infant calling. This calling behavior (and its inferred underlying affective state) develops as a communication system between mother and pup. Infant rat USVs are a powerful stimulus for the lactating rat, capable of causing her to interrupt an ongoing nursing bout, initiate searching outside the nest, and direct her search toward the source of the calls. The mother's retrieval response to the pup's vocal signals then results in renewed contact between pup and mother. This contact in turn quiets or comforts the pup.

The separation and comfort responses in "classical" attachment theory are described in terms of a single affective system, as expressions of interruption and reestablishment of a social bond. Instead, we found multiple regulators of infant ultrasonic calling "hidden" within the physical contact and behavioral interactions between mother and pup, including warmth, touch, texture, shape, and milk, as well as the mother's own scent (Hofer, 1996). The full "comfort" quieting response was elicited only when all sensory modalities were presented together, and maximum calling rates occurred when all were withdrawn at once. In essence, we found parallel regulatory systems involving different sensory systems, with the rate of infant calling reflecting both the composition

and the sum total of effective maternal regulatory stimuli present at any given time.

In the case of the most complex behaviors we studied, sleep–wake state organization, a *temporal patterning* of the intragastric delivery of milk and of tactile stimulation to the pups was necessary to maintain the pups normal sleep–wake state patterns through their 24-hour separation from their mothers. These rhythmic patterns of central brain states are evidently organized by the timing of the mother's periodic nursing bouts, as well as nutrient and sensorimotor exchanges with her under normal conditions.

For human infants, still more complex interactions such as attunement, imitation, and play are likely to have regulatory effects on developing infants' cognitive and affective systems. In this way, all these different interactions would appear to participate in the early formation of human infants' mental representations of their first relationship.

Hidden Regulators of Early Development

As we began to understand the infant's separation response as one of loss—loss of a number of individual regulatory processes that were hidden within the interactions of the previous relationship—an important implication of this finding emerged: These ongoing regulatory interactions can shape the course of development of an infant's brain and behavior throughout the preweaning period when mother and infant remain in close proximity. We could now think of mother–infant interactions as regulators of normal infant development, with variations in the intensity and patterning of these interactions gradually shaping infant behavior and physiology. Supporting this idea, Kuhn and Schanberg (1998) published a series of studies in which they found that removal of the mother from rat pups produced a rapid (30-minute) fall in the pups' growth hormone (GH) levels, and that vigorous tactile stroking of maternally separated pups (mimicking maternal licking) prevented this fall in GH. There are several biological similarities between this maternal deprivation effect in rats and the growth retardation that occurs in some variants of human reactive attachment disorders of infancy (Chatoor, Ganiban, Colin, Plummer, & Harmon, 1998). Applying this new knowledge about the regulation of GH to low-birthweight, prematurely

born babies, Field and coworkers (1986) joined the Schanberg group and used a combination of stroking and limb movement, administered three times a day for 15 minutes each time, and continued through the infants' 2 weeks of hospitalization. This intervention increased weight gain, head circumference, and behavioral development test scores in relation to those of a randomly chosen control group, with enhanced maturational effects discernible many months later. Clearly, early regulators are effective in humans, and over time periods as long as several weeks to months.

These processes go beyond the adaptive evolutionary role of the attachment "bond" as a protection against predators, as proposed by Bowlby (1969/1982). The rapid onset and prolonged duration of processes keeping infants close to their mothers, described earlier, provide the necessary conditions for long-term regulatory effects of early mother-infant interactions on infants' development. The processes underlying infants' proximity maintenance are likely to have evolved together with the hidden regulatory interactions because the two, acting together, created a developmental mechanism capable of shaping the offsprings' adaptive capabilities, as well as maternal behavior in the next generation, through selection over evolutionary time.

Lasting Effects of Early Relationships

One of the major tenets of attachment theory is the idea that an infant's early attachment pattern can have long-term developmental effects—in particular on the infant's early mental representations (which Bowlby sometimes called "internal working models" or "representational models"), on his or her later relationships with his or her own children, and on broader aspects of behavior, such as levels of anxiety and aggression, and the quality of social interactions. As described early in this chapter, such a transgenerational developmental system could evolve as a result of the competitive advantages to be gained by young who are shaped by their parents, in advance, to deal most effectively with the kind of environment they are likely to face as adolescents and adults.

What basis do we have for this evolutionary interpretation, or even for the existence of such very long-term developmental effects of variations in maternal behavior? In the 1980s, we began to

test the possible long-term developmental effects of the "hidden maternal regulators" we had uncovered within the mother-infant interactions in our separation studies. By observing naturally occurring variations in mother-infant interactions of an inbred strain of genetically identical rats that had been selectively bred as an animal model for hypertension, we were able to identify three maternal behaviors, observed in the first 2 postnatal weeks, that were correlated with the severity of hypertension in their offspring as adults (Myers, Brunelli, Shair, Squire, & Hofer, 1989). The use of genetically identical strains ensured that any differences between the adult offspring of different mothers could not be attributed to different genes being passed on to these offspring, but instead to differences in each mother's behavior toward them as infants. The behaviors we found most closely correlated with offspring blood pressure included the amount of maternal licking and grooming, the time mothers spent in a highly stimulating high-arched resting position, and their level of contact time. Thus, we were able to conclude that differences in specifiable patterns of mothers' interactions with their pups could produce developmental effects on autonomic/endocrine systems regulating blood pressure that lasted into adulthood. But we had no clue as to how these differences in maternal behavior were translated into changes in their pups' blood pressure regulation as adults.

The work of Michael Meaney, Frances Champagne, and their colleagues over the past decade and a half has greatly enlarged our understanding of the cell/molecular processes underlying the lasting effects of early mother-infant interactions on adult offspring behavior and physiology (reviewed in Chapter 8 by Bakermans-Kranenberg and Van IJzendoorn). In summary, they found that normally occurring differences between rat mothers involving the maternal behaviors we had described in our studies systematically modified the long-term development of the adrenocortical stress response and behavioral fear response of their adult offspring, with lower levels of these interactions leading to greater adrenocortical and fear responses. Then, in a remarkable series of cell biological experiments, Meaney and his colleagues (1996) were able, first, to trace the effects of these maternal behaviors to changes in offsprings' hippocampal glucocorticoid receptors. These receptors sense the level of endogenous adrenocortical hormone and inhibit this hormonal response to stress—a form of inhibitory feedback, as in a thermostat. Next, they traced these effects to differences in the

expression levels of genes regulating the number of active receptors, differences produced by newly discovered epigenetic processes acting outside the genes themselves but regulating their activity. Importantly, identical effects were found in cross-fostered pups born to other mothers, ruling out direct genetic inheritance of the traits. These findings linked differences in normally occurring levels of mother–infant interactions to molecular processes regulating gene expression in the brains of the developing young. Meaney and colleagues found similar epigenetic effects involving not only a variety of stress responses but also learning processes, aggression, and sexual and maternal behavior, as described below.

In more general terms, what these studies have done is uncover some of the component processes through which different patterns of early mother–infant interactions can regulate the long-term development of physiological and behavioral systems of offspring, extending into their adult lives. Given that the number of genes now known to be involved in this kind of long-term regulation number in the hundreds, it seems likely that the effects of different early mother–infant interaction patterns are more extensive and may well involve even more systems than those already identified.

As discussed earlier, we know that attachment patterns tend to be repeated by daughters in the next generation—an effect thought to be mediated by processes of psychological representation (Bowlby’s “internal working models”). Now we have good evidence for biological processes that underlie and contribute to this transgenerational process as well. Frances Champagne, when she was in Meaney’s laboratory (Champagne, Diorio, Sharma, & Meaney, 2001), found that mothers with high or low levels of licking/grooming and high-arched nursing position pass these maternal behavior patterns on to their daughters, along with the different levels of adult adrenocortical and fear responses just described. They could link this transgenerational effect on maternal behaviors to increases, or decreases, in the activity of genes regulating oxytocin receptors in the 1-week-old pups’ developing brain systems that later become central to their maternal behavior as adults, the medial preoptic area and lateral septum.

How do these widespread biological effects fit into the evolutionary perspective on attachment described at the beginning of this section? The changes in offspring physiology and behavior generated by the two different mother–infant interaction types showed widespread, recognizable

“preadaptations” to two different kinds of environments. Low levels of maternal interaction resulted in more fearful adult offspring with heightened startle responses and intense adrenocortical responses to stress (Claessens et al., 2011; Zhang, Chretien, Meaney, & Gratton, 2005). In other studies (e.g., Liu, Diorio, Day, Francis, & Meaney, 2000), researchers found that the offsprings’ capacity for avoidance learning was enhanced, whereas their spatial learning and memory were relatively impaired, as reflected in slower hippocampal synapse growth. In addition to transmitting their own low-level maternal behavior pattern to their offspring, young adults in this group showed more rapid sexual maturation (vaginal opening), greater sexual receptivity, more rapidly repeated sexual encounters, and a higher rate of pregnancy following mating than offspring of high-interaction-level mothers. These differences appear to be suited to a harsh, unpredictable, and threatening environment with few resources—an environment in which intense defensive responses, fearful avoidance of threats, and early increased sexual activity would be likely to result in both enhanced individual survival and more offspring born in the next generation.

In experimental support of this theoretical prediction, Champagne and Meaney (2006) went on to demonstrate that the experience of stress during rat mothers’ pregnancies reduced their subsequent licking and grooming of their pups, leading to the pups later developing the very behavioral characteristics just described.

High levels of mother–infant interaction in turn were found to lead to a pattern of slower sexual development, more exploration than fear of novelty, a predisposition to learn spatial maps rather than avoidance responses, and lower levels of adrenocortical responses—traits that would be liabilities in very harsh environments, but that allow optimal adaptation to a stable, supportive environment with abundant new opportunities and resources.

This remarkable research is revealing a network of biological processes—extending down to the regulatory mechanisms within the genome—that appear to be developmental and evolutionary precursors of the psychological processes, such as enduring mental representations, that are fundamental to concepts of human attachment. From an evolutionary perspective, maternal behavior not only prepares an infant for its likely adult environment but also can exert a transgenerational propagation of maternal behavior, extending effects into

a third generation and beyond. They provide not only a more generationally limited but also a more flexible way of passing biological information forward into the future, from one generation to the next, resembling the cultural inheritance of ideas, beliefs, and psychological predispositions. They fit remarkably well with previous human studies of transgenerational continuity in attachment patterns (e.g., Main, Kaplan, & Cassidy, 1985). Most recently, transgenerational effects of early experience acting through male or female germline genes in rodents have been reported (Curley & Mashoodh, 2010; Dias & Ressler, 2014), opening a new chapter in this story, one that awaits scientific assessment of its extent and importance in nature.

Applying the New Tools of Molecular Biology

One of the major insights of molecular biology is that genes—once viewed as static repositories of the information contained in the organism's basic plan, akin to a house's blueprint that is rolled up and stored away after construction—are active participants in all cellular processes throughout life, and their ongoing contributions are regulated from moment to moment. Now it is possible to manipulate the genes that are thought to regulate the biology and behavioral processes of attachment and separation. Genetic engineering can delete a gene (i.e., “knock it out”), add extra copies of it (a “transgene”), or add copies that make a dysfunctional product, which dominates the endogenous gene's normal product (a “transdominant negative”). One can then infer the gene's function from the consequences of these manipulations. To avoid “false-negative” results due to developmental compensation mechanisms, or “false-positive” results due to the mutation occurring in brain regions responsible for nonspecific behavioral disruptions, we can make “conditional” genetic manipulations that target specific parts of the brain, or that can be activated or deactivated at specific times in development.

Now, with the sequencing of the mouse genome, and the technology to introduce very precise mutations into the mouse oocyte's DNA, the mouse is beginning to take center stage in the study of filial attachment. To exploit the genetic techniques requires a mouse model of infant–mother attachment with enough behavioral and physiological detail to allow the investiga-

tion of important questions in depth. Behavioral researchers have now established that murine infant–mother attachment has all the essential elements that have made the rat model so productive, specifically, MDOBs, separation USVs, olfactory preference learning during a sensitive period, and a transport response to maternal retrieval.

We showed that the earliest manifestations of attachment, neonatal MDOBs, emerge in mice from PND 0 to 3, with the same motor action patterns in response to nearness of the mother's ventral body surface seen in same age rats (Masson et al., 2006). Mouse pups call in the ultrasonic range when separated from their mother and potentiate the rate of calling after brief reunion and reseparation (Moles, Kieffer, & D'Amato, 2004), just as do rats.

Sullivan's group has recently demonstrated a sensitive period for olfactory preference learning in infant mice that appears identical to that of same-age rats in all behavioral and neurophysiological aspects so far studied (Roth et al., 2013), including the support of a behavioral attachment to the mother, even in the face of treatment that is aversive or abusive.

The transport (or carry) response has also been shown to be present in both mice and rats, but unlike MDOBs, USVs, and olfactory preference learning, it has been explored more fully in mice than in rats. Elegant studies by the Kikusui, Kato, and Kuroda group (Esposito et al., 2013; Yoshida et al., 2013) revealed its developmental course, motor patterns, and sensory elicitors, and the accompanying physiological “calming” (reduced heart rate and ultrasonic calling). They also showed remarkably close parallels to the human infant's motor and physiological calming responses to being picked up and carried by his or her mother (Esposito et al., 2013).

Only a few models of the impact of genes on the filial behavior of infants and juvenile mice have so far been studied. In one, our collaborators knocked out the gene for glutaminase type 1 (GLS1), the enzyme responsible for most of the brain's main excitatory neurotransmitter, glutamate (Masson et al., 2006). Newborns that lack both copies of the gene (also called “null” or “knockout” mice) die within 1 or 2 days after birth, lacking milk in the stomach, whereas their siblings that have one copy of the gene (i.e., the heterozygotes) survive and develop, on gross inspection, normally.

We found that the nulls' failure to obtain milk was not due simply to behavioral debilita-

tion. They were as active as their heterozygote and wild-type littermates, but the nulls' MDOBs were disorganized. Under the mother's ventrum, the nulls attained, but failed to maintain, the supine orientation and emitted far too little audible calling (barking) when encountering the mother, whereas they engaged in undirected and inappropriately high frequencies of mouthing and licking, even when not in the mother's presence. These behavioral anomalies suggest that the nulls failed either to recognize the mother or to organize an appropriate response to her.

The heterozygotes had a behavioral phenotype intermediate between the nulls and wild types on all measures, demonstrating that they were not in fact "normal." Their mild deficit of glutamate neurotransmission caused them to hold the supine orientation under the mother's ventrum for less than half the time typical of the wild types. Supination is critical for the pup to be able to locate a nipple and nurse, and its absence is devastating for the null pups. But if supination is performed competently, even low amounts of it are evidently enough for the heterozygotes to survive and grow. As adults, the heterozygotes showed deficits of hippocampus-dependent contextual fear learning (Gaisler-Salomon et al., 2012). Whether they have deficits in the affective or social behavior domain has not yet been determined.

Another study examined the effects of the gene for the mu opioid receptor on the infant mouse's isolation-induced USV. As described earlier, USV is analogous to the human infant's separation cry and is regarded as a necessary indicator of the establishment of a "filial attachment bond" (Hofer, 1996). The mu receptor mediates the behavioral and physiological effects of many natural rewards. It has also been hypothesized to mediate the infant's response to social isolation, but the pharmacological evidence is controversial. Isolation-induced USV was recorded (1) for infant mice null for the mu receptor gene and (2) for wild-type controls (Moles et al., 2004). The knockouts exhibited significantly less USV during the first 2 postnatal weeks, and failed to "potentiate" their calling rates after being reexposed briefly to their mothers and then reisolated. However, the knockouts' sensitivity to physical (cold) or social (strange male) threats was not impaired; nor were the knockouts grossly deficient in olfactory competence. This study of the mu receptor knockout mouse lends support to the hypothesis that the infant's mu opioid receptor plays a specific role in mediating the reinforcing properties of maternal

stimuli. Neither of these knockout studies is definitive, but they represent the leading edge of emerging work on the effects of candidate genes on the formation and competence of filial behaviors.

A third study illustrates two other approaches taken in molecular studies to shed light on attachment (Gross et al., 2002). The investigators used a genetic model to examine the development of an emotion, anxiety, that figures critically in attachment. They knocked out the gene for the 1A type of receptor for serotonin—a neurotransmitter that is central to the maintenance of normal mood and affect and, when dysfunctional, permits pathological anxiety and depression. Since stimulation of the serotonin 1A receptor is anxiolytic, the knockout mouse was more anxious than the wild type on behavioral tests including exploration and food-sampling in a novel open (i.e., anxiety-provoking) field. When the researchers used the molecular method of turning the knocked-out gene's expression back on in the mouse's forebrain, they found that when this rescue occurred, in just the first 2 postnatal weeks, normal emotional responsiveness in adulthood was restored.

As shown by this study, we can now determine, at the molecular level, the quality, quantity, and timing of developmental provisions that support the emergence of normal emotional capacities. We know that experiences of maternal separation or variations in maternal care reprogram the stress axis, leading to altered levels of anxiety and stress responsiveness in adulthood (Cameron et al., 2005; Meaney et al., 1996). Meaney and others have hypothesized that maternal separation, and the altered maternal behaviors that occur with reunion, are transduced in part by the pups' serotonin systems. The serotonin 1A receptor knockout provides evidence that serotonin is indeed part of the mechanism by which altered infant separation and attachment experiences can reprogram the stress axis and its affective manifestation, anxiety.

Perspectives for Future Research

We concluded our chapter in the second edition of this handbook (Polan & Hofer, 2008) with a set of questions for future investigation. Some of these have been partially answered and explained in the main body of this chapter. We summarize these here, address others below, and now add some new questions arising in part from the answers to the

old ones and in part from the new perspectives that molecular methods have opened up.

We asked a set of related questions: Are early attachment experiences or their biological substrates responsible for the quality of adult attachment or the development of psychiatric disorders in adulthood? Are the processes of preference learning and stress axis programming during the sensitive period reversible, and, if so, what implications might this have for the treatment of abuse, neglect, or early abandonment?

The new information covered in this chapter allows us to summarize the answers as follows. We now understand that maternal maltreatment creates both vulnerability to psychopathology across development and a safety signal in adulthood. The discovery of symptoms in multiple realms of emotional behavior—social interaction deficits, signs of depression, and abnormal fear processing—and the brain substrates of these reveal the outlines of the developmental psychopathology of abusive attachment. Many details remain to be filled in. Nevertheless, we have sufficient behavioral, neurohumoral, and neural-circuit-level correlates of abusive attachment to suggest that the rodent models can be used for preclinical tests of primary preventions and early interventions for the later complicating psychopathologies. And we have learned that, paradoxically, the maternal cue that was associated with abuse in infancy still attracts the adult offspring, diminishes adult fear learning, and relieves depression. This suggests a new animal model of the role of ambivalent early object representations in the important clinical phenomenon of revictimization (Messman-Moore & Long, 2003).

We also asked: What is the precise relation between the development of proximity seeking (MDOBs) and separation or loss responses? Is the achievement of one necessary for the emergence of the other?

In the previous edition, we interpreted the increase in MDOBs in 2- to 3-day-old pups after an overnight separation from their mothers as evidence for the development of a “motivational” component in this behavioral system (Polan & Hofer, 2008). But the increase could also be viewed as an affect-driven intensification of these behaviors that evolved in response to the dangers posed by separation, or may be shaped by the loss of regulatory processes that had been “hidden” within the ongoing mother–infant interactions that normally inhibit or down-regulate MDOBs. Future research exploring the underlying neurobiological and be-

havioral mechanisms of MDOBs will help us to integrate these possible interpretations.

Finally, we asked whether there are genetically based differences in the neural and endocrine substrates for attachment and separation processes and, if so, how these might interact with the environmental and genetic mechanisms described earlier. Study of associations of human gene polymorphisms and attachment security has been limited by the same difficulty of replication that has slowed the entire field of genetic association and complex behavior (Roisman, Booth-LaForce, Belsky, Burtf, & Groh, 2013). As statistical power and methods improve, candidate genes found in humans can be tested for phenotypes and biological mechanisms in mice.

We now offer for this edition the following three questions for future investigations:

1. It has become clear that neonatal intensive care units (NICUs) are not only a source of (necessary) physical trauma for premature infants, but also of unavoidable, prolonged periods of mother–infant separation. Yet this situation has not become a major area for research on early attachment processes. The effects of the prolonged separations are almost as important for the mother as for the premature infant, so the development of infant attachment (as well as of maternal caregiving) under these circumstances will be an exceptionally interesting and growing area for future attachment research.

2. The limits and overall significance of epigenetic processes for development and evolution are not yet fully established. Although developmental processes are now established as a major source of variation for natural selection to act upon (the subject of the new academic field of study: evolutionary developmental biology), there are a number of well-established processes for such effects. Thus, the discovery of novel epigenetic mechanisms for transgenerational change (many in the area of attachment research) has generated skepticism among molecular geneticists who ask: How frequent and widespread such epigenetic effects actually are in nature? We should have some answers by the time the fourth edition of this handbook is undertaken.

3. What are the intervening links between particular behaviors of rat mothers toward their infants and the establishment of epigenetic “marks” on specific genes in her pups’ brains? A complex paper by the Meaney group (Hellstrom,

Dhir, Diorio, & Meaney, 2012) has worked out the cascade of cell and molecular events that bridges the gap between the dam's licking behavior on the one hand and the epigenetic events regulating the *exon-1₇* promoter of the glucocorticoid receptor gene in her offsprings' brains. But since many (literally hundreds) of the pups' brain genes are regulated by (presumably many different) dam-pup interactions, there is much more that we have yet to learn about these complex behavioral-genomic events.

Chapter 7

Attachment In Rhesus Monkeys

Stephen J. Suomi

Attachment is not an exclusively human phenomenon. Although the theory that John Bowlby developed during the 1950s and 1960s, and refined during the 1970s, reflected his clinical observations of infants and young children, it also had a strong biological foundation stemming in large part from his long-standing interest in ethological studies of developmental phenomena in animals, especially nonhuman primates (van der Horst, Van der Veer, & Van IJzendoorn, 2007). Indeed, it can be argued that Bowlby (1969/1982) specifically tailored the basic biological features of his attachment theory to account for clear-cut commonalities in the strong behavioral and emotional ties that infants typically develop with their mother, not only across virtually all of humanity but also among our closest evolutionary relatives.

Around the time that Bowlby published, with James Roberston, his seminal studies of mother-infant separation due to hospitalization (Robertson & Bowlby, 1952), he was also becoming familiar with the classic ethological studies of filial imprinting in precocial birds. During this period he developed a close friendship with the Cambridge University ethologist Robert Hinde, who at the time was in the process of shifting his own basic research interests from song learning in birds to mother–infant interactions in rhesus monkeys. Hinde soon had rhesus monkey mothers raising babies in small, captive social groups (e.g., Hinde, Rowell, & Spencer-Booth, 1964), and Bowlby came to recognize patterns of behavior

of the infant monkeys toward their mothers—but not toward other adult females in the group—that strikingly resembled recurrent response patterns of human infants and young children he had observed over years of clinical practice (van der Horst et al., 2007). During the same period, Bowlby became intrigued by the research of Harry Harlow, documenting the attachments that rhesus monkey infants developed with artificial (“surrogate”) mothers, differing systematically with respect to certain physical features (Harlow, 1958; Harlow & Suomi, 1970).

Indeed, virtually all of the classic features of human infant behavior that Bowlby’s attachment theory specifically ascribed to our evolutionary history could be clearly observed in the patterns of mother-directed activity exhibited by rhesus monkey infants, as described by Hinde, Harlow, and other primate researchers. For Bowlby (1958, 1969/1982), the fact that rhesus monkey infants and human babies share unique physical features, behavioral propensities, and emotional liabilities linked to highly specific social situations was consistent with the view that they also share significant parts of their respective evolutionary histories. He argued that these features, present in newborns of each species but often largely absent (or at least largely obscured) in older individuals, reflect successful adaptations to selective pressures over millions of years. To Bowlby, those characteristics common to both human and monkey infants represented evolutionary success stories that

should be viewed as beneficial, if not essential, for promoting the survival of both the individual infant and the species.

What are those common characteristics, and what is their relevance for attachment theory? This chapter begins with a description of how attachment relationships between rhesus monkey infants and their mothers are typically established and maintained throughout development. Next, those features that are unique to attachment relationships are examined. Attachment relationships in rhesus monkeys and other primates are subject to influence from a variety of sources, and some of these influences are reviewed next. Some long-term behavioral and biological consequence of different early attachment experiences are then examined in detail. Finally, the implications for attachment theory of recent findings regarding cross-generational transmission of specific attachment patterns in rhesus monkey families are discussed.

Normative Patterns of Infant–Mother Attachment in Rhesus Monkeys

The first detailed longitudinal studies of species-normative attachment relationships in rhesus monkeys were carried out a half-century ago (e.g., Hansen, 1966; Harlow, Harlow, & Hansen, 1963; Hinde & Spencer-Booth, 1967). These seminal investigations provided descriptions of infant behavioral development and emerging social relationships that not only appear remarkably accurate today but also have repeatedly been shown to generalize to other rhesus monkey infants growing up across a variety of natural and captive settings, as well as to infants of many other Old World monkey and ape species (see Higley & Suomi, 1986, for one of many comprehensive reviews). Virtually all infants in these species spend their initial days, weeks, and (for infant apes) months of life in near-continuous physical contact with their biological mothers, typically clinging to their mothers' ventral surface for most of their waking (and virtually all of their sleeping) hours each day.

Newborn rhesus monkeys clearly and consistently display four of the five “component instinctual responses” that Bowlby (1958) listed as universal human attachment behaviors in his initial monograph on attachment: sucking, clinging,

crying, and following (the fifth, smiling, is seen in chimpanzee but not in monkey infants). On their first postnatal day they can discriminate pictures and videos of faces from nonfacial stimuli, by the end of their first week of life they come to prefer female faces over male faces, and by 3 weeks of age they prefer faces of conspecifics to those of other species, including closely related primate species (Simpson, Paukner, Suomi, & Ferrari, 2015).

Some rhesus monkey infants, like some human infants, are also able to imitate specific facial expressions of their mother shortly after birth (Ferrari et al., 2006; Paukner, Ferrari, & Suomi, 2013), although this form of “mirroring” behavior largely disappears after the first 10–14 days of life (Paukner et al., 2013). Electroencephalographic (EEG) recordings from scalp electrodes have revealed a distinctive EEG “signature” (suppression of mu rhythms at low frequencies) that can be detected during bouts of imitative behavior on the first postnatal day, gets stronger and more distinctive over the first week, and appears to be modifiable by particular experiences with facial stimuli (Vanderwert et al., 2012, 2015). All of these response patterns involving face-to-face interactions arguably serve to facilitate efforts on the part of the infant to obtain and maintain physical contact with or proximity to its mother (Paukner et al., 2013).

Rhesus monkey mothers, in turn, provide their newborns with essential nourishment, physical and psychological warmth (e.g., Harlow, 1958), and protection from the elements, potential predators, and even other members of the infant's immediate family (e.g., jealous older siblings). During this time, a strong and enduring social bond inevitably develops between mother and infant, a bond that is unique in terms of its exclusivity, constituent behavioral features, and ultimate duration. The attachment bond that a rhesus monkey infant typically develops with its mother is like no other social relationship it will ever experience during the rest of its life, except (in reciprocal form) when a female grows up to have infants of her own. For a male infant, this bond will last at least until puberty, whereas for a female, it will be maintained as long as mother and daughter are both alive (Suomi, 1995).

In their second month of life, most rhesus monkey infants start using their mother as a “secure base” from which to begin exploring their immediate physical and social environment. At this age, monkey infants are inherently curious (Harlow, 1953), and most attempt to leave their

mother for brief periods as soon as they become physically capable of doing so. Mothers typically monitor these attempts quite closely, and they often physically restrain their infant's efforts—or retrieve them if they have wandered beyond arm's length—at the slightest sign of potential danger. Several studies (e.g., Hinde & White, 1974) have demonstrated that at this stage of infant development the mother is primarily responsible for maintaining mutual contact and/or proximity. With the emergence of social fear in the infant's emotional repertoire between 2 and 3 months of age—seemingly analogous to the appearance of “stranger anxiety” in 9- to 12-month-old human infants (Sackett, 1966; Suomi & Harlow, 1976)—this pattern reverses, and thereafter the infant is primarily responsible for initiating and maintaining proximity and physical contact with its mother. Once an infant monkey has become securely attached to its mother and begins to use her as an established base from which to make exploratory ventures toward stimuli that have caught its interest, it soon learns that if it becomes frightened or is otherwise threatened by the stimuli it has sought out, it can always run back to its mother, who usually is able to provide immediate safety and comfort via mutual ventral contact. Initiation of ventral contact with the mother has been shown to promote rapid decreases in the infant's hypothalamic–pituitary–adrenal (HPA) activity (as indexed by lowered plasma cortisol concentrations) and in sympathetic nervous system arousal (as indexed by reductions in heart rate), along with other physiological changes commonly associated with soothing (e.g., Gunnar, Gonzalez, Goodlin, & Levine, 1981; Mendoza, Smotherman, Miner, Kaplan, & Levine, 1978; Reite, Short, Seiler, & Pauley, 1981).

As they grow older, most monkey infants voluntarily spend increasing amounts of time at increasing distances from their mothers, apparently confident that they can return to their mother's protective care without interruption or delay should circumstances so warrant. The presence of their mother as a secure base clearly promotes exploration of their ever-expanding physical and social world (Dienske & Metz, 1977; Harlow et al., 1963; Simpson, 1979). On the other hand, some rhesus monkey infants develop less secure attachment relationships with their mothers, and their subsequent exploratory behavior becomes compromised (e.g., Arling & Harlow, 1967; McCormack, Sanchez, Bardi, & Maestripieri, 2006), consistent with Bowlby's observations regarding

human attachment relationships (e.g., Bowlby, 1969/1982, 1988), which I discuss later.

At approximately 3 months of age, monkey infants typically start developing distinctive social relationships with other members of their social group. Increasingly, these come to involve their peers—other infants of similar age and comparable physical, cognitive, and socioemotional capabilities. Following weaning (usually in the fourth and fifth months) and essentially until puberty (during the third or fourth year), play with peers represents the predominant social activity of young monkeys (Ruppenthal, Harlow, Eisele, Harlow, & Suomi, 1974; Suomi, 1979a). During this time social play becomes increasingly gender-specific and sex-segregated (i.e., males tend to play more with males, and females with females; Harlow & Lauerdorf, 1974). Play interactions with peers also become more and more behaviorally and socially complex, such that by the third year, the play bouts typically involve patterns of behavior that appear to simulate almost the entire range of adult social activity (e.g., Suomi & Harlow, 1976). By the time they reach puberty, most rhesus monkey juveniles have had ample opportunity to develop, practice, and perfect behavioral routines that will become crucial for normal functioning in adult life, especially patterns involved in reproduction and in dominance/aggressive interactions (Suomi, 1979b). Virtually all of these juveniles will also have maintained close ties with their mothers throughout their juvenile years (e.g., Berman, 1982).

The onset of puberty is associated with dramatic life transitions for both male and female rhesus monkeys, involving not only major hormonal alterations, pronounced growth spurts, and other obvious physical changes, but also major social changes for both sexes (Suomi, Rasmussen, & Higley, 1992). Males experience the most dramatic and serious social disruption: They typically leave their natal troop, severing all social ties not only with their mothers and other kin but also with all others in that troop. Most adolescent males soon join all-male “gangs,” and after several months to a year, typically attempt to enter a different troop, usually composed entirely of individuals largely unfamiliar to them. Field studies have revealed substantial individual differences among these males in the timing of their emigration, in the basic strategies they follow in attempting to join other established social groups, and in their ultimate success or failure in these efforts (Howell et al., 2007; Mehlman et al., 1995). It is clearly a time of great risk for most of them. Adolescent

females, by contrast, almost never leave their maternal family or natal social group (Lindburg, 1971). Puberty for them is instead associated with increases in social activities directed toward maternal kin, typically at the expense of interaction with unrelated peers. Rhesus monkey females continue to be involved in family social affairs for the rest of their lives, even after they cease having infants of their own. Thus, their experiences with specific attachment relationships tend to be lifelong (Suomi, 1998).

Unique Aspects of Primate Infant–Mother Attachment Relationships

Is infant–mother attachment fundamentally different from the other social relationships a young rhesus monkey (or, for that matter, a human infant) will establish during its lifetime? Clearly, some aspects of the attachment relationship are exclusive to the mother–infant dyad because the mother is the exclusive source of not only for all that passes through the placenta but also a prenatal environment uniquely attuned to her own circadian and other biological rhythms. In addition, there is increasing evidence of predictable fetal reactions that can be traced to specific activities (including vocalizations) of the mother, perhaps providing the basis for exclusive multimodal proto-communication between mother and fetus (e.g., Busnell & Granier-Deferre, 1981; DeCasper & Fifer, 1980; Fifer, 1987; Novak & Stuart, 2007; Schneider, 1992). Such types of prenatal stimulation are, of course, routinely (and exclusively) provided by pregnant females in all placental mammalian species.

Some of these unique aspects of maternal support and stimulation are basically continued into an infant’s initial postnatal weeks and months, including, obviously, the mother’s status as the primary (if not sole) source of its nutrition. Mothers also keep sharing their own specific antibodies with their infants postnatally via the nursing process. Moreover, the essentially continuous contact or proximity between a mother and her newborn provides the infant with extended exposure to its mother’s odor, taste (of milk, at least; see Dettmer, Woodward, & Suomi, 2015), relative warmth, sound, and sight, representing a range and intensity of social stimulation seldom, if ever, provided by any other family or group members. In addition, rhesus monkey mothers continue to communi-

cate their internal circadian and other biological rhythms to their offspring via extended ventral–ventral contact, and there is some evidence that their offspring typically develop synchronous parallel rhythms during their initial weeks of life (Boyce, Champoux, Suomi, & Gunnar, 1995). As before, these maternally specific postnatal aspects of infant support and stimulation are not limited to primates but instead are characteristic of mothers in many other mammalian species, at least until the time of weaning (e.g., Hofer, 1995). But other aspects of a rhesus monkey mother’s relationship with her infant are not shared by all mammalian mothers, not even by mothers of some other primate species.

What are these unique features of a rhesus monkey (and human) mother’s relationship with her infant? It turns out that they are the very characteristics that Bowlby made the defining features of maternal attachment: (a) the mother’s ability to reduce fear in her infant via direct social contact and other soothing behavior, and (b) the mother’s capacity to provide a secure base to support her infant’s exploration of the environment. Numerous longitudinal studies of rhesus monkey social ontogeny, carried out in both laboratory and field environments, have consistently found that mothers have a virtual monopoly on these capabilities—or at least the opportunity to express them with their infants (e.g., Berman, 1982; Ferrari, Paukner, Ionica, & Suomi, 2009; Harlow & Harlow, 1965). Thus, rhesus monkey infants rarely, if ever, use other group members (even close relatives) as secure bases, or even as reliable sources of ventral contact (Suomi, 1979a). Moreover, on those occasions when they “mistakenly” seek the company of someone other than their own mother, they are unlikely to experience decreases in physiological arousal comparable to those resulting from contact with their mother; instead, they are likely to experience *increases* in arousal.

The attachment relationship a rhesus monkey infant establishes with its mother differs in additional fundamental ways from all other social relationships it will ever develop during its lifetime. Although, as previously noted, rhesus monkeys routinely establish a host of distinctive relationships with different siblings, peers, and adults of both sexes throughout development, each of these relationships is strikingly different from the initial attachment they establish to their mother in terms of primacy, constituent behaviors, reciprocity, and course of developmental change (Suomi, 1979a, 2002). Given these findings, perhaps Bowlby was

not entirely correct when he argued that the infant's attachment to the mother provides the *prototype* for all of its subsequent social relationships (Bowlby, 1969/1982) because, at least for rhesus monkeys, the relationship an infant establishes with its mother is like no other. On the other hand, Bowlby was absolutely correct (at least for rhesus monkeys) when he argued that the nature of the specific attachment relationship an infant develops with its mother can profoundly affect both concurrent and future relationships the infant may develop with others in its social sphere, as I discuss in detail later.

A somewhat different issue concerns the question of whether attachment phenomena as Bowlby originally defined them generalize to other species, including other primates. As outlined earlier, Bowlby clearly believed that basic features of attachment phenomena are essentially homologous in rhesus monkey infants and human babies, but are these characteristic features of attachment seen in other mammalian species as well? It all depends on how one defines *attachment*, or related terms such as *partner preference* or *imprinting*.

Without question, infant preference for the mother (and vice versa) represents an exceedingly ubiquitous phenomenon across most mammalian and avian species, as well as in numerous other taxa (Wilson, 1975). One specific (and, for Bowlby, a particularly relevant) form of partner preference involves *imprinting*. According to Lorenz's (1937) classical definition, imprinting is restricted to those partner preferences that are (1) acquired during a critical period, (2) irreversible, (3) generally species-specific, and (4) typically established prior to any behavioral manifestation of the preference. According to a slightly broadened version of this definition, imprinting-like phenomena can be observed in numerous insect, fish, avian, and mammalian species, including most, if not all, primates (Immelmann & Suomi, 1981).

On the other hand, it can be argued that infant-mother attachment as Bowlby (1958, 1969/1982) originally defined it represents a special case of imprinting that may itself be limited largely to Old World monkeys, apes, and humans (Suomi, 1995). To be sure, infants of all the other primate species (i.e., prosimians and New World monkeys) are initially at least as dependent on their mothers for survival, and spend at least as much time in physical contact with them, as do rhesus monkey (and human) infants (Higley & Suomi, 1986). In these other primate species, however, the predominant form of mother-infant

physical contact is usually different (dorsal-ventral vs. ventral-ventral); the frequency and diversity of mother-infant interactions are generally reduced; the patterns of developmental change are also different (often dramatically so); and, most importantly, the specific defining features of attachment are largely absent.

Consider the case of capuchin monkeys (*Cebus apella*, a.k.a. *Sapajus libidinosus*), a highly successful New World species whose natural habitat covers much of South America, including both Amazonian and Andean regions. These primates are remarkable in many respects, not the least of which is an amazing capability for manufacturing and using tools to manipulate their physical environment both in captivity and in their natural habitats (Darwin, 1794; Visalberghi, 1990; Visalberghi et al., 2007). In this respect they are probably superior to rhesus monkeys and, for that matter, all other primates except humans and perhaps chimpanzees. On the other hand, capuchin mother-infant relationships seem somewhat primitive by rhesus monkey standards.

A capuchin monkey infant spends virtually all of its first 3 months of life clinging to its mother's back, moving ventrally only during nursing bouts (Welker, Becker, Hohman, & Schafer-Witt, 1987). During this time there is very little visual, vocal, or grooming interaction between mother and infant, in marked contrast to rhesus monkey infants, who by 1 month of age are already actively interacting with their mother in extensive one-on-one bouts involving a wealth of visual, auditory, olfactory, tactile, and vestibular stimulation, and who typically are already beginning to use their mother as a secure base. When capuchin monkeys finally get off their mother's backs in their fourth month, they seem to be surprisingly independent and can spend long periods away from their mother without getting visibly upset. If frightened, they are almost as likely to seek protective contact from other group members as from their mothers (Byrne & Suomi, 1995). At this age and thereafter, capuchin monkey youngsters spend only about one third as much time grooming their mother as do rhesus, and their other activities with her are not markedly different from their activities with siblings, peers, or unrelated adults (Byrne & Suomi, 1995; Welker, Becker, & Schafer-Witt, 1990), which is in sharp contrast to rhesus monkeys of comparable age. All in all, capuchin monkey infants, compared to rhesus monkeys, seem far less attached to their biological mothers in terms of the prominence of the relationship, the rela-

tive uniqueness of constituent behaviors, and the nature and degree of secure-base-mediated exploration. One wonders how Bowlby's attachment theory might have looked if Hinde and Harlow had been studying capuchin rather than rhesus monkeys!

Comparative studies of infant–mother relationships in other New World monkey and prosimian species indicate that in most cases the relationships more closely resemble those of capuchin monkeys than those of rhesus monkeys (e.g., Fragaszy, Baer, & Adams-Curtis, 1991); in a few species (e.g., some marmosets and tamarins), the mother is not even an infant's primary caregiver (Higley & Suomi, 1986). To be sure, infants in all these primate species appear to be *imprinted* on their mothers, according to Lorenz's (1937) definition. However, attachment involves considerably more developmental complexity and reciprocity, especially with respect to secure-base phenomena, than do classical notions of imprinting. It can therefore be argued that, strictly speaking, attachment represents a special, *restricted* case of imprinting. Moreover, because infant–mother attachment is most apparent in humans and their closest phylogenetic kin, it may also represent a relatively recent evolutionary adaptation among primates (Suomi, 1995).

Conflict in Rhesus Monkey Infant–Mother Relationships

The relationships that rhesus monkeys develop with their mothers over time involve many behavioral patterns that go beyond attachment phenomena *per se* (Hinde, 1976). Indeed, a rhesus monkey female is extensively involved in a wide variety of interactions with her mother virtually every day that both are alive (and a male is thus involved every day until adolescence). However, this does not mean that all of these interactions are uniformly positive and pleasant. To the contrary, conflicts between mothers and offspring are frequent and often predictable, if not inevitable, occurrences in everyday rhesus monkey social life.

Sociobiological theorists have long argued that although mothers and infants share many genes and (therefore) many long-term goals, their short-term interests are not always mutual; hence, periodic conflict is inevitable (Trivers, 1974). Regardless of the validity of this view, an

obvious instance of parent–offspring conflict occurs for virtually every rhesus monkey infant at approximately 20 weeks of age, when its mother begins to wean it from her own milk to solid food. Whether this process begins because the mother “wants” her infant to cease nursing (so she can stop lactating, begin cycling, and be able to produce another offspring, as sociobiologists have proposed); because she “knows” that she cannot continue to produce enough milk to sustain her infant's rapidly growing energy requirements; or because her infant's erupting teeth make nursing increasingly uncomfortable is certainly open to question. What is clear is that weaning is almost always associated with significant changes in the basic nature of the infant's relationship with its mother, and those changes are seldom placid (e.g., Hinde & White, 1974).

Mothers, for their part, make increasingly frequent efforts to deny their infants access to their nipples, albeit with considerable variation in the precise form, timing, and intensity of their weaning behavior, ranging from the exquisitely subtle to what borders on abuse. Infants, on the other hand, dramatically increase their efforts to obtain and maintain physical contact with their mothers, even when nipple contact is not attainable. As with mothers, there is substantial variation in the nature, intensity, and persistence of the infants' efforts to prevent or at least delay the weaning process (Berman, Rasmussen, & Suomi, 1993). In virtually all cases, an infant's newfound preoccupation with maintaining maternal contact clearly inhibits its exploratory behavior, and noticeably alters and diminishes its interactions with peers (and often other kin) as well. Indeed, it usually takes a month or more (if at all) before those interaction patterns return to some semblance of normality (Hinde & White, 1974; Ruppenthal et al., 1974). Weaning therefore appears to undermine basic attachment security for the infant, perhaps permanently in some cases.

Postweaning “normality” for a young rhesus monkey seldom lasts for more than a few additional weeks before a second form of conflict with its mother typically arises. Most mothers return to reproductive receptivity at about the time their infants are 6–7 months old, at which point the mothers begin actively soliciting selected adult males for the next 2 or 3 months (rhesus monkeys are seasonal breeders in nature). Throughout this period, they may enter into consort relationships with several different males, typically lasting 1–3 days each. During this time, a female and her

chosen partner usually leave the main body of the monkey troop for most (if not all) of the time they are together, often seeking relative seclusion to avoid harassment or other interruptions from other troop members (Manson & Perry, 1993). At the same time, a mother's offspring from the previous year's consort tends to be ignored, actively avoided, or even physically rejected by both the mother and her current mate (Berman, Rasmussen, & Suomi, 1994).

Not surprisingly, most rhesus monkey yearlings become quite upset in the face of such functional maternal separations; indeed, a few actually develop dramatic behavioral and physiological symptoms that parallel Bowlby's (1960, 1973) descriptions of separation-induced depression in human infants and young children (Suomi, 1995). Most of their cohorts likewise exhibit an initial period of intense protest following loss of access to their mothers but soon begin directing their attention elsewhere. Interestingly, female offspring "left behind" by their mothers during consorts tend to seek out other family members during their mothers' absence, whereas young males are more likely to increase interactions with peers while their mothers are away (Berman et al., 1994). These gender differences in the prototypical response to maternal separation at 6–7 months of age thus appear to presage the much more dramatic gender differences in life course that emerge during adolescence and continue throughout adulthood.

It would seem that a rhesus monkey mother would always have the upper hand in conflicts with her offspring during both weaning and breeding periods, given her great size and strength advantage over even the most persistent 5- to 7-month-old infant. A number of research findings, however, suggest that infants bring resources of their own into these conflicts. For example, Simpson, Simpson, Hooley, and Zunz (1981) reported that infants who remained in physical contact with their mothers more and explored less during the preweaning months were more likely to delay the onset of weaning by several weeks, and in some cases even to preempt their mothers' cycling during the normal breeding season; this pattern was especially clear for male infants. Berman and colleagues (1993) found that, in a semi-field environment, infants who achieved the most frequent nipple contacts with their mothers during the breeding season had mothers who were least likely to conceive, even if they entered into relationships with multiple consorts during that period. The end result in both cases was that these

infants could, by their own actions, "postpone" their mothers' next pregnancy for another year, thus gaining additional opportunities for unfettered access to her not shared by agemates whose mothers had become pregnant during the same period. In the process, such an infant was also able to postpone by at least a year the appearance of a new source of conflict—that of "rivalry" with the mother's next infant.

The birth of a new sibling has major consequences for a yearling rhesus monkey. From that moment on, the yearling's relationship with the mother is altered dramatically, especially with respect to attachment-related activities. No longer is a yearling the primary focus of its mother's attention. Instead, many of its attempts to use her as a source of security and comfort are often ignored or rebuffed, especially when its newborn sibling is nursing or merely clinging to the mother's ventrum (Suomi, 1982). Moreover, whenever the yearling tries to push its younger sibling off the mother, to obstruct its access to her, or to disrupt its activity when it moves away from her, the mother's most likely response is to physically punish the yearling quickly, without warning, and often with considerable severity. In contrast, the mother seldom, if ever, punishes the younger sibling when it interrupts the yearling's attempts to interact with her or otherwise disrupts the yearling's activities (Berman, 1992).

Thus, the arrival of a younger sibling inevitably alters the yearling's attachment relationship with its mother. This relationship generally continues to wane (i.e., proximity-seeking and secure-base exploratory behavior both diminish) throughout the rest of the childhood years, especially after the birth of each succeeding sibling. For males, the waning process continues into puberty, eventually culminating with their natal troop emigration, which effectively terminates any remnant of their relationship with their mothers. Although attachment-related activities likewise decline throughout childhood for females, the daughters tend to increase other forms of affiliative interaction with their mothers (e.g., mutual grooming bouts), most notably after they start having offspring of their own. Coincidentally, episodes involving obvious conflict with their mothers become increasingly frequent for both male and female offspring as they approach puberty; thereafter, any semblance of attachment-like behavior directed toward mothers is infrequent at best among daughters and, of course, impossible for sons once they have left their natal troop (Suomi, 1998).

Factors Influencing Attachment Relationships in Rhesus Monkeys

Although Bowlby (1969/1982) believed that attachment has a strong biological basis and represents the product of evolutionary processes, he also observed that there is substantial variation among mother–infant dyads in fundamental aspects of their attachment relationships, and he recognized the potential developmental significance of such variation. Indeed, he lived to see his collaborator Mary Ainsworth’s Strange Situation assessment paradigm become almost reified in its identification and characterization of different “patterns” (groups A, B, C, and, more recently, D) and even “subgroups” of human infant–mother attachment relationships (e.g., Ainsworth, Blehar, Waters, & Wall, 1978; Main & Solomon, 1986). Perhaps not surprisingly, there appears to be comparable variation in the attachment relationships formed by different rhesus monkey mother–infant dyads. Indeed, there exist compelling parallel examples in rhesus monkey attachment relationships to each of the major human attachment types, if not at least some of the subtypes (Higley & Suomi, 1989). Moreover, a substantial body of research has identified numerous factors that can significantly influence the nature and ultimate developmental trajectory of these different attachment relationships. Some of these influences derive from factors external to the mother–infant dyad, and others appear to be derived from specific behavioral and biological features of the mother and the infant themselves.

With respect to external factors, numerous studies carried out over the past half century have demonstrated that most rhesus monkey mothers are usually highly sensitive to those aspects of their immediate physical and social environment that pose a potential threat to their infants’ well-being, and they appear to adjust their maternal behavior accordingly. Both laboratory and field studies have consistently shown that mothers from low-ranking families typically are much more restrictive of their infant’s exploratory efforts than are mothers from high-ranking matriline, whose maternal style tends to be more “laissez-faire” (e.g., Fairbanks, 1996). The standard interpretation of these findings has been that low-ranking mothers risk reprisal from others if they try to intervene whenever their infants are threatened, so they minimize such risk by restricting their infants’ exploration. High-ranking mothers usually

have no such problem and hence can afford to let their infants explore as they please (Suomi, 1998). Other studies have found that mothers generally become more restrictive and increase their levels of infant monitoring when their immediate social environment becomes less stable, such as when major changes in dominance hierarchies take place or when a new male joins the social group (Fairbanks, 1989). They also tend to monitor their infant’s social activities with peers more closely and become more restrictive with respect to the range of social partners with whom they allow their infants to interact as the size of their troop increases (Berman, Rasmussen, & Suomi, 1997). For those infants whose opportunities to explore and to interact with peers are chronically limited during their first few months of life, their ability to develop species-normative relationships with others in their social group (especially peers) can be compromised, often with long-term consequences for both the infants and the troop itself (Suomi, 1999).

Changes in various aspects of the physical environment, such as the food supply becoming less predictable, have also been associated with alterations in the day-to-day relationships between monkey mothers and their infants, with significant short-term and surprising long-term consequences for the infants as they mature. In a series of landmark studies with bonnet macaques (*Macaca radiata*), Rosenblum and his colleagues (e.g., Rosenblum & Pauly, 1984) developed a laboratory procedure that provided for experimental manipulation of the amount of time and effort a mother must spend to obtain the nutrition needed to satisfy her own and her infant’s daily needs, specifically, a low-foraging demand (LFD) condition in which food is available *ab lib* and a high-foraging demand (HFD) condition in which the mother must spend several hours each day to obtain equivalent nutrition for both her infant and herself, but for which there is no food deprivation *per se*. These researchers found that although there were no major differences among bonnet macaque infants reared under either condition, there were profound consequences for infants whose mothers experienced a *shift* in foraging conditions (e.g., from LFD to HFD and back) every 2 weeks, a condition termed variable foraging demand (VFD) condition, even if this condition was in place for only a period of 12 weeks. They observed major changes in the amount of time and the manner in which the mothers interacted with their infants during VFD periods, largely due to changes in the

way the mothers were interacting with each other within their social group (Andrews & Rosenblum, 1991). The end result was that the attachment relationships of VFD mothers and infants became less secure (Andrews & Rosenblum, 1993).

Offspring raised by VDF mothers exhibited persistent effects of this experience when compared with those raised either in the LDF or HDF conditions only. As juveniles they showed less social affiliation, greater affective withdrawal, and more subordinate behavior toward others in their social group (Andrews & Rosenblum, 1994; Rosenblum, Forger, Noland, Trost, & Coplan, 2001). They also exhibited a different profile of HPA activity, with higher cerebrospinal fluid (CSF) concentrations of corticotropin-releasing factor (CRF) but, interestingly, lower CRF concentrations of cortisol than did non-VFD subjects, not only as infants immediately following the VFD manipulation (as did their mothers) but actually continuing well into adulthood (Coplan et al., 1996; Matthew et al., 2002). Interestingly, these VDF effects on offspring HPA activity patterns were significantly less pronounced for offspring of socially dominant mothers. Moreover, these effects were not limited to the HPA system: Infants whose mothers experienced VFD also had significantly higher CSF levels of 5-hydroxyindoleacetic acid (5-HIAA; the primary central serotonin metabolite), somatostatin, and homovanillic acid (HVA; the primary central dopamine metabolite) than did those whose mothers experienced only the LFD condition (Coplan et al., 1998). Significant VDF-LDV differences were also found in growth hormone levels and in several measures of immune response that also persisted into adulthood (Coplan et al., 2000). In summary, these findings clearly indicate that environmental factors that fall short of what might be characterized as truly traumatic in nature but are sufficient to alter attachment relationships between a mother monkey and her infant can have profound and long-lasting consequences not only for the infant's subsequent behavioral and emotional development but also for the functioning of a variety of biological systems throughout its ontogeny and beyond.

Individual Differences in Infant-Mother Relationships

Numerous other studies have shown that differences among monkey mothers' characteristic

maternal "style" can also affect the type of attachment relationships they develop with their offspring, even when they are living in the same physical and social-environmental settings. Although a comprehensive review of the relevant literature is beyond the scope of this chapter, it is worth noting that most primate females tend to be remarkably consistent in the specific manner in which they rear their infants, at least after their initial pregnancy (Higley & Suomi, 1986; Suomi, 1987). It is also worth noting that some of the differences one can observe among monkey mothers' respective maternal styles can be related to specific temperamental characteristics they displayed as infants, as well as the nature of the attachment relationship they formed with their own mothers (e.g., Champoux, Byrne, Delizio, & Suomi, 1992; Suomi, 1995, 1999; Suomi & Ripp, 1983).

It is now apparent that differences in maternal style can have major and lasting consequences for not only for the attachments their offspring develop to them but also, as in the case of external environmental influences described earlier, their offspring's behavioral and biological functioning throughout life. One of the most dramatic examples of the effects of differential maternal style comes from the work of Maestripieri and his colleagues at the Yerkes National Primate Center field facility near Atlanta, where large breeding groups of rhesus monkeys are maintained in outdoor corrals. These investigators observed that successive generations of females in several long-standing matriline maintained in this setting physically abuse most of their offspring to a degree not seen in other families. Most of the abuse occurs during their infant's first month of life and is rarely seen after the third month (Maestripieri, McCormack, Higley, Lindell, & Sanchez, 2006). In addition, these abusive mothers also tend to exhibit unusually high levels of infant rejection (i.e., preventing their infant from obtaining ventral or nipple contact, or pushing it away if such contact has been already established) and these high rates of rejection continue long after all incidents of abuse have ceased (McCormack et al., 2006). Thus, for females living in these families, high levels of infant neglect and abuse appear to be the norm rather than the exception across successive generations of mothers.

Such extreme styles of maternal care are not without behavioral and biological consequences for infants growing up in these matriline. The maternally abused and neglected infants exhibit much higher rates of screams, tantrums, and other

behavioral indices of obvious distress throughout their first 6 months of life, long after they are no longer being physically abused, than do offspring of nonabusive mothers. They also appear to become much more emotionally reactive than their nonabused agemates, including delayed independence from their mothers, less environmental exploration, and much lower levels of social play during this same developmental period (McCormack et al., 2006). In addition, as was the case for monkey infants whose mothers were exposed to VFD conditions during their initial 6 months, physically abused infants exhibit deviations from the normative pattern of HPA activity and central serotonin metabolism shown by nonabused infants, and these aberrant patterns continue well into the juvenile years, if not beyond. However, it appears that the nature of these deviations is quite different from that seen in VFD infants: Maltreated infants exhibit unusually high levels of HPA reactivity in their first month, but thereafter, HPA reactivity appears to be blunted relative to that of nonabused infants, and abused infants have significantly *lower* CSF concentrations of 5-HIAA, exactly the opposite of infants growing up under VFD conditions (Maestripieri et al., 2006; Sanchez, 2006). Moreover, it has now been well documented that a high proportion of females who experienced such abuse and rejection by their mothers early in life grow up to be maltreating mothers themselves (Maestripieri & Carroll, 1998). These and other findings clearly support the proposition that individual differences in maternal style, including attachment-related activities, among rhesus monkey mothers can have profound consequences for the behavioral and biological functioning of their offspring throughout development, especially when the differences are extreme. (For discussion of precursors of individual differences of attachment in humans, see Fearon & Belsky, Chapter 14, this volume.)

The Role of Infant Temperament

Finally, variance in rhesus monkey attachment relationships may come in part from differences among infant monkeys' temperamental characteristics and the physiological processes that underlie their behavioral expression early in life. Researchers studying rhesus and other monkey species in both laboratory and field settings have long recognized developmentally stable individual differences along certain temperamental dimensions.

One dimension involves relative *fearfulness*, as reflected by individual differences in prototypical behavioral and biological responses to environmental novelty and/or challenge. Some monkey infants consistently respond to such mildly stressful situations with obvious behavioral expressions of fear and anxiety, as well as significant (and often prolonged) cortisol elevations, unusually high and stable heart rates, and dramatic increases in norepinephrine metabolism (e.g., Capitanio, Rasmussen, Snyder, Laudenslager, & Reite, 1986; Clarke & Boinski, 1995; Kalin & Shelton, 1989; Suomi, 1981, 1991; Suomi, Kraemer, Baysinger, & Delizio, 1981). These distinctive behavioral and physiological features appear early in infancy; they show remarkable interindividual stability throughout development; and there is increasing evidence that they are highly heritable (Dettmer & Suomi, 2014; Higley et al., 1993; Williamson et al., 2003).

One consequence of these behavioral and biological proclivities is that such "high-reactive" infants tend to spend more time with their mothers and less time with peers during their initial weeks and months of life. High-reactive young monkeys are also more likely to exhibit depressive-like reactions to functional maternal separations during the breeding season, as described earlier, than the rest of their birth cohort (Berman et al., 1994; Suomi, 1995). On the other hand, a high-reactive infant may ultimately be more "successful" than others in its peer group in postponing its mother's next pregnancy and, eventually, a new sibling rival for her attention (Berman et al., 1993; Simpson et al., 1981; Suomi, 1998). These and other findings provide impressive evidence that temperamental reactivity on the part of the infant can influence, if not substantially alter, fundamental aspects of its relationship with its mother throughout development.

Another temperamental dimension for which there are obvious individual differences among rhesus monkey infants is relative impulsivity, especially in social settings in which inappropriately impulsive behavior often leads to aggressive exchanges. This temperamental pattern is most readily apparent in peer play interactions. Impulsive males in particular seem unable to moderate their behavioral responses to rough-and-tumble play initiations from peers, instead escalating initially benign play bouts into full-blown, tissue-damaging aggressive exchanges, disproportionately at their own expense (Higley, Chaffin, & Suomi, 2011; Higley, Suomi, & Linnoila, 1996). Prospective longitudinal studies have shown that individu-

als that develop such response patterns typically exhibit poor state control and significant deficits in visual orienting capabilities during their first month of life (Champoux, Suomi, & Schneider, 1994). They also tend to exhibit chronically low rates of central serotonin metabolism, a prominent inhibitory neurotransmitter implicated in ubiquitous aspects of metabolic, regulatory, and emotional functioning (Coccaro & Murphy, 1990). In particular, impulsive and aggressive monkeys consistently have lower CSF 5-HIAA than their peers throughout development (e.g., Champoux, Higley, & Suomi, 1997; Higley, King, et al., 1996; Higley & Suomi, 1996; Mehlman et al., 1994; Shannon et al., 2005). As is the case for high reactivity, these behavioral and biological characteristics of impulsive aggression are remarkably stable throughout development, and they appear to be highly heritable (Higley et al., 1993; Higley & Suomi, 1996).

Highly impulsive rhesus monkeys typically develop difficult attachment relationships with their mothers. They seem to be unusually fussy in their initial weeks (reflecting their generally poor state control; see Champoux et al., 1994), and their conflicts with their mother intensify substantially during and shortly after the time of weaning (Suomi, 1998). As they grow older, highly impulsive youngsters usually continue to exhibit difficulties in their social interactions with their mothers, with peers, and with others in their social group, and these social problems generally carry over into adolescence and adulthood—and sometimes into the next generation (Higley & Suomi, 1996; Higley et al., 2011; Suomi, 2006). (For discussion of attachment and temperament in humans, see Vaughn & Bost, Chapter 10, this volume.)

Effects of Differential Attachment Relationships on Long-term Developmental Trajectories for Rhesus Monkeys

Although considerable evidence from both field and laboratory studies has shown that individual differences among rhesus monkeys in certain temperamental characteristics tend to be quite stable from infancy to adulthood and are at least in part heritable, this does not mean that these behavioral and physiological features are necessarily fixed at birth or are immune to subsequent environmen-

tal influence. On the contrary, an increasing body of evidence from laboratory studies has demonstrated that prototypical behavioral and biological response patterns can be modified substantially by certain early experiences, especially those involving attachment relationships. This is perhaps most clearly illustrated by the results of experimental studies in which monkey infants have been separated from their biological mother at or shortly after birth and reared in the presence of other monkeys, species, or a variety of animate or inanimate objects. In most of these circumstances, rhesus monkey infants readily develop Bowlby-like attachments with whomever or whatever might be available, although some potential attachment objects are clearly preferred to others. The classic case is Harlow's (1958) seminal studies involving cloth- and wire-covered surrogates that Bowlby found so compelling (e.g., Bowlby, 1969/1982), but there have been many others. Over the years rhesus monkey infants have been reported to become attached to unrelated adult female conspecifics, adult male conspecifics, adult females from other primate species, dogs, cats, hobby horses, and a range of variations on the original Harlow cloth surrogate (e.g., Dettmer & Suomi, 2014; Mason & Gerson, 1975). Mason & Kenney, 1978; Redican & Mitchell, 1973). It is clearly in their nature to become attached, but attachments with these different classes of individuals and objects often have vastly different consequences, especially for different infants.

One extensive set of studies has focused on rhesus monkey infants raised with peers instead of their biological mothers. Infants in these studies were permanently separated from their biological mothers at birth; hand-reared in a neonatal nursery for their first weeks of life; housed with same-age, like-reared peers for the rest of their first 6–7 months; then moved into larger social groups containing both peer-reared and mother-reared age-mates. During their initial months, these infants readily developed strong social attachment bonds to each other, much as mother-reared infants develop attachments to their own mothers (Harlow, 1969). However, perhaps because peers are not nearly as effective as typical monkey mothers in reducing fear in the face of novelty, or in providing a secure base for exploration, the attachment relationships that these peer-reared infants developed were almost always dysfunctional in nature (Suomi, 1995). As a result, although peer-reared monkeys showed completely normal physical and motor development, their early exploratory be-

havior was somewhat limited. They seemed reluctant to approach novel objects, and they tended to be shy in initial encounters with unfamiliar peers (Suomi, 2006, 2011).

Even when peer-reared youngsters interacted with their same-age cagemates in familiar settings, their emerging social play repertoires were usually retarded in frequency, intensity, and complexity. One explanation for their relatively poor play performance is that their cagemates had to serve as both attachment figures and playmates, a dual role that neither mothers nor mother-reared peers have to fulfill. Another explanation is that they faced difficulties in developing sophisticated play repertoires with basically incompetent play partners. Perhaps as a result of either or both of these factors, peer-reared youngsters typically dropped to the bottom of their respective dominance hierarchies when they were grouped with mother-reared monkeys their own age (Higley, King, et al., 1996).

Several prospective longitudinal studies have found that peer-reared monkeys consistently exhibit more extreme behavioral, HPA axis, and other neurochemical reactions to social separations than do their mother-reared cohorts, even after they have been living in the same social groups for extended periods (Higley & Suomi, 1989; Shannon, Champoux, & Suomi, 1998). Such differences in prototypical behavioral reactions to separation persist from infancy to adolescence, if not beyond. Interestingly, the separation reactions of peer-reared monkeys seem to mirror those that occur naturally in high-reactive mother-reared subjects. In this sense, early rearing by peers appears to have the effect of making rhesus monkey infants generally more high-reactive than they might have been if reared by their biological mothers (Suomi, 1997).

Early peer-rearing has another long-term developmental consequence for rhesus monkeys: It tends to make them more impulsive, especially if they are males. Peer-reared males initially exhibit aggressive tendencies in the context of juvenile play; as they approach puberty, the frequency and severity of their aggressive episodes typically exceeds those of mother-reared group members of similar age. Peer-reared females tend to groom (and be groomed by) others in their social group less frequently and for shorter durations than their mother-reared counterparts, and, as noted earlier, they usually stay at the bottom of their respective dominance hierarchies (Higley, King, et al., 1996; Higley et al., 2011). These differences between peer-reared and mother-reared

agemates in aggression, grooming, and dominance remain relatively robust throughout the preadolescent and adolescent years (Higley, Suomi, et al., 1996). Peer-reared monkeys also consistently show lower CSF concentrations of 5-HIAA than their mother-reared counterparts. These group differences in 5-HIAA concentrations appear well before 6 months of age, and they remain stable at least throughout adolescence and into early adulthood (Higley & Suomi, 1996; Shannon et al., 2005). Thus, peer-reared monkeys as a group resemble the impulsive subgroup of wild-living (and mother-reared) monkeys not only behaviorally but also in terms of decreased serotonergic functioning (Suomi, 1997).

Other laboratory studies of peer-reared monkeys have disclosed additional differences with their mother-reared counterparts, differences that are not readily apparent in free-ranging populations of rhesus monkeys. Peer-reared adolescent monkeys consistently consume larger amounts of alcohol under comparable ad lib conditions than their mother-reared agemates (Higley, Hasert, Suomi, & Linnoila, 1991; Higley et al., 2011). Recent follow-up studies have demonstrated that the peer-reared subjects quickly develop a greater tolerance for alcohol; this can be predicted by their central nervous system serotonin turnover rates, which in turn appear to be associated with differential serotonin transporter availability (Heinz et al., 1998). Peer-reared adolescent and adult males require larger doses of the anesthetic ketamine to reach a comparable state of sedation. They also exhibit significantly higher rates of whole-brain glucose metabolism under mild isoflurane anesthesia, as determined by positron emission tomography (PET) imaging, than mother-reared controls (Doudet et al., 1995). Additional studies involving PET imaging have reported that peer-reared juveniles have significantly lower levels of serotonin binding potential and cerebral blood flow in multiple brain regions than do their mother-reared counterparts (Ichise et al., 2006) and that there are rearing condition differences in serotonin I-A receptors in various brain regions as well (Spinelli et al., 2010). Structural magnetic resonance imaging (sMRI) studies comparing mother- versus peer-reared juveniles have revealed significant structural differences. For example, peer-reared subjects have an enlarged vermis, as well as larger dorsomedial prefrontal cortical and dorsal anterior cingulate cortical regions, which can be attributed to similar differences in early rearing conditions early in life (Spinelli, Chefer, Suomi, Barr,

& Stein, 2009). Thus, the development of early attachments to peers in the absence of the mother can have significant long-term consequences for monkeys at levels of not only behavioral expression and emotional regulation but also neuroendocrine function, neurotransmitter metabolism, drug sensitivity, and even brain structure and function. Long-term follow-up studies have revealed that some of these consequences persist well into adulthood (Corcoran et al., 2012). (For discussion of the developmental trajectories associated with individual differences in attachment in humans, see Thompson, Chapter 16, and Ehrlich, Miller, Jones, & Cassidy, Chapter 9, both in this volume.)

Gene–Environment Interactions Involving Different Forums of Early Attachment Relationships

Clearly, a range of adverse early experiences, be they exposure to a mother dealing with the demands of a VFD environment, experience with an abusive and rejecting mother, or peer rearing in the absence of attachment opportunities with any adult, can have significant developmental consequences for individuals at multiple levels of analysis. It also seems apparent that heritable factors might influence individual developmental trajectories at one or more levels of analysis as well. But do these genetic and environmental factors operate separately, or do they interact in some fashion? Research over the past several years has demonstrated several significant *interactions* between specific genetic and experiential factors in shaping developmental trajectories for rhesus monkeys.

For example, the serotonin transporter gene (*5-HTT*), a candidate gene for impaired serotonergic function (Heils et al., 1996), has length variation in its promoter region that results in allelic variation in *5-HTT* expression. A heterozygous short allele (LS) confers low transcriptional efficiency to the *5-HTT* promoter relative to the homozygous long allele (LL), raising the possibility that low *5-HTT* expression may result in decreased serotonergic function (Lesch et al., 1996). Comparative studies have shown that rhesus monkeys possess a homologous serotonin transporter gene, as well as essentially the same allelic variation structurally and functionally (Lesch et al., 1997).

Several studies have now demonstrated that the consequences of having the LS allele differ dramatically for peer-reared monkeys and their mother-reared counterparts. For example, Champoux and colleagues (2002) examined the relation between early rearing history and *5-HTT* polymorphic status on measures of neonatal neurobehavioral development during the first month of life and found evidence of some sort of *maternal buffering*. Specifically, infants possessing the LS allele who were being reared in the laboratory neonatal nursery showed significant deficits in measures of attention, activity, and motor maturity relative to nursery-reared infants possessing the LL allele, whereas both LS and LL infants who were being reared by competent mothers exhibited normal values for each of these measures. One interpretation of this interaction is that effective mother-rearing, including the development of secure attachment relationships, appeared to *buffer* any potentially deleterious effects of the LS allele on these measures. Similarly, Bennett and colleagues (2002) found that CSF *5-HIAA* concentrations did not differ as a function of *5-HTT* status for securely attached mother-reared juvenile subjects, whereas among peer-reared juveniles, individuals with the LS allele had significantly lower CSF *5-HIAA* concentrations than those with the LL allele. Once again, mother rearing appeared to buffer any potentially deleterious effects of the LS allele on serotonin metabolism. A similar pattern appeared with respect to aggression: High levels of aggression were shown by peer-reared juveniles with the LS allele, whereas mother-reared LS monkeys exhibited low levels that were comparable to those of both mother-reared and peer-reared LL subjects, again suggesting a buffering effect of maternal rearing (Barr et al., 2003).

An even more dramatic pattern of gene–environment ($G \times E$) interaction was revealed by an analysis of alcohol consumption data: Whereas peer-reared monkeys with the LS allele consumed more alcohol than peer-reared monkeys with the LL allele, the reverse was true for mother-reared subjects, with individuals possessing the LS allele actually showing relatively low levels of alcohol consumption (Barr et al., 2004). Similar evidence of maternal buffering with respect to differing patterns of alcohol response and consumption were reported by Schwandt and colleagues (2010). Here, the LS allele appeared to represent a significant *risk* factor for excessive alcohol consumption among monkeys with adverse early attachment experiences but a significant

protective factor for mother-reared subjects, most of whom had experienced positive attachment experiences with their mother.

In summary, peer-reared monkeys with the LS allele displayed deficits in measures of neurobehavioral development during their initial weeks of life and reduced serotonin metabolism and excessive alcohol consumption as adolescents compared with those possessing the LL allele. In contrast, mother-reared subjects with the LS allele were characterized by normal early neurobehavioral development and serotonin metabolism, as well as reduced risk for excessive alcohol consumption later in life compared with their mother-reared counterparts with the LL allele. It could be argued on the basis of these findings that having the LS allele of the *5-HTT* gene may well lead to psychopathology among monkeys with adverse early rearing histories but actually be adaptive for monkeys who develop a secure early attachment to their mothers.

A parallel “maternal buffering” pattern of $G \times E$ interaction involving a polymorphism in the monoamine oxidase A (*MAOA*) gene was found for levels of aggressive behavior exhibited by mother-reared and peer-reared rhesus monkey juveniles; here, peer-reared subjects with the less functionally efficient *MAOA* allele had significantly higher levels of aggression than mother-reared subjects carrying the same allele and both mother- and peer-reared subjects carrying the more functionally efficient allele (Newman et al., 2005), essentially replicating findings reported for humans (e.g., Caspi et al., 2002). In addition, similar patterns of $G \times E$ interactions have been reported regarding functional polymorphisms in other rhesus monkey genes, including the corticotropin-releasing hormone (*CRH2A*) receptor gene (Barr et al., 2008), the neuropeptide Y (*NPY*) gene (Lindell et al., 2010), the *mu* opioid receptor (*OMRM1*) gene (Barr et al., 2008), the dopamine receptor *DRD1 5'UTR* gene (Newman et al., 2009), and the brain-derived neurotrophic factor (*BDNF*) receptor gene (Cirulli et al., 2009), among others, and a variety of behavioral and biological outcomes (e.g., Schwandt et al., 2011). For each of these “candidate” genes the significant $G \times E$ findings basically followed the same “maternal buffering” pattern (i.e., peer-reared monkeys carrying the functionally less efficient allele exhibited significant deficits relative to peer-reared subjects carrying the same allele), whereas peer-reared monkeys carrying the more efficient allele showed levels that were equivalent to, in a few cases, or

even better than those of mother-reared monkeys for most of the behavioral or biological measures that were the focus of each study.

The implications of these recent findings may be considerable with respect to the cross-generational transmission of these behavioral and biological characteristics in that, as previously mentioned, the particular attachment style of a monkey mother tends to be mirrored by her daughters when they grow up and become mothers themselves (Fairbanks, 1989; Maestripieri, 2005). If similar buffering is indeed experienced by the next generation of infants carrying, for example, the LS *5-HTT* polymorphism, then having had their own mothers develop a secure attachment relationship with them when they were infants may well provide the basis for a nongenetic means of transmitting its apparently adaptive consequences to that new generation. On the other hand, if contextual factors such as changes in dominance rank, instability within the troop, or changes in the availability of food were to alter a young mother's care of her infants in ways that compromised such buffering (e.g., Dettmer, Novak, Meyer, & Suomi, 2014; Dettmer et al., 2015), one might expect any offspring carrying the LS polymorphism to develop some, if not all, of the problems described earlier.

Cross-Generational Consequences of Early Attachment Relationships: Implications for Human Attachment Theory

One of the most intriguing aspects of the long-term consequences of different early attachment experiences, especially in light of the speculation outlined earlier, is the apparent transfer of specific features of maternal behavior across successive generations. Several studies of rhesus monkeys and other Old World monkey species have demonstrated strong continuities between the type of attachment relationship a female infant develops with her mother and the type of attachment relationship she develops with her own infant(s) when she becomes a mother herself. In particular, the pattern of ventral contact a female infant has with her mother (or mother substitute) during her initial months of life is a powerful predictor of

the pattern of ventral contact she will have with her own infants during their first 6 months of life (Champoux et al., 1992; Fairbanks, 1989, 1996). This predictive cross-generational relationship appears to be as strong in females who were foster-reared from birth by unrelated multiparous females as it is for females reared by their biological mothers. An even more impressive demonstration of cross-generational transmission of maternal characteristics comes from Maestripieri (2005), who cross-fostered female infants of abusive mothers to nonabusive multiparous females and also cross-fostered offspring of nonabusive mothers to unrelated females with a prior history of abuse. Maestripieri found that whereas approximately half of the female offspring of nonabusive mothers who were reared by abusive foster mothers grew up to be abusive toward their own offspring, *none* of the female offspring of abusive mothers who had nonabusive foster mothers subsequently abused their own infants! These findings clearly demonstrate that cross-generational transmission of at least some aspects of mother–infant attachment necessarily involves nongenetic mechanisms (cf. Suomi & Levine, 1998). What those nongenetic mechanisms might be, and through what developmental processes they might they act, are questions at the heart of extensive ongoing investigations, in particular those examining genomewide *epigenetic* changes contingent on different early social experiences (see Provencal et al., in press).

Two published studies investigated the effects of differences in early social rearing (mother rearing vs. a form of peer rearing) on genomewide patterns of messenger RNA (mRNA) expression in leukocytes, and on methylation patterns in prefrontal cortex (PFC) and in T-cell lymphocytes, respectively. The research involving mRNA expression examined expression patterns in differentially reared 4-month-old infants. In all, 521 genes were significantly more expressed in mother-reared infants than in peer-reared infants, whereas the reverse was the case for another 717 genes. In general, peer-reared infants showed enhanced expression in genes involved in inflammation, T-lymphocyte activation and cell proliferation, and suppression of antiviral and antibacterial responses (Cole et al., 2012). Since that initial study, the same investigators have embarked on a prospective longitudinal study in which differentially reared subjects were sampled at 14 days, 30 days, 6–7 months, and every 4 months thereafter, until they reached puberty. Data from that prospective longitudinal study are currently being analyzed.

The other study involved genomewide analyses of methylation patterns in differentially reared monkeys when they were adults. This study compared such patterns in PFC tissue and T-cell lymphocytes obtained from 8-year-old monkeys differentially reared for their initial 6–7 months of life and thereafter maintained under identical conditions until adulthood (Provencal et al., 2012). These analyses revealed that (1) more than 4,400 genes were differentially methylated in both PFC and lymphocytes; (2) although there was considerable tissue specificity, approximately 25% of the affected genes were identical in both PFC and lymphocytes; and (3) in both PFC and lymphocytes, methylated promoters tended to cluster both by chromosomal region and gene function. The same research team has since completed the data collection in a prospective longitudinal study of genomewide methylation patterns in lymphocytes, obtaining samples at exactly the same ages and from exactly the same monkeys as in the aforementioned longitudinal study of genomewide mRNA expression. Data from this second longitudinal study are also currently under analysis, although preliminary results have revealed that at least some of the massive rearing condition differences already present after the first month appear to be *reversible* during the second year after the original rearing conditions have been experimentally altered (Provencal et al., in press).

Proponents of human attachment theory have long focused on possible cross-generational continuities in attachment styles. Some authors have posited the likely existence of strong cross-generational continuities, such that mothers who experienced secure attachments when they were infants might tend to raise infants who are securely attached to them, whereas those who experienced avoidant or ambivalent attachments with their own mothers might tend to promote avoidant or ambivalent attachments as mothers themselves (e.g., Main, 1995). Moreover, current attachment theorists attribute these postulated infancy-to-parenthood continuities in attachment type to “internal working models” initially based on early memories and periodically transformed by more recent experience. Most of the empirical findings that have led to these hypotheses have come from comprehensive interviews of adults (e.g., with the Adult Attachment Interview) retrospectively probing memories of events and experiences. On the other hand, some of the most powerful empirical support for apparently parallel long-term continuities in attachment behav-

ior from the nonhuman primate literature comes from prospective longitudinal observations and physiological recordings, both in controlled experimental settings and in naturalistic habitats, as reviewed earlier.

One insight that the nonhuman primate data bring to discussions about long-term consequences of early experiences is that strong developmental continuities can unfold *in the absence of language or complex imagery*. It is difficult to argue that rhesus monkeys, for example, possess sufficient cognitive capabilities to develop anything remotely analogous to human internal working models requiring considerable self-reflection, given that they are clearly not fully capable of human-like self-awareness or self-recognition (e.g., Gallup, 1977; Povinelli, Parks, & Novak, 1992). Given those restricted capabilities, what cognitive, emotional, and mnemonic processes might underlie these empirically documented behavioral continuities, and do they have any parallels in human nonverbal mental processes? (See Cassidy, Ehrlich, and Sherman [2013] for discussion of noncognitive mechanisms of links between early experience and later functioning in humans.)

Alternatively, one might argue that working models are *exclusively* human constructions that are built upon a basic foundation that is essentially biological in nature and universal among the more advanced primate species. According to this view, cognitive constructions per se may not be necessary for long-term developmental or cross-generational continuities in attachment phenomena to transpire. That is, such continuities are essentially “programmed” to occur in the absence of major environmental disruption and are in fact the product of strictly biological processes that reflect the natural evolutionary history of advanced primate species, human and nonhuman alike. If this is the case, then working models (or other comparable cognitive processes) scaffolded on existing basic biological foundations perhaps actually represent a “luxury” for humans that might enable individuals to reinforce cognitively those postulated underlying biological foundation, in which case the predicted developmental continuity might actually be strengthened.

On the other hand, the existence of a working model that has the potential to be *altered* by specific experiences (and/or insights) in late childhood, adolescence, or adulthood might provide a basis for breaking an otherwise likely continuity between one’s early attachment experiences and subsequent performance as a parent (i.e., make it

possible to break an otherwise likely cross-generational cycle), especially when one is confronted with a recurrent cycle of early adversity. These important issues deserve not only further theoretical consideration but also empirical investigation. As Bowlby (1988) himself said, “All of us, from cradle to the grave, are happiest when life is organized as a series of excursions, long or short, from the secure base provided by our attachment figure(s)” (p. 62). Research with nonhuman primates has clearly provided compelling evidence in support of a strong biological foundation for attachment-like phenomena. Indeed, such a foundation may well serve as a secure base for future excursions in the realm of attachment research.

Chapter 8

Attachment, Parenting, and Genetics

Marian J. Bakermans-Kranenburg
Marinus H. van IJzendoorn

Attachment

Without doubt, forming attachments, as defined by Bowlby (1969/1982), is a genetic characteristic of human beings. The most general definition of attachment is one that considers it to be an inborn bias of human infants to seek proximity to a protective caregiver in times of stress, distress, illness, and other physical or psychological discomfort. Human offspring would not be able to survive without the care of a stronger or more experienced conspecific who is able to regulate body temperature, food intake, and stress levels because young infants cannot take care of these basic physiological and psychological needs by themselves. The early environment of evolutionary adaptedness among humans required the basic ability to become emotionally attached in order to survive and enhance inclusive fitness (Bowlby, 1969/1982).

Attachment, however, is also strongly dependent on the environment. Although all infants are born with the ability to become attached to a protective caregiver, they differ in the way in which this competence is expressed. Infants differ rather drastically in the quality of their attachment relationships, and attachment theory hypothesizes that this “attachment performance” is largely, albeit not exclusively, environmentally determined. Differences in attachment behaviors and relationships emerge in the course of the first few years of

life as a consequence of childrearing experiences with parents and other caregivers. Infants may develop secure or insecure attachments in response to a more or less sensitive or predictable social environment. The parallel to language development is useful here. Every child is born with the capacity to learn a language, but the specific language environment determines the kind of language to be learnt.

Paradoxically, the search for the genetic foundation of attachment seems to be inspired by two contrasting goals. On the one hand, cross-cultural researchers who study attachment wish to document the balance between universal and culture-specific influences on attachment *competence*, in order to test the core hypothesis that every human infant is born with a bias to become attached (see Mesman, Van IJzendoorn, & Sagi-Schwartz, Chapter 37, this volume). On the other hand, the behavioral and molecular genetics studies of attachment are aimed at elucidating the genetic versus environmental determination of attachment *performance*, with the assumption (on the part of attachment researchers) that attachment differences are mainly rooted in variations in the environment in which an infant grows up. Here we focus on the genetics of individual differences in attachment behavior and relationship quality.

Behavioral Genetics of Attachment

Twins have been a great source of information about human development. The comparison of monozygotic (MZ, or identical) twins, whose structural DNA is exactly the same, with dizygotic (DZ, or fraternal) twins, who share on average half of their DNA, is an experiment by nature. If children within an MZ twin pair are more similar to each other in terms of attachment (or any other trait) than children within a DZ twin pair, one might conclude that genetic similarity matters. In the case of strong similarity of attachment between MZ twins and much smaller similarity between DZ twins, attachment would be considered highly heritable. This conclusion is warranted, of course, only when we assume that parents do not treat MZ and DZ twins differently. The equal environments assumption has been examined and found to be valid for a variety of phenotypes (Cronk et al., 2002), but for parenting relevant to attachment development this information is not available.

Only a few, rather small twin studies of infants' and preschoolers' attachments have been reported (Bakermans-Kranenburg, Van IJzendoorn, Bokhorst, & Schuengel, 2004; Bokhorst et al., 2003; Finkel, Wille, & Matheny, 1998; O'Connor & Croft, 2001; Ricciuti, 1992; Roisman & Fraley, 2008), and the majority of these studies did not find differences in attachment similarity between MZ and DZ twin pairs. In general about 50% of the variance in attachment security could be attributed to the shared environment (parenting influences that make children within the same family similar), and about 50% of the variation could be explained by unique influences (that make children within a family more dissimilar) and measurement error. There seemed to be no room for genetic influences. Interestingly, the shared environmental variance in attachment security showed substantial overlap with the shared environmental variance in observed maternal sensitivity, suggesting that parental sensitivity is indeed an important part of the (shared) environment shaping children's attachment patterns (Fearon et al., 2006).

The only exception to the rule that young children's attachment security is not heritable was the study in which Finkel and colleagues (1998) found considerable heritability for attachment, but unfortunately used an attachment measure that was originally meant to assess temperament. In the study by Bokhorst and colleagues (2003), temperamental reactivity was estimated to be

highly heritable, whereas attachment security was mainly environmentally based. In a study of infant–father attachment using the Attachment Q-Sort (AQS; Vaughn & Waters, 1990), high heritability of temperament went with low heritability of attachment security to the father, using the same measure and the same sample as Bakermans-Kranenburg and colleagues (2004). It is important to note that the developmental roots of attachment and temperament seem to be different, which underlines their conceptual and functional differences (Groh et al., in press; Van IJzendoorn & Bakermans-Kranenburg, 2012; see Vaughn & Bost, Chapter 10, this volume).

Disorganized attachment has rarely been studied with a twin design. Disorganized attachment is observed in children who are maltreated or otherwise frightened by parental behavior, for example because their parents struggle with unresolved loss or other potentially traumatic experiences (Cyr, Euser, Bakermans-Kranenburg, & Van IJzendoorn, 2010; Schuengel, Bakermans-Kranenburg, & Van IJzendoorn, 1999; see Lyons-Ruth & Jacobvitz, Chapter 29, this volume). Disorganized attachment behaviors include, among others, frightened facial expressions; freezing or stilling of behavior; or avoidance in distress, when a parent returns following a brief separation in the Strange Situation (Main & Solomon, 1990). Heritability estimates of disorganized attachment approach zero, and in remarkable contrast to attachment security, no trace of shared environmental influence can be found (Bokhorst et al., 2003). Variance in disorganized attachment seems to be explained almost exclusively by a unique environment. This suggests that unique experiences with the parents trigger children's disorganized attachment. It may also imply a large error component in the assessment of disorganized attachment, which, indeed, is by far the most difficult part of the attachment coding system to master. Of course, low statistical power should be taken into account when considering the absence of heritability: The modest sample size and skewed distribution of disorganized attachment result in large confidence intervals around the estimates.

In several cases the influence of genetics on traits or characteristics such as cognitive development has been shown to increase with age. The influence of the environment seems to decrease as children grow older, undergo a variety of influences outside the family, and are more able to shape their own environments. Indeed, genetic studies of individual differences in mental development

and temperament confirm this view (e.g., Plomin, 1994; but see Haworth, Dale, & Plomin, 2009, for contrasting effects). In the largest twin study on attachment to date, Fearon, Shmueli-Goetz, Vidling, Fonagy, and Plomin (2014) used the semistructured Child Attachment Interview (CAI; Shmueli-Goetz, Target, Fonagy, & Datta, 2008) in a sample of 551 twin pairs age 15 years. The CAI is modeled after the Adult Attachment Interview (see Hesse, Chapter 26, this volume), assessing attachment security in terms of coherence of discourse when discussing childhood attachment experiences. Surprisingly, the authors found correlations between attachment security in MZ twins that were about twice as strong as correlations in DZ twins, and they concluded that attachment in this sample of young adolescents was about 40% heritable, whereas the influence of the shared environment was negligible (Fearon et al., 2014).

Of course, this finding might point at a genuine developmental phenomenon of increasing genetic influence with growing age. It should be noted, however, that adolescence is a somewhat difficult age period for the measurement of attachment because many adolescents are in the middle of a potentially confusing struggle for independence from their parents. This might be the reason that in this and other studies, dismissing attachments seem to be temporarily overrepresented (Bakermans-Kranenburg & Van IJzendoorn, 2009). Fearon and colleagues (2014) found insecure-preoccupied attachments in only 5% of the cases, and unresolved attachments in only 3% of their subjects, so any conclusion about heritability of adolescent attachment is limited to the specific security-dismissing dimension (see also Van IJzendoorn & Bakermans-Kranenburg, 2014). Clearly, more longitudinal studies going beyond adolescence are needed to test whether heritability of attachment indeed increases with age, and well into adulthood. One relevant study included adopted sibling pairs from the Iowa Adoption Studies who, on average, were 39 years old when the AAI was administered (Caspers, Yucuis, Troutman, Arndt, & Langbehn, 2007). Concordance rates showed substantial similarity of attachment representations between the siblings, although they were genetically unrelated; they only grew up in the same family. These findings do not support the idea of increased heritability with age, but they do point to an important role for shared environmental influences. Thus, the findings reported by Fearon and colleagues may be specific to adolescence.

Molecular Genetics of Attachment

Behavioral genetics studies of the kinds discussed so far involve inferring heritability from phenotypic (dis-)similarities between MZ and DZ twins, but participants' genetic makeup itself is not assessed. This indirect method of inferring heritability has several drawbacks, including dependence on the specific population distribution of relevant environmental and genetic features. In an environment with sufficient food for everyone, physical growth would appear to be much more heritable than in an environment with large variation in food supply. In contrast, in molecular genetics studies, structural DNA patterns are assessed directly, often with great precision, and variation in the environment does not play a critical role in estimating heritability except when the environment influences the expression of genes. (We discuss this issue—the study of epigenetics—later in this chapter.)

The first molecular genetics study of attachment, published by Gervai's Hungarian team (Lakatos et al., 2000), was conducted on a rather small, low-risk Hungarian sample ($N = 95$ infants) and is an example of the candidate gene approach (i.e., focusing on a particular gene of interest). It revealed a strong association between the dopamine receptor D4 gene (*DRD4*) and infant disorganized attachment. Child carriers of the *DRD4* 7-repeat allele appeared to run a fourfold elevated risk of disorganized attachment. The T-variant of the -521 (C/T) single-nucleotide polymorphism (SNP) in the regulatory region of the *DRD4* gene increased the risk for disorganization even further (Lakatos et al., 2002). *DRD4* had already acquired a bad reputation as a "risk" genotype for impulsivity, addiction, and attentional problems, and the neurotransmitter dopamine had been found to be involved in motivational and reward mechanisms (Robbins & Everitt, 1999). But did this *DRD4* genotype also deserve a bad reputation in relation to attachment?

Although the link between *DRD4* and attentional and motivational issues seemed to make the association with disorganization somewhat plausible, the findings were surprising against the background of the behavior genetics study of disorganization by the Leiden team (Bokhorst et al., 2003), which did not find any evidence for genetic influences on disorganized attachment. DNA was therefore collected in the Leiden twin sample to replicate the Hungarian findings, but without success (Bakermans-Kranenburg & Van IJzendoorn,

2004). Several other replication attempts followed, but the picture did not change: Across a series of studies (total $N = 542$) the combined effect size of the association between *DRD4* and disorganization was close to zero (Bakermans-Kranenburg & Van IJzendoorn, 2007). Compared to the combined effect size across studies of the association between parental frightening or anomalous behavior and disorganized attachment (Cohen's $d = 0.72$, total $N = 644$; Madigan et al., 2006), this was a disappointing outcome for advocates of genetic influences on attachment.

More molecular genetics studies involving candidate genes have been conducted in recent years. Some of the studies indicated a potential role for candidate genes. For example, Spangler, Johann, Ronai, and Zimmermann (2009) reported an association between attachment disorganization and the short variant of the serotonin transporter-linked polymorphic region (*5-HTTLPR*), qualified by an interaction with maternal responsiveness (see below). This genotype, one of the usual suspects in the study of psychiatric genetics, is considered to be a "risk" factor for depression and anxiety. Fearon and colleagues (Frigerio et al., 2009) studied the associations between several gene polymorphisms implicated in the serotonin and dopamine systems (*5-HTTLPR*, *COMT*, *GABRA6*, *DRD4*, *DRD4/521*) and attachment security as well as attachment disorganization in an Italian sample of 100 infants, but no association survived stringent statistical tests.

To date, the largest candidate gene study on attachment is the combination of the Generation R study, a large cohort study in Rotterdam, the Netherlands, and the National Institute of Child Health and Human Development (NICHD) Study of Early Child Care and Youth Development (SECCYD), which includes more than 1,000 infants in all (Luijk, Roisman, et al., 2011). It was the first study to replicate key findings across two relatively large samples. Associations of candidate genes involved in the dopamine, serotonin, and oxytocin systems (*DRD4*, *DRD2*, *COMT*, *5-HTTLPR*, *OXTR*) with attachment security and disorganization were examined. The only replicable significant finding was the association between *COMT* and attachment disorganization. Children with the Val/Met genotype had higher disorganization scores (combined effect size $d = 0.22$). This codominant risk model for *COMT* Val158Met was consistent across both samples but it is difficult to explain. Perhaps the broader range of plasticity in heterozygotes (the Val/Met carriers) increased sus-

ceptibility to environmental influences or, in case of a frightening environment, to dysregulation of emotional arousal (Luijk, Roisman, et al., 2011).

With increasing age, the heritability of traits might become more pronounced, as discussed earlier. In a German sample of 167 adults, the associations of adult attachment representations (using the AAI) and two candidate genes, *5-HTTLPR* and *DRD4*, were examined (Reiner & Spangler, 2010). Carriers of *DRD4* 7-repeat alleles were significantly more often securely attached and received higher coherence scores compared to carriers of the other alleles. The authors suggested that this main effect was qualified by an interaction with recollections of a loving caregiver, but because this "loving" scale was part of the AAI coding system for attachment representations, the variable cannot be considered an independent assessment of past childrearing environments. *5-HTTLPR* was not significantly associated with adult attachment, with or without taking reported experiences into account. The absence of molecular genetic evidence for heritability diverges from the Fearon and colleagues (2014) behavior genetics finding, but converges with the Caspers and colleagues (2007) results in adoptive families.

Failure to find replicable main effects of candidate genes is not unique for attachment security or disorganization. Publication bias may account for the lack of replicable genetic findings because initially positive results may be selectively published, whereas numerous negative results may remain unpublished. This is the so-called "winner's curse" (for an example involving the oxytocin receptor gene, see Bakermans-Kranenburg & Van IJzendoorn, 2013). Candidate genes are the proverbial needle in a haystack and cannot be solely or largely responsible for complex behaviors or traits such as attachment security. Candidate genes might serve as important and valid indices for broader underlying genetic pathways that modulate the production, transport, and reuptake of neurotransmitters involved in attachment-related behaviors and emotions. When isolated from the environment, however, it seems overly optimistic to expect them to explain more than a small amount of variance in the attachment phenotype.

Genomewide Association Studies and Genomewide Complex Trait Analysis

At least two ways to try to solve the complex puzzle of genetic determination of variance in attach-

ment security and disorganization remain to be explored. The first is to expand the number of genes involved in the hunt for attachment genes using the method of genome-wide association studies (GWAS; Plomin, 2013) and related approaches such as genetic pathway analysis (Plomin & Simpson, 2013) and genome-wide complex trait analysis (GCTA; Benjamin et al., 2012). The second approach is broadening the focus to include the interaction between genes and environment ($G \times E$) instead of limiting the search to main effects. Here we briefly discuss the GWAS, genetic pathways, and GCTA approaches; in the next section we discuss $G \times E$ studies of attachment.

GWAS differ from the candidate gene approach in associating a large part of the genome with a complex phenotype, such as attachment, in a hypothesis-free manner. Instead of including the usual genetic suspects with known biological functions, the GWAS approach covers the 1 million or so independent SNPs that are markers of the most common genotypic variation in humans. Using linkage disequilibrium to prune the number of markers, 1 million SNPs may efficiently represent the 16 million SNPs of the human genome. In the GWAS approach, associations of these SNPs with the targeted phenotype are tested with, of course, massive correction for multiple testing by an increase of the significance threshold to $p < .00000005$ to avoid chance results.

Although the GWAS approach was successfully used in the detection of the genetic basis of some diseases (e.g., macular degeneration) and led to new treatments, application to behavioral phenotypes and complex psychological traits has so far been disappointing. Plomin (2013) summarized GWAS results on reading, mathematics, and general cognitive ability, and showed that less than 0.5% of the variance could be explained by a small number of GWAS hits. The amazingly large gap between GWAS-based estimates of heritability and heritability found in twin studies is called the *missing heritability problem* (Manolio et al., 2009; Plomin & Simpson, 2013; Van IJzendoorn et al., 2011). The gap made Plomin (2013) sigh: "Gene hunters are still recovering from the shock of finding that the largest associations account for so little variance in the population" (p. 109).

In an exploratory effort to apply GWAS to attachment security and disorganization in the Generation R sample ($N = 641$), no significant hit was found, and the suggestive hits ($p < .00005$) did not replicate in an independent sample of similar size. Of course, the sample size was way too small

for the small effects to be expected on the basis of previous GWAS (Plomin & Simpson, 2013). But it is difficult to imagine how samples 100 times larger might ever be assembled given the time-consuming "gold-standard" attachment assessments at our disposal, let alone the usefulness of finding genes accounting for less than 1% of the variance in attachment.

Alternative approaches that may require fewer subjects are genetic pathways and GCTA, which might be more powerful in discovering the genetic basis of complex traits (Plomin, DeFries, Knopik, & Neiderhiser, 2013). Genetic pathways are functionally related genotypes potentially consisting of hundreds of SNPs that are associated with the phenotype as one block (Ramanan, Shen, Moore, & Saykin, 2012; Wang, Li, & Hakonarson, 2010), thus requiring less correction for multiple testing. GCTA pairs every individual in a sample with every other genetically unrelated individual and correlates any similarity in genotype with the phenotypic similarity within each pair (Yang, Lee, Goddard, & Visscher, 2011). When genotypic similarities go together with stronger similarity in a trait, the genetic component of the trait can be estimated (see Pappa, Fedko, et al., 2015, for an example). Both approaches have been used in Generation R (Jaddoe et al., 2012), the largest ethnically homogeneous (Caucasian) attachment sample to date, but these efforts have again failed to yield significant effects (Pappa, Szekely, et al., 2015).

$G \times E$ Effects

Overall, main-effects studies of the genetics of attachment have not yielded impressive effects. Given Bronfenbrenner's (1979) idea that *main effects are in the interactions* (see also Rutter, 2006), it seemed sensible to examine gene-by-environment ($G \times E$) effects on attachment. Certain genotypes may act as a "risk factor" that makes it more likely that insensitive or frightening and anomalous parenting will result in insecure or disorganized infant attachment. Alternatively, genes may act as "susceptibility factors" that increase the effects of both sensitive and insensitive parenting on children's positive or negative outcomes (Bakermans-Kranenburg, & Van IJzendoorn, 2010; Belsky, Bakermans-Kranenburg, & Van IJzendoorn, 2007; Ellis, Boyce, Belsky, Bakermans-Kranenburg, & Van IJzendoorn, 2011).

Although some have argued that the search for $G \times E$ effects is warranted only when genetic

main effects have been established (Munafò, Durrant, Lewis, & Flint, 2009; Risch et al., 2009), this point of view is not correct, as is evident from the following example: Imagine that for a specific gene, environmental effects are absent for one gene variant but present for the other gene variant. Imagine further that for this second gene variant, good outcomes are observed under favorable conditions and bad outcomes under unfavorable conditions. This pattern of effects, *for better and for worse*, in a specific subgroup, as proposed by the differential susceptibility model, has been documented in many studies (for reviews and meta-analytic evidence see Bakermans-Kranenburg, & Van IJzendoorn, 2011; Belsky & Pluess, 2009; Van IJzendoorn, Belsky, & Bakermans-Kranenburg, 2012). In that case $G \times E$ effects are found in the absence of a genetic main effect (the two directions *within* one genotype cancel each other out; Bakermans-Kranenburg & Van IJzendoorn, 2015).

Two types of $G \times E$ studies of attachment can be distinguished, depending on the role of attachment quality as an environmental factor or as an outcome. In both types of studies, the genetic factor is the moderator. In the first scenario, attachment security is used as an index of a supportive environment, for example, with emotion regulation or cortisol reactivity to a stressor as outcomes. The pertinent question in these studies is whether genotypes moderate the association between attachment quality (predictor) and these outcomes. In the second scenario, the moderating role of genotype in the association between caregiving quality (predictor) and attachment quality (outcome) is examined. We first review studies with attachment quality as the observed environmental predictor, then studies with attachment as outcome.

Attachment as Environment

Attachment security was used as an indirect index of a supportive caregiving environment in a $G \times E$ study of child self-regulation (Kochanska, Philibert, & Barry, 2009). Infant–mother attachment was assessed at 15 months, and children’s ability to self-regulate was assessed at 25, 38, and 52 months. Among children who carried a short *5-HTTLPR* allele, those who were insecurely attached developed poor regulatory capacities, whereas those who were securely attached developed as good regulatory capacities as children without the short allele. For children with two long alleles, attachment security did not predict self-regulation.

In a study of 7-year-old Dutch children, emotion regulation was observed during a stressful public speaking task, the Trier Social Stress Test for Children (TSST-C). *5-HTTLPR* moderated the association between attachment security as assessed with the Attachment Story Completion Task (Bretherton, Ridgeway, & Cassidy, 1990; Cassidy, 1988) and electrodermal reactivity during the TSST-C. There was a fan-shaped interaction pattern: Children with a secure attachment representation, as well as two long (LL) alleles, were less stressed during the TSST-C than all other children (Gilissen, Bakermans-Kranenburg, Van IJzendoorn, & Linting, 2008). Children who had the “double protection” of both the LL genotype and secure attachment were the only ones who experienced low levels of stress, perhaps indicating how much support is needed for being unconcerned about giving a public speech.

In a study with 4- to 6-year-old Norwegian children, the *COMT* gene polymorphism moderated the effect of disorganized attachment (assessed at age 4 with the doll play story completion task) on social development. Children homozygous for the *COMT**val* allele who were highly disorganized at age 4 became more aggressive over time and showed reduced social competence compared to highly disorganized children with one or two *met* alleles (Hygen, Guzey, Belsky, Berg-Nielsen, & Wichstrom, 2014).

Finally, Luijk and colleagues (2010) related attachment security to cortisol reactivity levels during the Strange Situation procedure and tested the moderating role of HPA-axis-related SNPs (*Bcl1*, *rs41423247*; *TthIII1*, *rs10052957*; *GR-9b*, *rs6198*; *N363S*, *rs6195*; *ER22/23EK*, *rs6189*, and *6190*; and *FKBP5* *rs1360780*) in more than 300 14-month-old infants. *FKBP5* *rs1360780* was related to cortisol reactivity and a double-risk for heightened cortisol reactivity was found in infants with one or two T-alleles of the *FKBP5* SNP and an insecure-resistant attachment relationship with their mother.

Attachment as Outcome

Based on data from the Minnesota Longitudinal Study, Raby and colleagues (2012) found no moderating effect of the *5-HTTLPR* genotype on the association between maternal sensitivity and attachment security. This study thus failed to replicate the $G \times E$ findings of Barry, Kochanska, and Philibert (2008), who observed mothers’ sensitivity at

7 months during lengthy naturalistic interactions combining Ainsworth, Blehar, Waters, and Wall's (1978) scales with time-sampled, event-triggered ratings of mothers' responses to each child signal. Infant attachment was assessed at 15 months. Infants with the short *5-HTTLPR* allele and insensitive mothers were more likely to be insecure than were infants with the same genotype whose mothers were sensitive, but infants with the LL genotype scored high on attachment security independent of the variation in maternal responsiveness.

Surprisingly, similar results emerged in conditions of severe deprivation. It is no wonder that institutional care has been shown to lead to insecure and disorganized attachment (Van IJzendoorn et al., 2011), since institutional care has so many characteristics of structural neglect (minimal physical resources, unfavorable staffing patterns, and socioemotionally inadequate caregiver-child interactions) that it fails to respond to children's basic need for stable and positive personal relationships, as well as adequate care and stimulation. In these conditions, environmental effects may be expected to overrule any genetic or $G \times E$ effect. However, some children appear to be surprisingly resilient to the adverse environment, and in a small hypothesis-generating study, the potentially moderating role of *5-HTTLPR* was explored (Bakermans-Kranenburg, Dobrova-Krol, & Van IJzendoorn, 2011). The study involved Ukrainian preschoolers reared in institutional settings or with their biological families. *5-HTTLPR* moderated the association between caregiving environment and attachment disorganization. Children with a short allele showed more attachment disorganization and less attachment security when they grew up in an institution than when they lived in a family, but when children had the LL genotype, they were not more disorganized when they grew up in an institution than children growing up in their biological families.

This seems to suggest that the protective role of the *5-HTTLPR* LL genotype is not limited to moderately adverse environments (as shown by, e.g., Barry et al., 2008; Gilissen et al., 2008) but also exists in extremely untoward circumstances. Notably, the findings are in line with the outcomes of adoptees in the English and Romanian Adoptee Study (Kumsta et al., 2010), in which adoptees with the LL genotype showed the lowest levels of emotional problems during adolescence even when they experienced severe early institutional deprivation, and with results of the Bucharest Early Intervention Project, in which children with

the LL genotype showed low levels of indiscriminate social behavior irrespective of their living arrangement (institutionalized care or high-quality foster care; Drury et al., 2012).

For disorganized attachment, Spangler and colleagues (2009) found an interaction between maternal responsiveness and child *5-HTTLPR*: Children with the short allele were more often disorganized when maternal responsiveness was low. Maternal responsiveness was observed during a 30-minute session, in which the mother was asked to complete a questionnaire but to respond to the infant as she usually would. Responsiveness was indexed with an aggregated score that combined the number and promptness of maternal responses to infant signals, irrespective of the (emotional) quality of the response. The proportion of disorganized infants increased with the number of short alleles, but only in the low responsiveness group (Spangler et al., 2009).

Van IJzendoorn and Bakermans-Kranenburg (2006) examined whether infants with the *DRD4* 7-repeat allele were more susceptible to parental unresolved loss and anomalous parenting behavior than infants without this allele. This turned out to be the case: Maternal unresolved loss or trauma was associated with infant disorganization in children with the *DRD4* 7-repeat allele, whereas children without this allele did not have higher scores for disorganized attachment when their mothers were unresolved. However, children with the *DRD4* 7-repeat allele who had mothers without unresolved loss showed the *lowest* levels of attachment disorganization. These findings support the notion that the *DRD4* 7-repeat allele constitutes not a genetic risk but a genetic marker of differential susceptibility (Ellis et al., 2011). The differential susceptibility model is described more extensively in the section on intervention (see below).

Gervai and colleagues (2007), combining a low-risk Hungarian and a high-risk U.S. sample, found that maternal affective communication was related to disorganized attachment in children *without* the *DRD4* 7-repeat allele and not in carriers of the *DRD4* 7-repeat allele. In light of the meta-analytic results (Bakermans-Kranenburg & Van IJzendoorn, 2011, 2015), the latter outcome is not convergent with the general finding of higher susceptibility of carriers of the 7-repeat allele, and this may have to do with the ethnically heterogeneous U.S. sample in the Gervai and colleagues (2007) study.

The moderating role of *DRD4* was also found for the adult equivalent of disorganized attach-

ment, unresolved loss or trauma, as assessed with the AAI. Participants were adopted adults from the Iowa Adoption Studies, interviewed with the AAI when they were on average 39 years old (Bakermans-Kranenburg, Van IJzendoorn, Caspers, & Philibert, 2011). Participants with the *DRD4* 7-repeat allele with independently reported parental problems in their adoptive families had the highest scores for unresolved loss or trauma, whereas participants with the *DRD4* 7-repeat allele who did not experience parental problems had the lowest ratings. Among participants without the *DRD4* 7-repeat allele, parental problems during childhood did not make a difference for unresolved loss or trauma, again pointing to heightened susceptibility to environmental influences for carriers of the *DRD4* 7-repeat allele.

In the Generation R study, two genes involved in the regulation of stress responses were examined: those for the glucocorticoid receptor (GR) and mineralocorticoid receptor (MR) (Luijk, Tharner, et al., 2011). In more than 500 infant–parent dyads, maternal sensitivity was observed during a psychophysiological assessment using Ainsworth’s rating scales for sensitivity (Ainsworth et al., 1978). Moreover, maternal extreme insensitivity was observed, including withdrawal and neglect, and intrusive, negative, aggressive, or otherwise harsh parental behaviors (Out, Bakermans-Kranenburg, & Van IJzendoorn, 2009). There were no main effects of MR or GR on infant attachment. However, infants with the minor MR allele (G) were more securely attached if their mothers were more sensitive, and less securely attached if their mothers showed more extremely insensitive behaviors, whereas these associations were not present in children without the G allele. No main or interaction effects were found for attachment disorganization.

Based on the combination of two large cohorts, the Generation R study and the NICHD SECCYD, the interactions between candidate genes involved in the dopamine, serotonin, and oxytocin systems (*DRD4*, *DRD2*, *COMT*, *5-HTTLPR*, *OXTR*) and maternal sensitivity were examined in more than 1,000 Caucasian infants in total. $G \times E$ interaction effects were not replicable across the two samples (Luijk, Roisman, et al., 2011).

Even though the combined sample size in this latter study was substantial, and indeed the largest available to examine the interplay between genetics and parenting, predicting attachment with state-of-the-art observational measures, the power to detect $G \times E$ effects may have been in-

sufficient. The power of correlational $G \times E$ studies is inherently limited by several factors (see Bakermans-Kranenburg & Van IJzendoorn, 2015; Van IJzendoorn & Bakermans-Kranenburg, 2015): The distributions of genotypes and parenting quality tend to be skewed, and genetic and environmental factors may not be independent because through passive or evocative gene–environment correlation (rGE), parenting may be related to either the parent’s or the child’s genotype. Unmeasured genotypes that elicit specific parental behaviors may play a role and, last but not least, power is reduced by measurement errors. Selective recruitment and attrition, processes that are unavoidable in cohort studies, result in low numbers of participants in the eccentric parts of the distribution, with consequences for the distribution of the interaction term. Duncan and Keller (2011) argued that the primary reason for reduced power to detect interactions in nonexperimental studies is that the variance of the product term tends to be low. Thus, replication and meta-analysis to document the replicability of any finding is essential (Cumming, 2014). At the same time, experimental designs constitute a powerful alternative to examine $G \times E$ effects (see the section “Interventions from a $G \times E$ Perspective”).

Epigenetics

In the past, behavioral and molecular genetics researchers assumed that the genetic makeup of every individual is invariable, originating from conception and remaining basically the same across the lifespan, except in rare cases of mutations through radiation or other toxic influences. This assumption is valid as far as it pertains to the structural properties of the double helix of DNA. But even MZ twins with identical DNA structures may grow apart in gene expression. They may develop radically different disease patterns because of changes in the epigenome that influences and regulates the expression of genes. Fraga and colleagues (2005) found, for example, that a 3-year-old MZ twin pair had about 1,000 genes with differential gene expression, whereas a 50-year-old MZ twin pair had more than 5,000 differently expressed genes. Differences in the epigenome increase with age and with nonshared environmental influences, implying that they are larger when twins have spent more time in separate environments.

One of the most widely studied epigenetic mechanisms is *methylation*, which is, simply put, the blocking of gene expression through the link-

ing of a methyl (CH_3) molecule to one of the bases, cytosine, at a CpG site (cytosine–phosphate–guanine) located in a gene promoter region. Methylation might be loosely compared to a cork on a bottle of champagne, down-regulating the escape of bubbles (the messenger RNA [mRNA]) and thus modulating the level of protein and enzyme production encoded for by the specific gene (Van IJzendoorn, Bakermans-Kranenburg, & Ebstein, 2011). Epigenetic studies of rodents (e.g., Meaney, 2010; Szyf, Weaver, Champagne, Diorio, & Meaney, 2005) have made clear that the caregiving environment (e.g., the amount of licking and grooming and arched-back nursing that parents provide) may radically alter methylation patterns and, consequently, gene expression in the pups, and not just in the pups exposed to sensitive parenting (or deprived thereof) but even in these pups' offspring (Meaney, 2010). In particular, altered methylation of the GR gene induces long-term changes in response to stress, affecting the next generation (Weaver et al., 2004; Zhang & Meaney, 2010).

One of the first epigenetic studies on human development that is relevant for attachment theory was conducted by Meaney's team (McGowan et al., 2009). They examined the brains of deceased young males stored in the Quebec Suicide Brain Bank, matching suicide victims with and without a history of abuse, and comparing these two groups with age- and gender-matched victims of fatal accidents. They found that through methylation, GR gene expression in the hippocampus of the suicide victims was decreased, but only when they had experienced child abuse. Hippocampal GRs play a crucial role in down-regulating the HPA axis, which is responsible for the level of the stress hormone cortisol. In other studies, similar epigenetic alterations have been found as a result of child maltreatment (Beach et al., 2010; Perroud et al., 2013) or structural neglect in orphanages (Nau-mova et al., 2012), and in adolescent children whose mothers were exposed to intimate partner violence during pregnancy (Radtko et al., 2011).

The first epigenetic study of adult attachment was conducted with participants in the Iowa Adoption Studies (Van IJzendoorn et al., 2010). The AAI was administered, and participants ($N = 143$) reported on any loss or other potentially traumatic event during their childhood years in the adoptive family. The AAI scale for Unresolved Loss or Trauma was not associated with *5-HTTLPR*. When the level of methylation was taken into account, genotype predicted Unresolved Loss or Trauma. Carriers of the long variant of *5-HTTLPR* showed

more Unresolved Loss or Trauma but only when more methylation was observed. Thus, the potentially protective effect of the long variant seemed to be mitigated by the effects of methylation suppressing the activity of this variant. The short variant of *5-HTTLPR* appeared to be associated with more Unresolved Loss or Trauma but only with low levels of methylation. Unexpectedly, high levels of methylation of the short variant led to lower Unresolved Loss or Trauma, a finding that still needs an explanation (Van IJzendoorn et al., 2010). What this study shows, however, is that genetic effects on attachment might be hidden behind interactions with epigenetic changes, which in turn might be critically dependent on environmental input, such as abusive or neglectful parenting. This first study on methylation and attachment is relatively small and should be considered exploratory.

Jones-Mason (2011) administered the AAI to 101 participants of various ethnic backgrounds (half of them Asian American, one-third European American). DNA was genotyped for *5-HTTLPR* as well as GR, and methylation analyses were conducted in the upstream regions of these genotypes. GR methylation was not associated with any of the variables. The author suggested that in the Asian American group, more methylation in the *5-HTTLPR* short allele carriers was associated with less Unresolved Loss or Trauma, and that methylation seemed to have protected them from the potentially traumatizing effects of low socioeconomic status (SES). Similarly, in the Iowa Adoption Study, high methylation in carriers of the short alleles might have blunted their susceptibility to the environment, resulting in low Unresolved Loss or Trauma scores. Because of ethnic heterogeneity and the lack of power for multivariate analyses, the Jones-Mason (2011) study can only be used as a takeoff point to generate hypotheses to be tested in larger and more homogeneous samples.

At present, the study of the epigenetics of attachment is in an embryonic stage and much more work needs to be done to find out whether epigenetics mediates the influence of insensitive and abusive parenting on the development of attachment relationships and representations.

Parenting

The study of intergenerational transmission of attachment involves the assessment of adult attach-

ment representations in the parent and relating these representations to infant–parent attachment quality (see Hesse, Chapter 26, this volume; Van IJzendoorn, 1995). For the study of intergenerational transmission of *parenting*, it would be ideal if we could observe parents interacting with their offspring, then come back two or three decades later and observe the toddlers of the first wave now interacting with their own offspring. This is exactly what has been done by Kovan, Chung, and Sroufe (2009). They videotaped interactions of parents and their 2-year-old offspring, and did so again several decades later, when the offspring had children of their own who were approximately 2 years of age. Comparing the interactions across the two generations, they found substantial similarity in parenting behaviors ($r = .43$), even when various confounds were taken into account.

Can genetic factors play a role in the explanation of intergenerational transmission of parenting? Unfortunately, traditional studies of parents and their biological children cannot disentangle the effects of shared genes from those of the environment. As with attachment, genetically informative twin or adoption studies are needed to examine the etiology of parenting.

Behavioral Genetics of Parenting

Two types of behavioral genetic studies of parenting can be found. The first is that of *parent-based twin designs*. Such studies involve adult twin siblings parenting their offspring, and heritability estimates are computed based on a comparison of the similarity between MZ twins' and DZ twins' parenting. In terms of estimations of variance explained by genetic factors, shared environmental factors, and nonshared environment, parent-based twin designs are directly comparable to twin studies on infant attachment. Such studies, however, are scarce. One of the obvious reasons is that twin siblings—notwithstanding the anecdotal and proverbial similarity of their life courses—usually do not have children at the same point in time. The comparability of parenting behaviors in case of divergent timing, numbers, gender, and ages of children is thus hampered.

The second type of study involves parents of twins and is called a *child-based twin design*. These studies compare the similarity between parents of MZ twins and DZ twins. The extent to which parenting behavior toward MZ twin siblings is more similar than parenting behavior toward DZ twin

siblings indicates genetic influence on parenting because genetically influenced characteristics of the children (e.g., temperament) apparently elicit these parenting behaviors. Child-based genetic effects on parenting are thus indicative of evocative rGE: The child's genetic makeup evokes certain parenting behaviors, and these are child-driven genetic influences on parenting.

Shared environmental influences on parenting are due to parents' own characteristics (personality or parenting attitudes), or due to similar behaviors of siblings that result from siblings' shared experiences, regardless of their degree of genetic relatedness. These shared environmental influences include factors such as family SES and cultural environment because they increase similarity in the parenting that children receive. Somewhat counterintuitively, this implies that in child-based twin studies, effects of parents' genes are included in estimates of the shared environment. Last, parents may treat siblings differently for reasons unrelated to the children's genetically influenced characteristics, such as the specific experiences they have with each of their children, with nonshared environmental effects as a result. As always, measurement errors are included in the nonshared environmental effect estimates. It is important to note that child-based twin designs cannot be informative regarding the impact of the parents' own genes or early experiences on their parenting. Only parent-based twin designs can be used to estimate these genetic and (shared and nonshared) environmental effects.

Parent-Based Twin Designs

A recent meta-analysis of behavioral genetics studies of parenting identified a modest number of six unique parent-based studies (Klahr & Burt, 2014). Most studies were based on questionnaires; in only one study (Neiderhiser et al., 2004) were these combined with observations. Heritability estimates in individual studies varied greatly, ranging from 0% for maternal overprotection to 48% for parental authoritarianism. Distinguishing three dimensions of parenting (i.e., warmth, control, and negativity), combined genetic estimates were moderate for parental warmth and negativity (28–37%), but zero for parental control. Nonshared environmental influences accounted for the largest proportion of variance (63–90%). Heritability estimates were similar for father and mothers. The substantial role for nonshared environmental

influences points to parents' unique experiences and the specific conditions in which they find themselves, including the relationship with their spouses and characteristics of their children.

Child-Based Twin Designs

The same meta-analysis identified 27 studies with child-based twin designs, presenting combined estimates for genetic, shared environmental, and nonshared environmental influences on parental warmth, control, and negativity (Klahr & Burt, 2014). Estimates were largely similar across these three parenting dimensions, with genetic influences ranging from 23 to 40%, shared environmental influences, from 27 to 39%, and nonshared environmental influences, from 32 to 44%. Remember that the genetic influences represent child evocative rGE effects on parenting. Evocative genetic influences on parenting were larger for negativity than for warmth and control, whereas shared environmental influences were largest for warmth, and nonshared environmental influences were largest for control.

Shared environmental influences in child-based twin studies may, among other things, reflect genetic influences in parent-based studies; the results for parental warmth may point in that direction, since moderate genetic estimates for warmth were found in parent-based studies. In child-based twin studies maternal control and negativity were explained to a greater extent by genetic influences than paternal control and negativity. Fathering was more influenced by shared environmental factors than was mothering. Unfortunately, and similar to parent-based twin studies, most child-based twin studies used questionnaire measures of parenting. Notably, observer-rated parenting yielded lower estimates of heritability than child-report or parent-report; for observed parenting, genetic influences on warmth and negativity were not significant.

Evocative Gene–Environment Correlation

In the meta-analysis of parent-based and child-based twin studies, genetic influences on negativity were found in both types of studies. This may indicate a process in which, in addition to potential passive rGE (parents give their genes, as well as the environment, to their children), children inherit the genetic tendency toward negative behavior from their parents, then through evocative

rGE elicit negative parental behavior in their parents (Klahr & Burt, 2014).

Indeed, in a recent child-based twin study in the United Kingdom, Oliver, Trzaskowski, and Plomin (2014) found that the negative side of parenting showed significantly more genetic influence than the positive side. Again, a weakness of the design was that self-reports were used, and that the same parent completed the questionnaire twice, once for each twin sibling, creating non-independent scores with similar response biases. Importantly, a different U.K. child-based twin study (Jaffee et al., 2004) showed a genetic effect for harsh parenting but not for physical maltreatment; in other words, the child's behavior may evoke harsh discipline, but risk factors for physical maltreatment are more likely to reside in characteristics of the parent and the environment.

The disadvantages of self-reports were overcome in a multivariate child-based twin study of observed parental sensitivity as related to attachment, a study that was somehow left out of Klahr and Burt's (2014) meta-analyses. Fearon and colleagues (2006) examined the extent to which genetic and environmental aspects of maternal sensitivity accounted for the pattern of similarity and dissimilarity of twins' attachments to their mothers (see the section "Behavioral Genetics of Attachment"). Bivariate behavioral genetics modeling is based on the pattern of within-twin and cross-twin correlations to estimate genetic, shared environmental, and nonshared environmental correlations between two measures (Plomin, DeFries, McClearn, & McGuffin, 2001). No genetic factor (residing in the infants) explained differences in maternal sensitivity. The variance in maternal sensitivity was explained by shared environmental (66%) and nonshared environmental (34%) factors. Thus, in line with attachment theory, shared environmental effects were found to underlie the association between maternal sensitivity and attachment security. The shared environmental component of maternal sensitivity accounted for approximately one-third of the twins' similarity in attachment security. Note that this shared environmental component may reflect genetic influences on the level of the parent, perhaps in line with the findings for parental warmth. Exploring the nonshared environmental effect, it appeared that sensitivity toward Twin 2 (that was not shown to Twin 1) affected Twin 1's attachment security *positively*. The attachment security of one child thus depends on the relationship the parent has with the other child, and not just on his or

her parenting behavior. These findings underscore the importance of effects of relationships within a family system (Hinde & Stevenson-Hinde, 1988) and point to the need for studies including more than one child per family.

Molecular Genetics of Parenting

The gene systems that have been examined in relation to parenting behavior converge with the gene systems that have been central to studies of attachment. These are genes related to the neurotransmitters dopamine and serotonin, and to the neuropeptide oxytocin. Here we first review studies on potential main effects of these genes on human parenting, then review $G \times E$ studies. Our focus is on human parenting. A review that also includes nonhuman mammals can be found elsewhere (Mileva-Seitz, Bakermans-Kranenburg, & Van IJzendoorn, in press).

Dopamine

What makes dopamine-related gene polymorphisms candidate genes for associations with parenting? Part of the answer lies in the demonstrated implication of dopamine for maternal behavior in rats (Miller & Lonstein, 2005; Stolzenberg et al., 2007). Individual differences in their licking and grooming behavior have been found to be related to variations in dopamine levels in the nucleus accumbens (Champagne et al., 2004). Another part of the answer can be found in studies of humans. Dopamine is related to motivational and reward mechanisms (Robbins & Everitt, 1999), and infants are expected to be rewarding to parents, motivating parents to respond to them and initiate and maintain interaction with them. Variation in dopaminergic system genes may therefore be related to variation in parenting.

In a sample of more than 200 mother-child dyads, Lee and colleagues (2010) tested the association between the dopamine transporter (*DAT1*) gene and three dimensions of observed maternal parenting behavior (positive parenting, negative parenting, and total maternal commands). The sample consisted of a group of children with attention-deficit/hyperactivity disorder (ADHD) and demographically matched comparison children without ADHD. The observed interaction included free play, as well as tasks that were frustrating for the child (e.g., cleanup, sit and count geometric shapes, play while the mother reads a

magazine and takes a telephone call). Maternal *DAT1* was significantly associated with negative parenting and commands, also when child disruptive behavior and various other confounds were taken into account. Mothers with the 9/9 genotype showed the least negative parenting: Mothers with the 9/9 and 10/10 genotypes showed less negative parenting than mothers with the 9/10 genotype, and mothers with the 9/9 genotype used fewer commands than mothers with the 9/10 and 10/10 genotypes. *DAT1* genotype was not related to positive parenting.

In the Maternal Adversity, Vulnerability, and Neurodevelopment (MAVAN) study, Mileva-Seitz and colleagues (2012) found an association between genetic variation in several SNPs in the *DRD1* and *DRD2* genes, and maternal orienting away and infant-directed vocalizing during 20 minutes of free play at 6 months. In three out of five *DRD1* SNPs (*rs 265981*, *rs4532*, and *rs686*) the heterozygote group oriented away from the infant less frequently than the two homozygous genotypes, which may be associated with dopamine-related distractibility. Two of the three *DRD2* SNPs were associated with infant-directed vocalizing: *rs6277* and *rs1799732*. Although the observations were also rated with Ainsworth's sensitivity rating scales (Ainsworth et al., 1978), the associations with *DRD1* and *DRD2* polymorphisms were not found with these more global sensitivity ratings, but only with the frequencies of the discrete maternal behaviors. The absence of an association with global ratings for maternal sensitivity replicated findings of Mills-Koonce and colleagues (2007), who in a mixed sample of African American and European American families found no relation between *DRD2* and maternal sensitivity or negativity during free play. The authors suggest that discrete behavioral tendencies may show stronger molecular genetic associations than complex phenotypes such as overall sensitivity (Mileva-Seitz et al., 2012).

Serotonin

The serotonin transporter gene *5-HTTLPR* has been studied extensively in relation to depression (e.g., Caspi et al., 2003; Lesch et al., 1996), biased attention for emotional information (Pergamin-Hight, Bakermans-Kranenburg, Van IJzendoorn, & Bar-Haim, 2012), and increased amygdala activation in response to emotional stimuli (Hariri et al., 2002). Usually short and long alleles are distin-

guished, but strictly speaking, taking into account an adjacent upstream polymorphism, three allelic variants exist: S, LG (functionally similar to S), and LA. Short alleles (including LG) are associated with lower transcription of *5-HTT* mRNA, which encodes for a protein involved in serotonin reuptake. Some, but not all, studies on *5-HTTLPR* and parenting take this additional allelic variant into account. Given the increased attention to emotional stimuli found in carriers of the short allele, the expected direction of the association between *5-HTTLPR* and parenting quality is not unequivocal: Carriers of the short allele may be more attentive to children's emotional signals and respond more promptly and sensitively than carriers of the long alleles, but they may also be more easily overwhelmed by negative child signals and more prone to depression, with compromised parenting as a result.

In the previously mentioned MAVAN study, Mileva-Seitz and colleagues (2011) found support for the former hypothesis: At 6 months postpartum, mothers with the short allele were more sensitive during their interactions with their infants, and they less often oriented away from their infants.

Pener-Tessler and colleagues (2013) found that in families with twins, maternal positive parenting was related to *5-HTTLPR* in different ways for mothers of boys and mothers of girls: In mothers of boys, positive parenting significantly decreased with the number of maternal short alleles, whereas in mothers of girls, positive parenting nonsignificantly increased with the number of short alleles. Three-way interactions, however, are notoriously difficult to replicate.

In a Dutch study, maternal sensitivity was observed in a community sample of 159 white, middle-class mothers with their 2-year-old toddlers at risk for externalizing behavior problems. The dyads were asked to solve puzzles that were too difficult for the child, and mothers were instructed to help their child in the way they usually did. Mothers' supportive presence, intrusiveness, and clarity of instruction were rated on 7-point scales drawn from Egeland and colleagues (1990). These observation scales extend Ainsworth and colleagues' (1978) original scales with an age-appropriate concept of sensitivity that includes the developmental domain of coping with cognitive challenges. The short allele was related to lower levels of maternal sensitive responsiveness (Van IJzendoorn, Bakermans-Kranenburg, & Mesman, 2008).

Oxytocin

Given the important role of oxytocin in parturition, breastfeeding, and parenting (for a review, see Galbally, Lewis, Van IJzendoorn, & Permezel, 2011), it is only natural that research on parenting has examined associations between various aspects of maternal behavior and oxytocin-related genes. Moreover, oxytocin receptor levels were found to be related to maternal behavior in various types of mammals (Carter, 2014; Dwyer, 2008; Insel & Shapiro, 1992). With regard to studies of human mothers, a few have focused on single-nucleotide polymorphisms (SNPs) in the *OXT* peptide gene, and somewhat more studies have included SNPs in the *OXTR* receptor gene.

Although the functionality of these polymorphisms has not yet been demonstrated, two SNPs in the third intron of *OXTR* have been suggested as particularly promising candidates to explain differences in oxytocinergic functioning: *rs53576* and *rs2254298* (Meyer-Lindenberg, Domes, Kirsch, & Heinrichs, 2011). For both SNPs, the A alleles are hypothesized to confer risk in comparison to the G alleles. It should be noted, however, that a meta-analysis covering 82 studies, 48 ($N = 17,559$) for *OXTR rs53576* and 34 ($N = 13,547$) for *OXTR rs2254298*, with five domains of outcomes (biology, personality, social behavior, psychopathology, and autism), did not yield significant combined effect sizes for any of the domains, or for all domains combined (Bakermans-Kranenburg & Van IJzendoorn, 2013).

Notably, only one study on parenting was included in the meta-analysis (Bakermans-Kranenburg & Van IJzendoorn, 2008). That specific study tested the association between *OXTR rs53576* and sensitive parenting of mothers in interaction with their 2-year-old toddlers at risk for externalizing behavior problems. Controlling for differences in maternal education, depression, and marital discord, parents with the A allele showed lower levels of sensitive responsiveness to their toddlers.

Since then, a number of additional studies on oxytocin-related genes and parenting have been conducted. Replication of the effect found in the first study was provided by the Twin Study of Behavioral and Emotional Development in Children (TBED-C), including 500 families with twins ages 6–10 years old (Klahr, Klump, & Burt, 2015). Three dimensions of parenting were observed—warmth, negativity, and control—for both fathers and mothers. Parents as well as children were genotyped for *OXTR rs53576*. Child *OXTR* genotype

did not predict the type of parenting received, and the father's genotype was also not associated with his parenting behavior. But the mother's genotype was related to maternal warmth; mothers with the AA genotype showed less warmth in interaction with their children than mothers with the GG or AG genotypes. Importantly, the association between maternal *OXTR* genotype and warmth was unchanged when controlling for child *OXTR* genotype, age, and gender (i.e., controlling for child-driven evocative effects).

In a longitudinal study of children with ADHD and matched controls, selection of 40 mothers was based on their extreme scores on positive or negative parenting of their 4- to 6-year-old children to maximize variation in parenting (Michalska et al., 2014). Parenting was observed during free play and a series of tasks, for a total of about 20 minutes, and 15 years later, mothers were exposed to pictures of their own and other children in a functional magnetic resonance imaging (fMRI) session. *OXTR* rs53576 and rs1042778 were both associated with quality of parenting, although only rs53576 survived correction for multiple testing. In contrast with studies reviewed earlier, not the G allele but the A allele was associated with higher levels of positive parenting. Note, however, that an interaction with ethnicity suggested that the association with parenting might be different for African American mothers (almost half of the sample) and European American mothers. Looking at pictures of their own child rather than an unknown child, A-allele carriers showed greater activation in the orbitofrontal cortex (OFC, involved in orienting toward, monitoring, and evaluating infant cues and emotional stimuli in general) and the anterior cingulate cortex (ACC, involved in regulating emotional responses). Finally, when exposed to pictures of their own child's inappropriate versus appropriate behavior, A-allele carriers showed more right hippocampus activation. As the activation of oxytocin receptors in the hippocampus is related to inhibited behavioral reaction to stress in rats (Cohen et al., 2010), this may suggest that increased hippocampal activation helps to inhibit a strong negative behavioral reaction to child transgressing behavior.

In another small study, adult females without children of their own were exposed to bouts of infant crying. Cries produce autonomic arousal in adults, which in turn facilitates a quick response to the infant in order to terminate the cry (Del Vecchio, Walter, & O'Leary, 2009). Almost half of the variance in adults' cardiac reactivity to an

experimental paradigm with bouts of infant crying of varying pitch (Crowe & Zeskind, 1992) was shown to be explained by genetic factors in a behavioral genetic study with adult twins (Out, Pieper, Bakermans-Kranenburg, & Van IJzendoorn, 2010), and this cry paradigm was thus used to test whether *OXTR* rs53576 would be related to variation in reactivity to cry sounds. Women with the GG genotype had greater heart rate responses to infant cries, but only when they had low depression scores (Riem, Pieper, Out, Bakermans-Kranenburg, & Van IJzendoorn, 2011). The participants were female twins, and the results were replicated in their twin sisters.

In an Israeli study, three SNPs were investigated: *OXTR* rs2254298 and rs1042778, and *CD38* rs3796863 (Feldman et al., 2012). *CD38* is a regulator of oxytocin release and has been found related to autism spectrum disorders (Munesue et al., 2010). In mice without *CD38*, reduced oxytocin levels and marked deficits in social and maternal behavior were observed (Jin et al., 2007). During the observation, infants sat on an infant seat, parents sat next to them, and parents were asked to play with their infants as they would typically do. Gaze synchrony and parental touch were coded. Parents with the *CD38* CC genotype touched their infants less frequently than those carrying the A allele, and parents with the *OXTR* rs1042778 TT genotype touched their infant less than parents carrying the G allele. For gaze synchrony, no genetic effects were found.

In the MAVAN study mentioned earlier, two polymorphisms in the oxytocin peptide gene (*OXT* rs2740210, rs4813627) and one polymorphism in the oxytocin receptor gene (*OXTR* rs237885) were genotyped and related to mother–infant interaction (Mileva-Seitz et al., 2013). At 6 months, the two *OXT* SNPs were related to infant-directed vocalizing, though not to maternal sensitivity, as assessed with Ainsworth's maternal sensitivity scales (Ainsworth et al., 1978). A allele carriers showed less infant-directed vocalizing. Because the two SNPs were in high linkage disequilibrium (i.e., specific allelic combinations were found more often than would be expected based on the allele frequencies in the sample), they cannot be considered independent effects, and the effect may also be due to some other SNP in linkage disequilibrium with these two SNPs. *OXT* rs2740210 was also related to breast-feeding duration, with replication in an independent sample (Jonas et al., 2013). The *OXTR* (rs237885) genotype was not related to vocalizing, maternal sensitivity, or breastfeeding.

Although the role of oxytocin in parenting is undisputed, variations in the *OXT* peptide gene and in the *OXTR* receptor gene have not yet produced a convincing picture of associations between particular polymorphisms and sensitive parenting. The link between particular *OXTR* genotypes and parenting has been suggested as an important direction for research into parenting (Taylor, 2008), but so far the results are at best promising and not as consistent as might be expected on the basis of animal research. The possibility to have much more control over environmental variation in animal studies may allow for stronger genetic effects in studies of parenting in rats compared to studies on human parenting.

In a similar vein, findings regarding associations between maternal dopamine- and serotonin-related genotypes and observed parenting are inconclusive. All studies published so far have been based on relatively small samples. The lack of convergence in the results points to the risk of chance results, and replication in larger samples is badly needed. Unfortunately, in the two large studies with child genotype and attachment data reviewed earlier (Generation R and NICHD SEC-CYD), measures of parenting quality are available, but maternal DNA has not (yet) been genotyped.

Of course, genes may play additive or interactive roles that so far have not been taken into account. Dopamine and oxytocin work together to regulate behavioral responses to social stimuli. In rats, there is a direct effect of oxytocin on dopamine release within the mesocorticolimbic dopamine system (Shahrokh, Zhang, Diorio, Gratton, & Meaney, 2010). In a similar way, genetic variants in dopamine- and oxytocin-related genes may interact to affect parenting in humans. This may be an important future step for studies on parenting, along with the examination of genetic pathways and genomewide association studies (see earlier sections on GWAS and GCTA).

G × E Interactions

$G \times E$ interactions may explain why some parents are more affected and others are less affected by disadvantageous childhoods or concurrent daily stresses in responding sensitively to their offspring's signals (Rutter, 2006). For example, in the MAVAN study, *OXT* *rs2740210* moderated the effect of early life experiences on breastfeeding through depression. In women with the CC genotype, childhood abuse experiences were related

to lower maternal mood at 6 months postpartum, which in turn was associated with reduced breastfeeding duration across the first year (Jonas et al., 2013). Parents may also be differentially susceptible to environmental influences *for better and for worse*. In an Israeli study with mothers of twins, mothers with the *DRD4* 7-repeat allele who experienced more stress around childbirth (e.g., their twin children had low gestational age, low birthweight, and prolonged stay at the neonatal intensive care unit) were less sensitive when interacting with their children at age 3.5 than other mothers, whereas mothers with the *DRD4* 7-repeat allele whose children had few complications around birth showed the highest levels of sensitivity (Fortuna et al., 2011).

Including not only *DRD4* but also *COMT* gene polymorphisms, mothers and toddlers were observed in a series of problem-solving tasks, and parents reported on their daily hassles (Van IJzendoorn et al., 2008). The two dopamine-related genes moderated the negative influence of daily hassles on sensitive parenting behavior to their offspring. In parents with the combination of genes leading to the least efficient dopaminergic system functioning (*COMT* *val* allele, *DRD4* 7-repeat allele), more daily hassles were associated with less sensitive parenting, but in this group, lower levels of daily hassles were associated with more sensitive parenting. The other combinations of *COMT* and *DRD4* polymorphisms did not show significant associations between daily hassles and maternal sensitivity.

The latter two studies (Fortuna et al., 2011; Van IJzendoorn et al., 2008) yielded interaction effects that are reminiscent of the $G \times E$ effect found for infant disorganization (Van IJzendoorn & Bakermans-Kranenburg, 2006). Remember that in this study, infants with the *DRD4* 7-repeat allele were more susceptible to parental unresolved loss than infants without this allele. Infants with the *DRD4* 7-repeat allele and mothers with unresolved loss had relatively high levels of infant disorganization, but infants with the *DRD4* 7-repeat allele and mothers without unresolved loss showed the lowest levels of attachment disorganization. In children without this allele, maternal unresolved loss was not related to disorganized attachment.

Here similar patterns of results emerge: Parents with the *DRD4* 7-repeat allele (and, in one study, an additional *COMT* *val* allele) were more affected by stress than parents without this specific genotype. Under conditions of stress, they were among the least sensitive parents, but lower lev-

els of stress were accompanied by an increase in caregiving sensitivity, much stronger so than in parents without this genotype. The role of *DRD4* as a susceptibility marker may therefore not be limited to children but may extend to adults as well. Support for this idea is also provided by the Iowa Adoption Studies, showing that adults with the *DRD4* 7-repeat allele were most susceptible to the absence or presence of parental problems in their adoptive families (Bakermans-Kranenburg, Van IJzendoorn, et al., 2011). Differential susceptibility has important implications for interventions. Susceptible individuals, whether parents or children, may profit more from interventions that systematically improve the environment.

Genetically Moderated Intervention Efficacy

Interventions with the aim of enhancing parental sensitivity or reducing attachment insecurity are manifold (see Berlin, Zeanah, & Lieberman, Chapter 32, this volume). They vary in scope and intensity, from brief and focused to covering a broad range of topics and approaches over a period of several years. What the vast majority of these interventions have in common is that their impact is only modest, with intervention effects that are disappointing in relation to the large investments in terms of time and money. In this section we delineate the role of genetics in explaining differences in susceptibility to intervention that may mask the efficacy of interventions in specific groups (Bakermans-Kranenburg & Van IJzendoorn, 2015).

Differential Susceptibility

The differential susceptibility model is of particular importance to intervention research. If environmental effects are more pronounced for specific groups compared to others, the effect of interventions will also be stronger for some than for others. As a consequence, the average intervention effect would underestimate the effectiveness/efficacy in the most susceptible groups. This is a completely different perspective on intervention, and for that reason, we dig somewhat deeper into differential susceptibility in general and into genetic differential susceptibility in particular.

The first three decades of $G \times E$ research were characterized by approaches such as the transac-

tional/dual-risk (Sameroff, 1983), cumulative risk (Rutter, 2010), and diathesis–stress models (Monroe & Simons, 1991). These approaches share a focus on psychopathology: Children with a vulnerable constitution (“risk” genes) and poor developmental experiences (e.g., insensitive parenting, low-quality child care, stressful life experiences) are expected to be at increased risk for bad outcomes. A typical example would be that children with the *5-HTTLPR* short allele were more often disorganized when maternal responsiveness was low (Spangler et al., 2009), or that infants with the minor MR allele (G) were less securely attached if their mothers showed extremely insensitive behaviors, whereas these associations were not present in children without the G allele (Luijk, Tharner, et al., 2011). The G allele might easily be indicated as the “risk allele.” In the latter study, however, infants with the G allele were more securely attached if their mothers were more sensitive. Genetic variation in MR thus modulated infants’ sensitivity to care, for better (increased susceptibility to maternal sensitive behavior) and for worse (increased vulnerability to maternal extreme insensitivity), and it would be a mistake to consider the G allele a risk allele when it also enhances the chance of developing secure attachments with sensitive caregivers.

In short, the same genotype that makes individuals vulnerable to adversity may also make them disproportionately likely to benefit from contextual support (Belsky et al., 2007). The differential susceptibility hypothesis proposes that in positive environments, “vulnerable” children may flourish even more than their peers who are less susceptible to both supportive and unsupportive environments (Bakermans-Kranenburg & Van IJzendoorn, 2007; Belsky et al., 2007; Ellis et al., 2011). The differential susceptibility model is not so much complementary to the diathesis–stress model; it is fundamentally different from it. Its evolutionary foundation implies that certain genotypes must be called “susceptibility” genes instead of “risk” genes (Bakermans-Kranenburg & Van IJzendoorn, 2015).

Evidence for genetic moderation of environmental effects according to the differential susceptibility model has been specifically tested for serotonin- and dopamine-related gene polymorphisms, although other genotypes have been identified as potential markers of susceptibility as well (e.g., monoamine oxidase A [*MAOA*], brain-derived neurotrophic factor [*BDNF*], MR). The first $G \times E$ differential susceptibility study showed that chil-

dren with the *DRD4* 7-repeat allele displayed the most externalizing behavior at 39 months, when their mothers were observed to be insensitive during home observations at 10 months of age, but the least externalizing behavior when their mothers were highly sensitive (Bakermans-Kranenburg & Van IJzendoorn, 2006). The findings of this pioneering small study were confirmed in a meta-analysis on dopamine-system-related genotypes (15 studies, $N = 1,232$). The combined effect sizes for the association between adverse rearing influences and behavioral disturbance amounted to $r = .37$ for carriers of the “risk alleles” and only $r = .10$ for the comparisons without the risk alleles. But the combined effect sizes for association between support and better adaptation were $r = .31$ for carriers of the putatively risk alleles, and $r = -.03$ for those without the risk alleles (Bakermans-Kranenburg & Van IJzendoorn, 2011). Thus, genotypes that in adverse contexts put children at risk for behavior problems allowed them to benefit more from support.

For *5-HTTLPR* as a genetic susceptibility marker, quite similar meta-analytic results were found, but with a difference depending on the inclusion of samples with mostly non-Caucasian and mixed ethnicities (Van IJzendoorn et al., 2012). In the total set of studies (77 studies, $N = 9,361$) children with short alleles were more negatively affected by adverse contexts than carriers of two long alleles with regard to negative outcomes, but they did not benefit significantly more from positive environments. The pattern of results was thus convergent with the diathesis–stress model; with short alleles as “risk alleles” rendering individuals more vulnerable to environmental adversity but not more open to supportive contexts. In studies with predominantly (>80%) Caucasian participants (52 studies, $N = 6,626$), carriers of short alleles were more sensitive to negative ($r = .18$) as well as positive ($r = .17$) environmental influences than individuals with two long alleles ($r = .04$ for negative environments, $r = .05$ for positive environments), in accordance with the differential susceptibility model. These differences point to ethnicity as an important moderator in $G \times E$ studies, including genetic differential susceptibility studies.

Most of these first studies that formed the basis for the two meta-analyses were correlational. More often than not, the studies did not specifically aim at testing the “bright side” of better outcomes in carriers of “risk alleles” in positive environments. In a way, this is an advantage because

it implies that those results that were derived as part of the meta-analytical process were not the focus of the specific study, which counters the risk of publication bias. The crucial test of the differential susceptibility model is, however, whether in randomized controlled trials (RCT) individuals with the susceptible genotypes profit more from interventions, that is, from experimental improvement of the environment.

Interventions from a $G \times E$ Perspective

$G \times E$ experiments (or $G \times eE$ [*experimental E*]) are RCTs with random assignment of participants to intervention and control groups. $G \times E$ experiments have at least three advantages compared to correlational $G \times E$ studies (see Van IJzendoorn & Bakermans-Kranenburg, 2015).

First, G and E are uncorrelated. Correlational $G \times E$ studies may test for gene–environment correlation (rGE) and set it aside when the genetic marker is not correlated with the environmental factor, but this provides no definite proof of the absence of rGE , because unmeasured genes may be related to the environmental factor under study. In RCTs, the environment is manipulated in standard ways, and randomization breaks any possible rGE . Only random assignment to experimental and control conditions can disentangle genetic and environmental factors (Van IJzendoorn, Bakermans-Kranenburg, Belsky, et al., 2011).

Second, $G \times E$ experiments decrease the risk of unequal measurement errors in the $G \times E$ equation. If genetic assessments are done in a careful way but broad or “quick-and-dirty” measures are used for the environment (e.g., self-reported retrospective childhood experiences), the error components are smaller for G than for E , creating risks for type I and type II errors. Experiments with well-defined, standardized manipulations of specific dimensions of the environment reduce measurement error in E . Of course, ineffective interventions do not contribute to a reduction of measurement error in E . Assessing the change in the environment is important to check the impact of the manipulation and to examine dose–response relations between environmental change and outcome in the experimental condition. As an example, in a study on the efficacy of the Video-feedback Intervention to promote Positive Parenting and Sensitive Discipline (VIPPSD) in the reduction of child externalizing behavior, the way in which parental

discipline strategies were affected by the intervention was measured, and the change in parental strategies was related to decreased externalizing behavior in children with the *DRD4* 7-repeat allele (Bakermans-Kranenburg et al., 2008).

Third, $G \times E$ experiments have more statistical power compared to rGE studies. Experimental studies make participants in the experimental condition maximally different from participants in the control condition, and this creates more variance in the product term. Correlational studies tend to contain few observations at the extremes of the distribution and many observations close to the center of the distribution. Selective recruitment and attrition, especially in the tails of the distribution, are responsible for this effect, and they can hardly be avoided. Experimental $G \times E$ studies lead to better distributed variables, and as a result, the power can be more than 10 times larger compared to correlational studies (McClelland & Judd, 1993). This is not a trivial issue because lack of power has been identified as one of the major problems in $G \times E$ research.

Randomized controlled intervention studies thus offer great opportunities to examine $G \times E$ interaction effects. Randomized controlled intervention studies can also provide insight in variation in intervention effectiveness among different groups. This is an important step in uncovering which intervention works best for whom, and provides hints relating to the mechanisms involved. Finally, they enable testing of whether the dopamine-related and serotonin-related genotypes that emerge as “susceptibility” factors from correlational $G \times E$ studies are indeed related to larger intervention effects.

Meta-Analysis of Genetic Differential Susceptibility Experiments

In the past decades, a number of genetic differential susceptibility experiments have been conducted. These RCTs address the question of whether intervention effects are moderated by a genetic susceptibility marker. In a meta-analysis of these experiments, we tested whether genotypes that were once considered risk factors and that were later suggested to be susceptibility (or “plasticity”) factors were related to larger intervention effects.

Twenty-two RCTs could be identified (Van IJzendoorn & Bakermans-Kranenburg, 2015), some of which had attachment as the outcome—for example, the intervention study of maltreat-

ing families conducted by Cicchetti, Rogosch, and Toth (2011), and the Bucharest Early Intervention Project (Brett et al., 2015; Nelson, Fox, & Zeanah, 2014). The 22 RCTs included 3,257 participants in total, 38% of whom were carriers of susceptibility genes. The combined effect size of the interventions for carriers of the susceptible genotypes amounted to $r = .33$, which is a large effect even in terms of Cohen's (1988) conventional criteria. In contrast, the hypothesized nonsusceptible group was less affected by the interventions; the combined size of the intervention effects in this group was not significant, $r = .08$. Intervention effects were thus much stronger in the a priori hypothesized susceptible group.

In the 14 studies with predominantly (>80%) Caucasian participants ($N = 2,060$), the findings were replicated, with significantly larger intervention effects for the susceptible genotypes ($r = .26$) than for the nonsusceptible genotypes ($r = .12$). Considering the genetic marker of susceptibility, dopamine-related genes were indeed markers of susceptibility. The 11 studies with dopamine-related genotypes as moderators showed larger intervention effects in susceptible genotype groups ($r = .35$) than in nonsusceptible genotype groups ($r = -.00$). Seven studies with *5-HTTLPR* as moderator showed significant combined effects in the susceptible genotype group ($r = .30$) but also in the nonsusceptible genotype group ($r = .16$); the difference between these two effect sizes was in the expected direction but not statistically significant ($p = .15$).

As an important final step, the difference between the effect sizes for the susceptible and nonsusceptible groups within each study was computed. The combined effect size for the difference between susceptible and nonsusceptible genotypes within studies was significant, with a medium effect size. We tested this combined effect size for publication bias and did not find any, which indicates that the combined effect size was not based on selective publication of studies that reported significant moderation of intervention effects by genotype at the expense of studies that did not find such moderation.

Conclusion

The study of the role of genetics in explaining differences in attachment security began only around the year 2000, so it is a relatively young branch of

the growing attachment tree. On the one hand, this is remarkable because attachment theory might be considered the first application of evolutionary theory to human development—after Charles Darwin but before so-called “evolutionary psychology” emerged. From evolutionary theory, John Bowlby (1969/1982) derived one of the core hypotheses of current attachment theory, the idea that every human infant is born with an innate bias to become attached to a protective conspecific. The genetic basis of this specieswide bias and related behavior in the various stages of attachment development has not yet received any attention.

On the other hand, attachment theory has always emphasized environmental influences, more specifically, effects of parenting, on the development of individual differences in attachment relationships and representations. Central to attachment theory is the idea that attachment starts as a dyadic construct, shaped mostly by parents, to be gradually internalized by the child and to become a defining feature of the growing individual. Behavior genetics studies seem to confirm this idea because most twin and adoption studies document the large role of the environment in explaining variance of attachment security and disorganization at a young age.

For three reasons, one should be careful deriving strong conclusions from behavior genetics. First, twin studies partition variation in attachment within a specific population and environment, and results are therefore sample-specific and dependent on variation in the environment. In more homogeneous environments, higher estimations for heritability are found. Second, results pertain to the group level, and should not be taken to indicate individual genetics. Third, the influence of genetics might grow with age, and twin studies on attachment beyond adolescence are lacking. As a relatively new development, GCTA extends behavior genetics in that it is not dependent on twin studies. Similar to behavioral genetics, GCTA leads to estimates of heritability without pointing at specific genes or gene pathways that play a role in the phenotype.

Molecular genetics has been used as a tool in search for specific genotypes related to parenting and to attachment security and disorganization. However, few, if any, clues for finding “attachment genes” have emerged. Considering the complex phenotypic signature of attachment and the necessarily limited sample sizes involved in studies of infant or adult attachment, this should not come as

a surprise. In fact, the search for main effects in genetics of human behaviors and disorders has been generally disappointing even to the most influential and optimistic gene hunters (Plomin, 2013). Ever larger samples account for ever smaller variance in traits on the level of singular genotypes. Gene pathways, mirroring more closely complex neurobiological endophenotypes of attachment, such as the dopamine system, may characterize the next generation of molecular genetics studies.

It seems safe to conclude that the intergenerational transmission gap between parental and child attachments (Van IJzendoorn, 1995) cannot be bridged by genes alone or by separate accounts of genetic and environmental input. $G \times E$ interactions may be better suited for this challenge. Correlational studies have documented the important role of $G \times E$ interactions in explaining human development, and experimental studies have provided even more compelling evidence of the importance of the interplay between genes and environments. In particular, the concept of genetic differential susceptibility generates support for the hypothesis derived from Belsky’s (1997) notion that children might differ in their openness to parenting influences in a *for better and for worse* manner. Although conclusive evidence is still missing, particularly in the area of attachment, genetic makeup might make some children vulnerable to the development of insecure attachments in less supportive environments, whereas the same genetic endowment enables children to profit more from supportive environments (i.e., sensitive parenting). This is a new perspective on the old issue of the transmission gap, to be explored more carefully in the next decade of attachment studies. In a clinical and practical sense, the implication is that the efficacy of attachment-based interventions may have been over- and underestimated depending on the proportions of susceptible parents or children.

In his revised edition of the trilogy *Attachment*, Bowlby (1969/1982) has already argued that the antithesis of innate versus acquired behavioral traits is unreal and unproductive: “Just as area is a product of length multiplied by width so every biological character . . . is a product of the interaction of genetic endowment with environment” (p. 38). Meaney (2001) attributes this wonderful rectangle metaphor to Donald Hebb and dates it back to the 1960s of the previous century. Meaney adds that it is impossible to explain to the general public that one ever could make sense of a rectangle by studying only length isolated from width, or the other

way around. Nevertheless, this is exactly what has happened in the study of human development, including attachment. Genetic differential susceptibility, incorporating epigenetics, may offer a viable window to study the interplay between genes and environment in attachment.

Chapter 9

Attachment and Psychoneuroimmunology

Katherine B. Ehrlich
Gregory E. Miller
Jason D. Jones
Jude Cassidy

At the core of attachment theory is the notion that the availability of a responsive and dependable caregiver is critical to healthy development across the lifespan (Bowlby, 1973, 1980, 1982). During the first several decades of the scientific study of attachment, developmental, clinical, and social researchers focused primarily on how attachment shapes individuals' social and emotional functioning. More recently, researchers have undertaken investigations of the links between attachment and physiological systems, shedding light on the ways in which attachment security may influence various systems in the body. For example, some studies have identified individual differences in infants' autonomic nervous system activity during the Strange Situation procedure (e.g., Sroufe & Waters, 1977), and other work has demonstrated individual differences in neuroendocrine stress reactivity to novel stimuli as a function of infant attachment classification and temperament (e.g., Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996). Furthermore, recent evidence suggests that attachment figures can attenuate adults' threat-responsive neural activity following a stressor (e.g., Coan, Schaefer, & Davidson, 2006). These studies provide some of the first evidence for connections between attachment and psychophysiology

(see also Dozier & Kobak, 1992; Eisenberger et al., 2011), and this area of research continues to generate new insights into the dynamic connections between attachment and physiological systems.

During the years that Bowlby was developing his theory of attachment, other researchers were focused on the connections among psychological processes, neural and endocrine activity, and immune functioning, a field that became known as *psychoneuroimmunology* (PNI) (Ader, 1980, 2001; Ader & Cohen, 1975; Solomon & Moos, 1964; for a review, see Kiecolt-Glaser, McGuire, Robles, & Glaser, 2002). This interdisciplinary area of research has revealed the ways in which emotions, social support, and stressful life experiences—in addition to many other psychosocial and behavioral factors—are connected to immune and endocrine function, and to physical health. These studies show how the social world can “get under the skin” to affect immune and neuroendocrine systems in ways that might have consequences for later health.

With the exception of a few studies, these two areas of research—attachment and psychoneuroimmunology—have proceeded independently of each other. Yet it is becoming increasingly clear that many of the same guiding principles of attach-

ment theory, which explain why early experiences with caregivers have long-lasting connections to social and emotional health, may also explain how attachment-based experiences can shape individuals' immune processes and physical health across development. At the same time, conceptual models guiding research on connections between social experiences and immune functioning (e.g., Fagundes, Glaser, & Kiecolt-Glaser, 2013; Miller, Chen, & Parker, 2011) are instrumental in providing a foundation for how attachment experiences might be associated with the immune system. Furthermore, evidence suggests that attachment is associated with physical health outcomes in childhood and adulthood (Anderson, Gooze, Lemeshow, & Whitaker, 2012; Anderson & Whitaker, 2011; McWilliams & Bailey, 2010; Puig, Englund, Simpson, & Collins, 2013).

Our goal in this chapter is to provide an introduction for attachment researchers who may be unfamiliar with the field of PNI. We begin with a theoretical framework for the study of attachment and the immune system, drawing on existing theoretical models that outline how social experiences can become embedded in the body (e.g., Miller et al., 2011; Uchino, Cacioppo, & Kiecolt-Glaser, 1996). Consistent with the notion that attachment experiences are important for social and emotional health from “the cradle to the grave” (Bowlby, 1979, p. 129), we propose that connections between attachment and the immune system can be observed across the lifespan. We then provide a general overview of common indicators of immune system function, with a specific focus on inflammation, which is the predominant focus of contemporary human PNI research. We present some preliminary evidence for a connection between attachment experiences and inflammatory processes, followed by a review of relevant research that has examined links between attachment-related social factors (e.g., maternal warmth) and various biological mechanisms. To date, studies of attachment and inflammation have focused on adult samples, but when available, we include studies that have examined relevant caregiving experiences and immune function in children. We conclude with a discussion of future directions for this emerging area, as well as some words of caution for researchers who are interested in embarking on this ambitious interdisciplinary work. Because other chapters in this handbook cover research on the neuroscience of attachment (see Coan, Chapter 12) and links between attachment and the endocrine system (see Hane & Fox, Chap-

ter 11), our review focuses on attachment and its potential links to the immune system.

Attachment, Stress Regulation, and Inflammation: A Theoretical Framework

In this section, we describe our thinking about how attachment-related experiences may be associated with inflammation. A large body of research supports the notion that stressful experiences are associated with inflammation, and we begin this section with a review of an existing model that explains how stressors shape inflammatory processes over time. We then describe how attachment-related stress regulatory capabilities and the presence (or absence) of a secure base may contribute to inflammatory processes. After that, we describe two models that may explain how attachment orientations are associated with inflammatory processes.

Stress and Inflammation

Stressful experiences are thought to alter inflammatory processes via the autonomic nervous system. Fibers from the sympathetic nervous system directly connect brain regions involved in emotion processing and regulation to the lymphoid organs, where immune responses take place. Evidence from animal studies suggests that stressful experiences can increase the density of these fibers (e.g., Sloan et al., 2007), which release epinephrine, norepinephrine, and other neurotransmitters. These neurotransmitters in turn bind to receptors on white blood cells, resulting in changes to their patterns of trafficking, cytokine release, proliferation, and differentiation. Hormonal pathways also influence immune processes. Immune cells respond to cortisol, oxytocin, and other molecules whose expression can be affected by stress (e.g., Fries, Ziegler, Kurian, Jacoris, & Pollak, 2005; Miller et al., 2009).

Miller and colleagues (2011) outlined how stressful experiences in childhood are associated with inflammatory processes. In this model, exposure to chronic stressors incites a *proinflammatory phenotype*, which becomes embedded within key cells of the immune system: monocytes and macrophages. According to this model, these cells (which play a critical role in the initial immune response to injury and infection) become

programmed to launch exaggerated responses to stimuli and become desensitized to inhibitory signals (e.g., from cortisol; described in more detail in the next section). Across development, this proinflammatory phenotype can result in chronic, low-grade inflammation, which is increasingly recognized in the biomedical literature as a fundamental contributor to many of the chronic diseases of aging, including cardiovascular disease, diabetes, stroke, some cancers, and various autoimmune conditions (Danesh, Collins, Appleby, & Peto, 1998; Libby, Ridker, & Hansson, 2009; Ridker, 2007; Yeh & Willerson, 2003). Inflammation is especially likely to occur when individuals face severe and chronic stressors, in part because these stressful experiences take a toll on individuals' self-regulation resources. As a result, individuals are more likely to develop unhealthy lifestyle practices (e.g., poor diet, smoking, substance use, sedentary behavior) and form poor social relationships. These factors in turn have been associated with inflammation (Miller et al., 2011).

Attachment and Stress Regulation

Attachment theory suggests that individuals develop capacities for regulating stress as a result of experiences with caregivers in times of distress. Bowlby (1982) proposed that children develop experience-based mental representations of their caregivers' availability and responsiveness during times of need. These representations, or *internal working models*, develop as early as the first year of life and reflect the extent to which the child perceives the parent as a "secure base" from which to explore and as a "safe haven" to which to return in times of threat or distress. Over time, as children become more autonomous, they learn regulatory strategies for managing their own emotions but continue to seek comfort from attachment figures when distressed. Even in adulthood, individuals use attachment figures (e.g., parents, romantic partners) for support and comfort when upset (Ainsworth, 1989; Mikulincer & Shaver, 2007).

According to attachment theory, access to a secure base is critical because it provides a sense of security that enables individuals to explore the world and seek help or comfort when confronted with threat (Bowlby, 1973). In other words, individuals who have a secure base feel assured that, when faced with difficulties, someone will be available to come to their aid; this assurance allows them to confront stressors without becoming overwhelmed. Furthermore, within close re-

lationships, secure individuals are able to engage in open, flexible expression of emotions, thus allowing expression and mitigation of negative feelings. In contrast, individuals without a secure base have not had the experience of being able to rely on a consistent caregiver to meet their emotional needs, and as a result, they struggle to manage their negative emotions.

Of course, not everyone has a history of experiences with caregivers in which negative feelings were acknowledged, comforted, and alleviated. Some individuals may have experienced minimizing or punitive responses from their attachment figures, and others may have experienced inconsistently available attachment figures who were only sometimes responsive to their needs. These individuals, who are likely to be classified as insecurely attached, are unable to use their attachment figures effectively as a secure base and safe haven (Ainsworth, Blehar, Waters, & Wall, 1978). As a result, these individuals develop strategies for managing their negative emotions (Main, 1990), either by minimizing, suppressing, and denying their negative feelings (labeled *attachment-related avoidance*), or by maximizing and heightening their distress in order to capture the attention of attachment figures (labeled *attachment anxiety*). Although these strategies may be adaptive for bringing coherence to an inconsistent or unsupportive caregiving environment, they are ineffective for long-term stress regulation (see Mikulincer & Shaver, Chapter 24, this volume). Indeed, individuals who are high in avoidant and/or anxious attachment have more depressive symptoms, anxiety, and substance use problems than do secure individuals (see DeKlyen & Greenberg, Chapter 28, and Stovall-McClough & Dozier, Chapter 31, both in this volume).

Models Linking Attachment and Inflammation

We propose that associations between attachment orientations and inflammatory processes are likely to occur in one of two principal forms. First, we expect there to be direct links between insecure attachment and inflammation. Insecurely attached individuals have difficulty regulating stress, and exposure to chronic stressors may foster the proinflammatory phenotype described earlier (e.g., Miller et al., 2011). Second, we argue that attachment orientation may serve as an important moderator of the already documented connections between psychosocial stressors and inflammation (e.g., Glaser & Kiecolt-Glaser, 2005; Segerstrom

& Miller, 2004). For example, attachment security may buffer against the heightened inflammatory consequences associated with low socioeconomic status (SES) (e.g., Miller et al., 2011). Conversely, insecurely attached individuals who are also facing chronic or acute stressors may have greater inflammatory responses than securely attached individuals who are experiencing similar levels of stress. We discuss these models in more detail in “Future Directions.”

In the next section, we provide an overview of some of the most common biological measures that indicate inflammation in the body. After that, we describe research that has used these measures to examine connections between attachment-related indices and inflammatory processes.

Biological Measures of Interest

In the last several decades, significant progress has been made in understanding biological correlates of social experiences, such as social isolation, maltreatment, and poverty, and it is plausible that attachment-related experiences are among these important influences on underlying biologic processes. In this section, we describe some of the most common measures of the immune system, with a specific emphasis on indicators of inflammation because of their influence on many of the chronic diseases of aging.

This section is divided into four parts. In the first part, we review systemic measures of inflammation, which provide an index of circulating inflammation in the body. After that, we discuss functional measures of inflammatory processes, which provide information about the extent to which an individual's immune system is aggressive in its response to pathogens and sensitive to signals to reduce the inflammatory response. We then review several indicators of gene regulation, including epigenetic modifications and gene expression. In the final part of this section, we review a number of laboratory-based measures of the immune system; these laboratory measures require a deliberate (though minor) injury to an individual, oftentimes to the skin, with systematic follow-up measures regarding repair and recovery.

Systemic Inflammation

Inflammation occurs when cells of the innate immune system, including neutrophils, dendritic cells, monocytes, and macrophages, gather at the

site of an infection or injury. These cells attempt to eliminate the pathogen, rid the body of infected tissue, repair any damage the pathogen caused, and begin the process of healing. The inflammatory response is essential for survival: Without it, minor injuries or infections would be lethal. The inflammatory response must be carefully regulated, however; otherwise, inflammation can become persistent and disseminated, thereby contributing to multiple chronic diseases.

Inflammation is orchestrated by signaling molecules known as cytokines, which are released by immune cells and the damaged tissue. The major cytokines involved with inflammation are interleukins 1 and 6 (IL-1, IL-6), and tumor necrosis factor alpha (TNF- α). Researchers sometimes use concentrations of these molecules in circulation as a rough estimate of ongoing inflammatory activity. However, these cytokines are fairly unstable in blood, so a more common approach is to measure C-reactive protein (CRP), a molecule produced by the liver during inflammation. CRP provides a reliable index of low-grade chronic inflammation over the preceding month or so, and is prognostic of morbidity and mortality from a number of chronic diseases of aging. CRP's role is particularly well established in the progression of cardiovascular disease, where, in apparently healthy individuals, it presages disease risk in a roughly dose-response manner.

To be most effective in research studies, researchers should attempt to measure inflammation at multiple time points, which allows for a better understanding of both *stability* and *change* in inflammation over time. Longitudinal studies, with multiple assessments of inflammation, will help to clarify the extent to which attachment-related experiences predict chronic disparities in inflammation. These types of studies will also help to clarify whether such experiences can precipitate changes in inflammation, whether favorable or unfavorable. For inflammation to be involved in accelerating some diseases, such as atherosclerosis, the inflammation would need to be long-standing. Only with multi-wave studies can researchers ascertain whether inflammation is transitory or chronic. On the other hand, short bursts of inflammation could initiate a cascade of biological processes, ultimately leading to a heart attack (Maseri & Fuster, 2003). One important caveat is that most studies of inflammation capture ongoing inflammatory activity in peripheral blood rather than inflammation in tissues or organs where disease processes are happening (e.g., the coronary arteries for heart disease, the joints for rheumatoid arthritis). The

assumption is that blood provides a window to inflammatory activity at these sites. The available research generally supports this assumption, and suggests that, if anything, blood-based measures underestimate the association between stressors and inflammation in tissue (Glaser et al., 1999).

To date, the majority of PNI studies have focused on proinflammatory processes, which is not surprising given the role of inflammation in the progression of chronic disease. But anti-inflammatory signals play an important role in regulating the balance of inflammatory activity. Some cytokines, such as IL-10, are involved in terminating the inflammatory response. These cytokines act as “brakes” and help prevent inflammatory responses from proceeding in an unchecked manner. Thus, researchers should include measures of both pro- and anti-inflammatory signals to capture a more comprehensive picture of how the immune system responds to social experiences.

Measures of systemic inflammation are arguably the best starting point for attachment researchers who are interested in expanding their research to include inflammation. These measures are relatively easy to obtain, with only a peripheral blood draw or finger prick needed to obtain samples. Many hospitals process samples at an affordable rate, allowing researchers to minimize costs associated with necessary laboratory facilities. Moreover, the clinical implications of chronic inflammation are clear. Studies have shown that elevated CRP predicts adults’ cardiovascular events in a roughly dose–response manner, even within the normal range of values (Ridker, 2003). Notably, CRP is often viewed as a marker rather than as a causal actor in the progression toward disease. Other cytokines (e.g., IL-1, TNF- α) play a more direct role in the generation of inflammation that contributes to plaque formation that may trigger later coronary events. Despite these advantages, measures of some indices, such as CRP, may be less appropriate for samples with children and adolescents. At younger ages, children often have levels of CRP that are below the detection threshold for standard assays, which may contribute to a “floor effect” when trying to link attachment experiences to inflammation. Although this issue is less of a concern for other measures of inflammation, such as TNF- α , IL-6, and IL-8, these measures often lack variability in scores, and the clinical implications of low scores are unclear. Given these developmental considerations, researchers working with children and adolescents may want to explore the possibility of using functional mea-

asures of inflammation, which are described in more detail in the next section.

Functional Measures of Inflammatory Processes

As described earlier, systemic measures reflect the amount of ongoing inflammation circulating in peripheral blood. Functional measures, in contrast, provide insight into how cells respond when confronted with pathogens (e.g., bacteria) or signaling molecules (e.g., cortisol). It is unclear whether functional measures are diagnostic or predictive of chronic disease, but they are useful for capturing individual differences in proinflammatory response patterns that, if sustained, could put individuals on an accelerated trajectory toward chronic disease.

When macrophages encounter signs of injury or infection, one of their initial responses is to secrete cytokines, including IL-1- β , IL-6, and TNF- α . These molecules attract cells to the site, activate their killing functions, call in other more specialized cells, and initiate systemic processes (e.g., fever) that decapacitate the invading microorganisms. As mentioned earlier, this inflammatory response is critical for survival from acute infections and injuries. However, it must be carefully regulated because, if sustained in an unchecked manner, inflammation can bring about tissue damage and contribute to chronic diseases (Hotamisligil, 2006; Libby & Theroux, 2005).

Cortisol plays an important role in helping the body regulate immune responses, particularly inflammation. Cortisol binds to glucocorticoid receptors located in immune cells and, under normal circumstances, this complex regulates the magnitude and duration of inflammation, helping to ensure that the response does not overshoot in a manner that causes tissue damage (Sapolsky, Romero, & Munck, 2000; Sternberg, 2006). Over time, however, long-term exposure to stress can result in the desensitization of glucocorticoid receptors to cortisol, particularly in the cells (monocytes and macrophages) that initiate and sustain most inflammatory responses (e.g., Marques, Silverman, & Sternberg, 2009; Miller et al., 2008; Raison & Miller, 2003; Rohleder, Marin, Ma, & Miller, 2009). One result of this desensitization is that cortisol has a reduced ability to regulate these cells’ responses to infections and injuries, which gives rise to chronic low-grade inflammation even in the absence of acute events (Miller, Cohen, &

Ritchey, 2002; Raison & Miller, 2003). Thus, reduced sensitivity to the anti-inflammatory effects of cortisol may contribute to a poorly regulated inflammatory response to injuries, infections, and other stimuli.

Of course, researchers cannot easily expose participants (particularly children) to infection or injuries (but see Eisenberger, Inagaki, Mashal, & Irwin, 2010, for an example of exposing adults to endotoxins, and Cohen, Doyle, Turner, Alper, & Skoner, 2004, for an example of exposing participants to viral challenge). Instead, researchers collect white blood cells and then expose these cells to bacteria *in vitro*, a process known as *microbial challenge*. Cells are then cultured with a bacterial stimulus, such as lipopolysaccharide (LPS), which is a molecule found in the outer membrane of gram-negative bacteria. Following a predetermined incubation period (e.g., 24 hours), *supernatants* (i.e., the remaining fluids minus the white blood cells) are harvested, and researchers can determine the amount of cytokines produced following exposure to LPS. Greater levels of inflammatory cytokine production (e.g., IL-6) are indicative of a more aggressive inflammatory response. Again, as described earlier, an acute aggressive response may be advantageous when combating a pathogen or responding to an injury because it can accelerate repair and recovery; on the other hand, if this aggressive inflammatory response persists over an extended period of time, individuals may be susceptible to tissue damage and accelerated aging. As such, interpretation of stimulated cytokine production responses will depend on the context in which the inflammatory response occurs.

In addition to measuring how aggressively an individual's cells respond to bacterial challenges, researchers can measure the extent to which cells are sensitive to the anti-inflammatory signals from cortisol, which is a measure known as *glucocorticoid sensitivity*. This procedure is often conducted in unison with the microbial challenge procedure described earlier. To perform this assessment, cells are incubated with bacteria (e.g., LPS), as well as doses of hydrocortisone in varying concentrations. Following the incubation period, cytokine levels are measured across the different doses of hydrocortisone, which can then be used to create a dose–response curve. The area under the curve reflects the participant's glucocorticoid sensitivity; larger values indicate that the immune cells are *less sensitive* to cortisol's anti-inflammatory signals. In other words, glucocorticoid sensitivity reflects the extent to which the cytokine response

is tightly controlled and responsive to signals to attenuate it.

These measures often provide more variability in inflammatory processes, compared to systemic measures of inflammation, and this variability can be helpful for detecting links between inflammatory processes and social experiences. Nevertheless, these assessments are considerably more complicated to perform than systemic measures of inflammation. One complication is that cell cultures need to be prepared with fresh (i.e., not frozen) blood under sterile conditions, and by a technician experienced with this methodology. Thus, close proximity to a laboratory equipped to process blood samples and greater technical expertise is needed. These measures are also significantly more expensive than most systemic measures, which can be a limiting factor for most research laboratories with tight budgets. As such, studies of connections between attachment and functional measures of inflammatory processes might be best conducted in collaboration with laboratories that already incorporate these research techniques.

Epigenetic Modifications and Gene Expression

All cells within an individual carry an identical DNA sequence that is established at conception and fixed for life. (Lymphocytes and cells that have acquired mutations are exceptions to this rule.) The DNA sequence serves as a blueprint for *transcription*, the process whereby cells synthesize RNA molecules—a process known as *gene expression*. RNA molecules are later translated into proteins that cells use for structural and functional purposes. Not all genes are active at all times, however, and some genes are thought to be “socially sensitive,” altering their expression patterns as a function of social experiences (Cole, 2013).

The term *epigenetics* refers to stable changes in gene expression activity that arise without changes in the DNA sequence (Jaenisch & Bird, 2003; Jirtle & Skinner, 2007). A principal function of epigenetic alterations is to allow cells to develop and maintain specialized functions. For example, epigenetic alterations can modify a cell's ability to transcribe a particular gene into RNA. Because RNA serves as a template for the translation of proteins, these epigenetic alterations often (although not always) have downstream influences on how much of the gene's protein is ultimately synthesized. When this process takes

place across many different genes, it can give rise to significant phenotypic diversity among cells of the body. This variability is thought to play a role in the long-term development of physical disease (e.g., Rakyán, Down, Balding, & Beck, 2011), although the nature of these pathways remains largely unknown.

Epigenetic modifications to DNA typically occur in one of two ways (Whitelaw & Garrick, 2006). The first modification is DNA methylation, which involves the attachment or removal of a methyl group to cytosine residues in a gene's promoter. The methyl groups prevent transcription factors from interacting with DNA to modulate gene expression, which makes the gene inactive. The second form of epigenetic modification involves changes to the chromatin structure that packages the DNA. This process occurs by attaching or removing chemicals from the histone proteins that hold DNA within the cell's nucleus. These proteins cause the DNA near the gene to become more or less tightly coiled, which makes it more or less difficult for RNA polymerase and transcription factors to access their promoters (Whitelaw & Garrick, 2006).

Assessments of epigenetic modifications and gene expression can take a variety of forms. Measurement of epigenetic modifications typically relies on microarray analysis of DNA methylation patterns. This process assesses the presence of methylation at multiple sites in each of many thousands of different genes (e.g., these analyses can quantify the proportion of sites that are methylated). Quantification of messenger RNA (mRNA) can be done by focusing on candidate genes or thousands of genes using DNA microarrays. Although the cost of this technology has dropped substantially, costs remain high, making this assessment prohibitively expensive for some researchers. Nevertheless, these assessments provide unique insight into early mechanisms that go on to shape systemic inflammation, and greater utilization of these methods will be an important direction for future research.

It may be that attachment experiences bring about changes in methylation patterns, which in turn affect expression of mRNA and then synthesis of cytokines and other proteins that are involved with inflammation. The notion that caregiving experiences could bring about epigenetic changes has already been demonstrated in animal models (Weaver et al., 2004), wherein maternal caregiving experiences triggered changes in methylation and acetylation patterns for the glucocorticoid receptor gene in the offspring hippocampus.

These epigenetic modifications affected regulation of the hypothalamic–pituitary–adrenal (HPA) axis—the hormonal system that controls the release of cortisol in response to stress. Some preliminary evidence suggests that similar processes occur in early human social experiences (e.g., Bick et al., 2012; McGowan et al., 2009). But to date, most of these investigations with human samples have focused on childhood maltreatment rather than attachment security, and have relied mostly on white blood cells and buccal cells rather than cells in the brain, where these epigenetic effects would be most relevant to individual differences in emotion regulation and stress responsivity. Thus, future epigenetic research would be most helpful if methylation data were supplemented with studies of functional consequences for gene expression (e.g., by quantifying mRNA expression).

Laboratory Measures of the Immune System

For studies using the measures described in the previous sections of this chapter, participant burden is quite minimal. Researchers collect peripheral blood samples, and all subsequent processing and analysis steps are done without direct interaction with participants. We now describe several techniques that require more direct involvement with participants. These measures require the administration of a minor injury, typically to the skin, with follow-up assessments to examine repair and recovery. Although considerably more invasive than standard venipuncture, these procedures provide an opportunity to observe how the immune system repairs damaged tissue. The skin is the largest organ in the body and is often viewed as the first layer of defense of the immune system (Salmon, Armstrong, & Ansel, 1994). Cytokines play an important role in maintaining skin barrier function and are recruited to repair damaged tissue. Stress is thought to slow cytokine production at the site of damaged skin tissue (e.g., Glaser et al., 1999; Kiecolt-Glaser, Marucha, Malarkey, Mercado, & Glaser, 1995). By temporarily disrupting the skin's surface, researchers can examine the length of time needed for recovery, as well as clinical indicators of wound healing (e.g., cytokine production).

Of the two skin disruption measures, the less invasive measure utilizes a tape stripping procedure to disrupt the skin barrier and is followed by examination of skin barrier recovery (Fluhr, Feingold, & Elias, 2006). Prior to the procedure, researchers

measure the vapor pressure gradient in the layers close to the skin surface, which reflects the skin's ability to prevent water loss. Then, researchers repeatedly apply tape to the surface of the skin (anywhere from five to 60 times, on average), which disrupts the site and removes the superficial layer of dead skin on the surface. Following this treatment, researchers take periodic assessments of the vapor pressure gradient to quantify the skin's recovery from the tape-stripping procedure. Delayed skin barrier recovery is indexed by slower return to baseline pressure gradient.

The second procedure involves the administration of skin blisters to the forearm of participants (Kuhns, DeCarlo, Hawk, & Gallin, 1992). Researchers create small, standardized blisters using a suction blister device. Following generation of the blisters, trained assistants remove the top of the blister and attach a collection device to the site to collect fluid from each wound over a predetermined period of time. This procedure is often accompanied by a behavioral task, such as a conflict or support-seeking discussion with a spouse, to examine links between observed behaviors and wound healing (e.g., Kiecolt-Glaser et al., 2005). Blister healing can be assessed using measures of the vapor pressure gradient.

Participants generally report minimal discomfort from these procedures, and there is little risk for long-term injury. Not surprisingly, however, this procedure requires significant participant compliance, often involving overnight stays in the hospital/laboratory setting in order to collect blister fluid over the course of a day. Researchers frequently control for diet by standardizing food intake over the course of the study to minimize variation due to individual differences in health behaviors. The administration of blister wounds is not appropriate for studies with children, but it has yielded important insights into connections between stress and immune functioning in adults (e.g., Kiecolt-Glaser et al., 2005).

Attachment and Inflammation: Empirical Evidence

In the previous section, we highlighted the various immune measures at the disposal of researchers who are interested in exploring associations between attachment and immune functioning. In this section, we review the empirical evidence for links between attachment (and attachment-related constructs) and inflammation. We have focused

our review on measures of inflammation given increasing evidence that inflammation plays an important role in the progression of many chronic diseases. We note, however, that other studies have examined links between attachment and other measures of immune functioning, including measures of the adaptive immune system (e.g., Picardi et al., 2007, 2013); review of these studies is beyond the scope of this chapter, however.

Below, we first review the sparse literature on the associations between attachment and inflammation. Then, we review studies that have demonstrated links between attachment-relevant constructs (e.g., maltreatment in childhood, marital quality in adulthood) and inflammatory processes.

Almost all of the research in this area has focused on adults, with examination of links between individual differences in self-reported adult attachment style and laboratory measures of inflammatory responses to some type of stressor. Self-report measures of adult attachment style yield scores on two dimensions: attachment-related avoidance and anxiety. Avoidance reflects the extent to which individuals are uncomfortable with intimacy and emotional disclosure in close relationships. Anxiety reflects the extent to which individuals fear rejection and abandonment, and desire high intimacy and closeness in relationships (Shaver & Mikulincer, 2002).

Two studies examined how attachment-related avoidance and anxiety relate to individuals' inflammatory responses following interactions with their romantic partners that were designed to be mildly stressful (Gouin et al., 2009; Robles, Brooks, Kane, & Dunkel Schetter, 2013). In these studies, couples participated in two consecutive laboratory visits. During one visit, each partner discussed a personal concern (i.e., something the individual would like to change about him- or herself). During the other visit, the partners were instructed to discuss and try to resolve sources of conflict in their relationship. Gouin and colleagues (2009) measured serum levels of IL-6 at each visit, whereas Robles and colleagues (2013) measured skin barrier recovery following a tape-stripping procedure (described in detail earlier) at each visit. The results of the Gouin and colleagues study revealed that individuals higher in attachment-related avoidance produced more IL-6 following the relationship conflict discussion than did individuals lower in avoidance, after researchers adjusted for various inflammation-related covariates. No significant attachment-related differences in IL-6 production emerged during the

personal concern discussion visit, and attachment anxiety was unrelated to inflammatory responses to either discussion task. No gender differences emerged in the link between attachment style and IL-6 production. The finding that attachment style was associated with inflammatory responses only after the conflict discussion is consistent with theory suggesting that attachment-related individual differences are likely to be most evident under conditions of threat or stress (Bowlby, 1982). The authors proposed a potential behavioral mechanism underlying the link between attachment and IL-6 production, which may also account for the fact that significant findings emerged for avoidance only. Greater avoidance, but not anxiety, was associated with more negative behaviors and fewer positive behaviors during the conflict discussion. Prior research with the same sample revealed that a higher frequency of negative behavior during both discussions was associated with larger IL-6 responses (Kiecolt-Glaser et al., 2005, discussed further in the next section).

Although Gouin and colleagues (2009) found that links between attachment style and IL-6 emerged for both men and women, Robles and colleagues (2013) identified gender differences in the association between attachment style and skin barrier recovery during the two visits. Specifically, among females, greater attachment-related avoidance was related to slower skin barrier recovery across both discussion tasks, indicating a delay in tissue repair following the procedure. In contrast, among males, greater attachment anxiety was related to slower skin barrier recovery during the discussion about a personal concern only. These results provide additional support for a link between attachment style and inflammatory responses. Contrary to the authors' expectations, however, greater attachment anxiety among females was associated with *faster* skin barrier recovery across both discussion tasks. Drawing from the animal literature pertaining to physiological responses to repeated social threats or injuries, the authors speculated that the faster skin barrier recovery among anxious women may reflect a "preparative" response to anticipated social injury (i.e., lack of support from or rejection by a romantic partner) that facilitates a rapid inflammatory response to injury. Additional research is needed to replicate these findings and clarify the reasons for the unexpected positive association between attachment anxiety and skin healing in women.

A third study examined the association between adult attachment style and inflammatory response to a different type of acute stressor: coro-

nary artery bypass graft surgery (CABG; Kidd et al., 2014). Cardiac patients completed a self-report measure of attachment style prior to surgery. Serum levels of IL-6, CRP, and TNF- α were measured before and after surgery. Attachment style was unrelated to postsurgery levels of CRP and TNF- α . However, greater attachment anxiety (but not avoidance) was related to higher levels of IL-6 following surgery, after adjusting for presurgery IL-6 levels. These results provide additional evidence for a link between attachment style and inflammatory responses to a stressor; however, the pattern of findings differed from the pattern observed in the study by Gouin and colleagues (2009) that examined IL-6 responses to a laboratory-based conflict discussion. Whereas Gouin and colleagues found that avoidance, but not anxiety, predicted greater IL-6 production following a stressor, Kidd and colleagues (2014) found that anxiety, but not avoidance, predicted greater IL-6 production. Although speculative, the inconsistent findings across these two studies could be due to differences in the type of stressor (i.e., laboratory-based discussion vs. surgical procedure), poststressor consequences (i.e., momentary discomfort in relationship following conflict vs. extensive recovery following the surgery), and sample characteristics (i.e., healthy adults vs. adults suffering from heart disease). It is also important to note that Kidd and colleagues found that attachment style was only related to one out of three measured inflammatory markers. Future research will help determine whether attachment style is associated with other measures of inflammatory responses to a stressor.

To our knowledge, only one study has examined the association between self-reported attachment style and systemic inflammation (i.e., inflammation that is not in response to a specific stressor). In a sample of mostly white, healthy married couples, Uchino and colleagues (2013) did not find any significant links between attachment style and levels of IL-6, CRP, or fibrinogen. Because this is only study to test the association between adult attachment style and systemic inflammation, and the participants did not complete the full attachment style measure (10 selected items from a 36-item scale), it is hard to reach any firm conclusions from these null findings. Additional research will shed light on whether attachment style plays a role in systemic inflammation or is more reliably related to inflammatory responses to acute stressors.

Only one study has examined how attachment prior to adulthood prospectively predicts systemic inflammation in adulthood. Using longitudinal data from the Maryland Adolescent De-

velopment in Context Study (MADICS; principal investigators: Jacquelynne S. Eccles & Arnold J. Sameroff), we (Jones et al., 2015) examined the prospective association between perceptions of parents as a secure base and adult CRP levels in an African American sample. The secure base construct reflects the degree to which adolescents feel they can depend on their parents in time of need or distress. Although perception of parents as a secure base is not a measure of attachment per se, the secure base construct is central to attachment theory, and the ability to rely on one's parent(s) as a secure base is the defining feature of attachment security (Ainsworth et al., 1978; Bowlby, 1988).

In early adolescence (~12 years) and early adulthood (~20 years), participants rated the extent to which they felt they could depend on their parents in times of need—the core feature of a secure base. When participants were 32 years old, we conducted home interviews and collected serum to measure CRP. We hypothesized that perceptions of parents as a secure base in early adolescence would predict lower CRP levels in adulthood. We advanced no specific hypotheses about perceptions of parents as a secure base in early adulthood. To test our prediction that the perceived ability to depend on parents for support in times of need specifically would predict adult CRP (as opposed to other forms of support), we also included measures of more general parental support not specific to the secure base function (e.g., providing praise for successful accomplishments) and peer support in the analyses. As expected, after adjusting for inflammation-related confounds (e.g., tobacco and alcohol use, body mass index), perceptions of parental secure base support in early adolescence, but not peer support or other forms of parental support, predicted lower CRP values at age 32. None of the support variables in early adulthood predicted CRP at 32 years.

As discussed at the beginning of this chapter, one possible mechanism by which having a secure base may influence systemic inflammation is stress regulation. Given that stress is associated with elevated levels of inflammatory markers (Glaser & Kiecolt-Glaser, 2005), the enhanced emotion regulation and coping skills that having a secure base promotes may result in lower levels of inflammation in adulthood. Mounting evidence suggests that caregiving experiences influence the calibration and ongoing regulation of the child's HPA axis (Gunnar & Quevedo, 2007), and it may be that HPA axis functioning acts as a mechanism linking early secure base experiences with adult inflammatory activity. It is noteworthy that only parental

secure base support in early adolescence, but not early adulthood, predicted adult CRP. This finding is consistent with recent conceptualizations of adolescence as a sensitive period during which experiences may have long-lasting influences on development (Steinberg, 2005). Additional longitudinal research will help to shed light on how the timing of parental secure base experiences relates to later inflammation.

In summary, the studies reviewed here provide initial evidence for links between individual differences in attachment and inflammatory functioning, particularly inflammatory responses to an acute stressor. However, it is important to note that in one study, attachment style was significantly related to only one of three inflammatory markers (Kidd et al., 2014) and in another, attachment style was unrelated to three markers of systemic inflammation (Uchino et al., 2013). In addition, the available evidence is inconsistent with regard to which dimension of adult attachment is related to inflammatory responses, and the findings of Robles and colleagues (2013) indicate the possibility of gender differences. Clearly, the links between attachment and inflammation are complicated, and much more work needs to be done. Nonetheless, the few studies reviewed in the section provide an important foundation upon which future studies can build.

Attachment-Related Constructs and Inflammation

Although few studies have examined links between attachment specifically and inflammatory activity, several studies have reported associations between constructs that are related to attachment and inflammatory outcomes. In this section, we first review studies within the domain of parent-child relationships, followed by studies within the domain of romantic relationships.

Parent-Child Relationships and Inflammation

Childhood Maltreatment and Harsh Family Climate

A parent who is abusive or neglectful is the antithesis of a secure base for a child. Although nonmaltreated children are likely to turn to their attachment figure in times of threat, maltreated children are faced with a difficult paradox in which their attachment figure is both the source

of the threat and the source of protection (Main & Hesse, 1990). This paradox may result in a lack of an organized strategy for dealing with threats or stressors, which in turn may have negative consequences for immune functioning. Not surprisingly, low rates of secure attachment and high rates of disorganized attachment have been observed in samples of children of maltreating parents (e.g., Cicchetti, Rogosch, & Toth, 2006). In addition, one meta-analysis suggests that the effect of maltreatment on attachment security is large (Cyr, Euser, Bakermans-Kranenburg, & Van IJzendoorn, 2010). Thus, although maltreatment is not a measure of attachment, it has important implications for child attachment security.

Mounting evidence suggests that childhood maltreatment is associated with elevated levels of inflammatory markers in adulthood (see Coelho, Viola, Walss-Bass, Brietzke, & Grassi-Oliveira, 2013, for a review of 20 studies). For example, in the Dunedin Longitudinal Study, childhood maltreatment (a composite of observed maternal rejection at age 3, parent-reported harsh discipline at ages 7 and 9, repeated caregiver changes through age 11, and physical abuse retrospectively reported at age 26) predicted higher CRP at age 32 (Danese et al., 2009; Danese, Pariante, Caspi, Taylor, & Poulton, 2007). Similarly, older adults who reported abuse during childhood had significantly higher circulating IL-6 levels and marginally higher TNF- α levels than adults who did not report being abused as children (Kiecolt-Glaser et al., 2011). Interestingly, one study of women found that retrospectively reported sexual abuse, but not physical abuse, during adolescence was associated with heightened CRP and IL-6 in adulthood (Bertone-Johnson, Whitcomb, Missmer, Karlson, & Rich-Edwards, 2012). Studies utilizing retrospective reports of a harsh, chaotic, and unsupportive family environment also revealed associations between such an environment and heightened inflammatory activity in adolescence and adulthood (Miller & Chen, 2010; Slopen et al., 2010).

In addition to examining systemic inflammation, several studies have tested the association between childhood maltreatment and inflammatory responses to acute stressors in adulthood. For example, Carpenter and colleagues (2010) found that adults who reported maltreatment during childhood showed elevated levels of IL-6 following the Trier Social Stress Test (an acute laboratory stressor) relative to adults who did not report maltreatment during childhood. Similar results

have emerged in relation to naturally occurring daily stressors. Gouin, Glaser, Malarkey, Beversdorf, and Kiecolt-Glaser (2012) found that adults who reported childhood abuse showed greater IL-6 responses to daily stressors than did adults who did not report childhood abuse.

Warm and Supportive Parenting

The studies reviewed here provide compelling evidence for a link between negative parenting practices (i.e., maltreatment) and later inflammation. A related question is whether positive experiences with caregivers are also associated with inflammation in adulthood. Although research in this area is limited, the tentative answer to this question appears to be yes.

In a sample of adults who grew up in low-SES homes, a risk factor for heightened inflammation in adulthood (e.g., Pollitt et al., 2007), those who retrospectively reported high maternal warmth during childhood exhibited reduced proinflammatory signaling in adulthood relative to those who reported low maternal warmth (Chen, Miller, Kobor, & Cole, 2011). In addition, evidence suggests that psychosocial interventions with at-risk children may protect individuals from later heightened inflammation. In a study by Miller, Brody, Yu, and Chen (2014), low-SES African American children and their mothers were randomly assigned to either the Strong African American Families (SAAF) program—a program designed to improve family relationships, parenting behaviors, and children's self-esteem—or a control condition when children were 11 years old. Children who participated in the SAAF intervention had lower levels of six markers of inflammation (IL-1- β , IL-6, IL-8, IL-10, TNF- α , and interferon gamma [IFN- γ]) at age 19 compared to children in the control condition. Mediation analyses suggested that the effects of the SAAF program on later inflammation were partly attributable to improved parenting quality. These studies provide preliminary evidence suggesting that positive parenting practices may be a protective factor that buffers at-risk children from subsequent elevated levels of inflammatory markers. An interesting direction for future research is examination of whether links emerge between positive parenting practices and inflammatory outcomes in low-risk samples.

In summary, the studies in this section indicate links between aspects of the parent-child relationship relevant to attachment and inflam-

matory activity. Much of this work is based on retrospective self-reports of childhood experiences with parents. Prospective studies and the inclusion of observational measures of parenting that are not susceptible to self-report biases would help advance research in this area. In addition, future research should include other measures of parenting and the parent–child relationship. For example, parental sensitivity holds a privileged position within the attachment framework. An interesting question for future research is how early parental sensitivity relates to later inflammation and whether global sensitivity or sensitivity in response to child distress specifically is more strongly predictive of inflammatory functioning.

Romantic Relationships and Inflammation

Nearly three decades of research indicate that adult attachment has major implications for how individuals think, feel, and behave in the context of romantic relationships (see J. A. Feeney, Chapter 21, for a review). Furthermore, the majority of adults consider a spouse or romantic partner to be their principal attachment figure (Zeifman & Hazan, Chapter 20). Thus, although romantic relationship functioning is not a measure of attachment, attachment plays an important role in couple relationships, with secure individuals typically reporting more positive romantic relationships than do insecure individuals. Several studies have examined associations between various aspects of romantic relationship functioning and markers of inflammation. We review these studies below.

Relationship Quality

Two studies using data from the National Survey of Midlife Development in the United States (MIDUS) examined how self-reported marital strain and marital support relate to inflammatory markers in married adults (Donoho, Crimmins, & Seeman, 2013; Whisman & Sbarra, 2012). Whisman and Sbarra included all married participants who participated in the biomarker component of the MIDUS study, whereas Donoho and colleagues (2013) focused specifically on MIDUS participants who had been married for 10 years or longer. Interestingly, both studies found that marital support was associated with lower levels of inflammation in women only. Furthermore, Whis-

man and Sbarra (2012) found that age moderated the association between marital support and IL-6 levels in women: Marital support was related to lower IL-6 levels only among women 53 years old or younger. The link between marital strain and inflammation was inconsistent across the two studies. Donoho and colleagues found that marital strain was associated with higher levels of IL-6 among both men and women, but this association disappeared after adjusting for biobehavioral factors associated with inflammation. Whisman and Sbarra found that marital strain was associated with heightened IL-6, but only among women 53 years old or younger. Given prior evidence that being married (vs. unmarried) is associated with lower levels of inflammation for men only (Sbarra, 2009), one possible interpretation of the gender differences observed in these two studies is that just being married has beneficial health effects for men but, for women, the salutary effects of marriage are much more dependent on marital quality. This interpretation is also consistent with evidence that the effects of marital interactions on physiology are stronger for women than for men (see Kiecolt-Glaser & Newton, 2001, for a review). It is unclear why links between relationship quality and inflammation emerged for younger women only. Given that the mean age of menopause in the United States is 51 years (National Institute on Aging, 2010), 2 years prior to the age cutoff reported by Whisman and Sbarra, it is possible that hormonal changes are involved in observed age differences, although more research is needed to explore whether changes in hormones can explain the age effects observed by Whisman and Sbarra.

Two other aspects of romantic relationship quality that have been examined in relation to inflammatory activity include self-reported couple mutuality and ambivalence about one's spouse. In a study of women with rheumatoid arthritis (RA), perceptions of more couple mutuality—conceptualized as one's own and one's partner's levels of empathy, engagement, authenticity, zest, diversity, and empowerment in the relationship (Genero, Milller, Surrey, & Baldwin, 1992)—were associated with lower levels of inflammation (indicated by erythrocyte sedimentation rate [ESR] 6 months later; Kasle, Wilhelm, McKnight, Sheikh, & Zautra, 2010). The link between mutuality and ESR remained significant after researchers controlled for disease-modifying antirheumatic and anti-inflammatory drugs, suggesting that positive couple relationships may have benefits for RA patients

beyond the benefits associated with traditional pharmacological treatments.

In a study of middle-aged and older adult married couples, Uchino and colleagues (2013) examined how perceived spousal ambivalence (i.e., rating a spouse as a source of both positivity and negativity) in three different contexts relates to serum levels of IL-6, fibrinogen, and CRP. Participants reported how positively and negatively they perceived their spouses during support-seeking, capitalization (i.e., when happy or excited), and routine daily interactions. Participants who simultaneously reported both positive and negative perceptions of their spouse in a support-seeking context had higher levels of IL-6 and fibrinogen, and marginally higher levels of CRP, compared to participants who held completely positive perceptions of their spouse. Perceived spousal ambivalence during capitalization was associated with higher fibrinogen only. No links emerged between perceived spousal ambivalence during routine daily interactions and the markers of inflammation. These findings highlight the importance of taking into account relational context (i.e., support-seeking vs. capitalization) when examining links between romantic relationships and inflammation. Although this study suggests that ambivalent perceptions of one's spouse are worse than completely positive perceptions in terms of inflammatory outcomes, it does not shed light on how ambivalent perceptions compare to completely negative perceptions of one's spouse. However, as the authors note, there are likely few individuals in long-term marriages who have completely negative perceptions of their spouse. Future research involving couples who have been married for shorter periods of time or who have relationship difficulties could provide insight into how ambivalent perceptions of one's spouse compare to completely negative perceptions.

Observed Behavior during Marital Interaction

Kiecolt-Glaser and colleagues (2005) instructed married couples to engage in personal concerns and marital conflict discussions across two consecutive laboratory visits. Using the Rapid Marital Interaction Coding System (Heyman, 2004), the researchers rated each couple's level of hostility during the two discussions. Partners' hostility scores were combined, and couples were classified as high conflict or low conflict using a

median split. The researchers then examined how hostility during the interactions related to blister wound healing and circulating levels of inflammatory markers following the interactions. Couples high in observed hostility had blister wounds that healed more slowly compared to those of couples low in observed hostility. In addition, highly hostile couples showed larger increases in IL-6 and TNF- α levels the morning after the conflict discussion compared to the personal concern discussion, whereas hostile couples low in hostility showed similar increases in IL-6 across both discussions and smaller increases in TNF- α levels after the conflict discussion compared to the personal concern discussion. These findings suggest that hostility in the marital relationship has a deleterious effect on inflammatory regulation, with implications for the speed of wound healing.

Loss of Spouse

The loss of a spouse is, in most cases, the loss of a principal attachment figure. In the third volume of his trilogy, Bowlby (1980) devoted considerable space to discussing the psychological consequences of the loss of an attachment figure. In addition to psychological difficulties, substantial research has documented the negative health consequences associated with the loss of a spouse (e.g., Martikainen & Valkonen, 1996). Schultze-Florey and colleagues (2012) compared circulating levels of inflammatory cytokines in bereaved versus married/partnered individuals. The results revealed that bereaved individuals had higher levels of IL-6 compared to nonbereaved individuals. These results suggest that heightened systemic inflammation may be one mechanism by which the loss of a spouse results in negative health outcomes.

In summary, the studies reviewed in this section demonstrate links between aspects of romantic relationships relevant to attachment and inflammatory activity. As is the case with the studies of the parent-child relationship, much of this work is based on self-reports of marital functioning (the study by Kiecolt-Glaser et al. [2005] is a notable exception). Additional studies utilizing observational measures of couple interactions will help to advance knowledge in this area. An interesting question for future research is whether adult attachment style has an indirect effect on inflammatory activity through romantic relationship functioning. An abundance of research has shown that attachment style predicts many different as-

pects of romantic relationship functioning (see J. A. Feeney, Chapter 21, this volume, for a review), and the studies reviewed here indicate that couple relationships are associated with inflammatory markers. Thus, an indirect effects model seems tenable, and such a model could advance our understanding of the processes by which attachment influences inflammatory outcomes.

Research on the role of attachment in inflammation is only just beginning, and much work remains. The studies reviewed in this section offer initial support for how an attachment theory perspective can provide a useful framework for gaining insight into inflammatory processes in adolescence and adulthood. In addition to the evidence for direct links between attachment and inflammation, there is growing evidence that both predictors (e.g., maltreatment) and outcomes (e.g., marital quality) of attachment security and insecurity are associated with inflammation. Taken together, these findings suggest that attachment is a useful and potentially important construct to consider (as a predictor, mediator, or moderator) when examining associations between relationships and inflammation.

Future Directions

As we mentioned earlier, sufficient evidence exists to warrant further study of the ways in which attachment may be associated with immune functioning in general, and inflammatory processes in particular. We are excited about the many opportunities for advancing the scientific study of attachment and immune processes, and we are confident that researchers who choose to bridge these two areas of study will find that this research adds to the field's understanding of the role of attachment across the lifespan. As others have argued (e.g., Kiecolt-Glaser, 2009), it will be important for researchers to acquire training across disciplines in order to develop sound research studies. As a note of caution, we advise attachment researchers to form collaborations with researchers who already have an established program of PNI research. These partnerships will ensure that research questions are grounded in appropriate theory, that study designs take into account the practical realities of conducting biomedical research, and that proper analytical techniques are used. Below, we have identified several opportunities for future research.

Establishing Basic Links

As we reviewed earlier, although a large body of research has examined links between inflammation and measures that are correlated with attachment (e.g., warmth, marital quality), only a handful of studies have tested links between measures of attachment and inflammatory processes. As such, a critical first step is to build a foundation of studies that examine these associations in a diverse set of samples, with children and adults, and with different measures of attachment (e.g., self-reports, observations, interviews). These studies will help refine our understanding of how attachment is associated with inflammation and other immune processes, and whether this pattern should be expected to emerge across development, at key developmental transition periods, or only within specific age groups (e.g., later in life, when inflammation becomes increasingly prevalent). We have no reason to suspect that these hypothesized links will be limited to particular racial or ethnic groups; nevertheless, examination of these proposed links across diverse sample populations will be important for determining whether these proposed connections are robust across populations.

Two questions are important to keep in mind as researchers continue with studies of attachment and immune functioning. First, what are the limits of attachment as a predictor of immune function and physical health? We cannot expect attachment to predict *all* indicators of immune functioning. In this chapter, our focus has been on inflammation, which is part of the innate immune response that begins within hours of exposure to infection. Although we have deliberately excluded studies of *adaptive immunity* (the branch of the immune system involved in acquired or "learned" immunity), there is some evidence that attachment may play a role in adaptive immune responses as well (see Picardi et al., 2007, 2013). Some models of stress-immune system links, however, propose that stress may differentially affect innate and adaptive immune responses (Fagundes et al., 2013; Segerstrom & Miller, 2004). Thus, an important direction for future research will be to chart the contours of attachment's relation to various dimensions of immune functioning. The second question that researchers need to keep in mind is: In what ways can attachment add to the existing body of research on links between inflammatory processes and other relationship factors, such as warmth, hostility, and support? Some researchers will understandably be concerned that

attempts to study links between attachment and inflammation simply constitute a rebranding of existing research that has examined relationship characteristics and inflammatory processes. One way to tackle this concern is to include measures of additional nonattachment components of relationships in analytical models in order to compare the unique role of attachment in shaping inflammatory processes (e.g., Jones et al., 2015). Our hypothesis is that attachment—and the presence of a secure base in particular—represents a unique characteristic that should help people when confronted with stressful experiences. As we move forward with this research, it will be important to consider how attachment can add to our growing understanding of how the social environment contributes to health and disease.

Special Populations

Much of the work on psychosocial processes associated with inflammation has been done with healthy samples of children and adults, under the premise that if the risk exposure is sustained over time (e.g., if individuals experience poverty for long periods), then people will experience chronic inflammation and therefore be at risk for disease later in life. Another option is to do research with people who are already sick in order to examine how psychosocial influences shape disease-relevant inflammatory processes, and whether these changes in inflammation result in changes in disease symptoms.

Some examples of the value of a disease-centered approach can be found in studies of children with asthma (e.g., Chen & Schreier, 2008; Kaugars, Klinnert, & Bender, 2004; Marshall, 2004; Wright, 2008). Asthma, a chronic respiratory disorder and one of the most common chronic diseases in childhood, affecting over 7 million children in the United States (Bloom, Cohen, & Freeman, 2012), is a complex multifactorial disease, characterized by reversible airway hyperactivity and obstruction that develops in response to allergens, pollutants, irritants, and other stimuli (Busse & Lemanske, 2001). The immune system plays a key role in many cases of asthma, launching exaggerated responses to stimuli that cause mucus production, airway constriction, and difficulties breathing. In recent years, researchers have documented associations between psychosocial factors and the expression of asthma symptoms (Marshall, 2004; Wright, 2008). Notably, some of

the most reliable psychosocial predictors of asthma expression are family-related stressors (Chen & Schreier, 2008; Kaugars et al., 2004). Furthermore, a growing body of evidence suggests that family stressors might amplify children's immune responses to environmental stimuli (e.g., allergens and pollutants) in a manner that exacerbates asthma symptoms (Chen et al., 2006). Some evidence suggests that insecure attachment is a risk factor for asthma (Cassibba, Van IJzendoorn, Bruno, & Coppola, 2004; Mrazek, Casey, & Anderson, 1987), although investigations of connections between attachment and asthma-relevant measures of inflammatory processes have been lacking.

Attachment as a Moderator

As we mentioned earlier, we hypothesize that attachment may play an important moderating role in the already established links between stressors (e.g., early adversity) and inflammatory processes. Our central premise for this hypothesis is that the presence of a reliable and sensitive caregiver is known to attenuate stress responses (Adam, Klimes-Dougan, & Gunnar, 2007; Cassidy, Ehrlich, & Sherman, 2013), so, for securely attached individuals, exposure to stressors may be less overwhelming, leading to a less aggressive inflammatory state. Some recent evidence suggests that parents can indeed serve as buffers for children who are exposed to adverse conditions (e.g., Chen et al., 2011; Evans, Kim, Ting, Teshler, & Shanis, 2007; Miller et al., 2011). It will be important to determine the extent to which sensitive parenting can shield children from the inflammatory consequences often associated with adversity.

Even in the absence of extreme adversities, secure attachment may serve a protective function for individuals who experience other acute and chronic stressors. Attachment influences individuals' perceptions, interpretations, and memories of relationship experiences (Dykas & Cassidy, 2011). Securely attached individuals may view stressful experiences (particularly within a relationship context) through a lens that reduces the negative impact. For example, interpersonal conflict might be viewed as a way to resolve differing opinions and reach a mutually beneficial solution for secure individuals, but it might be viewed as a threat to the relationship for insecure individuals. Thus, despite evidence that conflict is associated with inflammation (e.g., Fuligni et al., 2009), this link may not exist or may be attenuated for those who are securely attached.

Interventions

A compelling body of research suggests that exposure to stressful experiences shapes long-term health outcomes, and systemic inflammation may play an important mediating role in this link (Ehrlich, Miller, & Chen, 2016; Miller et al., 2011). Most of the research supporting this model, however, has been correlational—with many studies relying on cross-sectional designs or retrospective reports—and these study designs rightly come with some criticisms. Researchers' ability to draw conclusions about the causal nature of these links is sharply limited with correlational studies. It is understandable that the bulk of this research would rely on correlational data in light of the concerns about manipulating social experiences, but intervention studies offer a useful avenue for pursuing experimental studies of the causal connections between caregiving experiences and inflammation. As described earlier in this chapter (Miller et al., 2014), there is evidence that family-oriented interventions can reduce inflammation in at-risk children. Additional evidence with a sample of healthy adolescents suggests that an intervention aimed at increasing volunteering was effective at lowering inflammation (Schreier, Schonert-Reichl, & Chen, 2013). Further analyses suggested that these effects may have been partially due to increases in empathy and altruistic behaviors. Researchers with ongoing longitudinal studies aimed at improving attachment security should consider including assessments of physical health and inflammation in order to examine whether the intervention had an effect on these measures. Ideally, new interventions will include baseline measures of inflammation to ensure that the groups do not differ at the outset, but we encourage researchers with existing samples to include measures of inflammation in follow-up assessments as a first step.

Dyadic Approach

Both parent–child relationships and adult romantic relationships are bidirectional and transactional (i.e., relationship partners reciprocally influence each other). Yet much of the research on attachment (and attachment-related constructs) and immune processes to date has focused on intrapersonal predictors of immune function (i.e., one's own attachment style or report of marital adjustment). Some researchers have already called for a more dyadic approach to studying links between close relationships and health. For example, Pi-

etromonaco, Uchino, and Dunkel Schetter (2013) presented a theoretical model outlining how each partners' adult attachment style and dyadic processes (e.g., each partner's responsiveness) in close adult relationships may influence health behaviors and outcomes. We echo Pietromonaco and colleagues' call for a greater focus on dyadic processes and encourage researchers to test dyadic predictors of inflammation and other immune markers. For example, does a wife's degree of attachment-related avoidance or anxiety predict her husband's inflammatory response to some type of acute stressor, and vice versa? Furthermore, do spouses' attachment styles interact to predict immune markers in each individual? In a sample of married dyads, Gouin and colleagues (2009) did not find evidence for effects of partner attachment style on a spouses' IL-6 production, but additional research on dyadic effects on inflammatory processes is warranted.

This dyadic and transactional approach to studying immune processes can also be extended to parent–child relationships. One study found links between psychological characteristics of parents and inflammation in their children (Wolf, Miller, & Chen, 2008). Specifically, Wolf and colleagues (2008) found that more parental depressive symptoms and greater parental stress predicted increases in children's asthma-related inflammatory processes over time. This finding raises many interesting questions that may be of particular interest to attachment researchers and should be the focus of future research. For example, do children of insecure parents differ from children of secure parents in terms of inflammation? Conversely, do parents of insecure children differ from parents of secure children on immune measures? Furthermore, in two-parent families, do parents' respective attachment styles or states of mind interact to predict child immune outcomes? Finally, the observational methods that have been used to examine inflammatory responses following interactions with a romantic partner (e.g., Kiecolt-Glaser et al., 2005) can be adapted for use with parent–child dyads. For example, how do parent and adolescent attachment style (and the interaction of the two) relate to inflammatory responses following a discussion of a source of conflict in their relationship? In summary, taking a dyadic approach in the study of attachment and inflammatory processes will help to capture the richness and complexity of relationships and will help to provide insight into how attachment, in both parent–child and romantic relationships, relates to immune functioning.

Developmental and Lifespan Focus

Much of the existing literature on attachment (and attachment-related measures) and immune functioning has been conducted with adults; it will be important to conduct studies across all developmental periods, including studies with infants, children, and adolescents. We acknowledge that this work will not be easy given participant fears of blood draws. But a developmental approach to the study of attachment and immune functioning is critical to understanding how caregiving experiences influence health-relevant biological processes and at what point in development these processes begin to unfold. Furthermore, many biological systems are especially sensitive to environmental effects, particularly in infancy and adolescence, so examination of attachment during these sensitive periods is especially pertinent. Moreover, many biological systems undergo a rapid period of development, expansion, and specialization in early childhood and adolescence, and it may be that caregiving experiences during these developmental periods are especially likely to influence biological systems, with long-term implications.

A truly developmental research approach begins with prenatal studies. The *fetal-programming model* (Lucas, Fewtrell, & Cole, 1999) argues that *in utero* experiences shape infants' development by exposing them to maternal signals about environmental conditions after birth. Pregnancy brings a number of physiological adaptations, including changes to the immune system to reduce the risk of fetal rejection, maintain protection against infection, and prepare for childbirth (Challis et al., 2009; Sacks, Sargent, & Redman, 1999). A growing number of studies have examined the ways that maternal stressful social relationships shape adverse pregnancy outcomes, including preterm birth, preeclampsia, and gestational diabetes, and accumulating evidence suggests that inflammatory processes play a critical role in mediating these links (Christian, 2012; Coussons-Read, 2012). To what extent does maternal attachment insecurity shape inflammatory processes that shape pregnancy outcomes?

Attachment security can be stable across the lifespan, but it can also change as a function of caregiving experiences and changes in the family environment. Another question that will be important to consider is the relative timing of attachment experiences across the lifespan, and how variations in attachment security over time shape inflammatory processes and health. Are there

particular sensitive periods (e.g., infancy) during which attachment security is most likely to shape inflammatory processes in the decades to follow? Alternatively, can attachment be viewed from a cumulative risk framework, wherein a dose-response relation exists between the number of years of insecure attachment and inflammation? These questions require large data sets, with many years of assessment of both attachment and inflammation, in order to test competing hypotheses about the nature of attachment-inflammation links (see, e.g., Eisenberger et al., 2010, for discussion of the direction of effects in the link between inflammation and depressive symptoms). Nevertheless, the answers to these questions will help elucidate the role of attachment for immune functioning across the lifespan.

Conclusions

Because examination of the links between attachment and immune functioning is a new area of research, the number of documented links between these two factors remains quite small. Nevertheless, we believe that the field is reaching a tipping point, and we are eager to see what new insights emerge in our understanding of how attachment experiences shape our immune systems across the lifespan. This interdisciplinary research has the potential to shed light on the varied ways that attachment experiences come to shape development and functioning. We hope that researchers will not be deterred by the complexities of embarking on this program of research, and that they will be motivated to pursue the exciting task of bridging these two fields.

Chapter 10

Attachment and Temperament as Intersecting Developmental Products and Interacting Developmental Contexts Throughout Infancy and Childhood

Brian E. Vaughn
Kelly K. Bost

For developmental scientists, the principal motivations for engaging in developmental research are (1) the desire to describe the emergence of organismic forms in the material, behavioral, psychological, and/or historical realms and (2) the desire to both characterize and explain the progressive transformations of those forms over the lifespan. An additional, but also vital, motivation is to use the information obtained from basic understandings of the emergence and transformation of forms to describe and explain individual, group, and population variability in developmental trajectories, especially with reference to the antecedents of favorable and unfavorable life course outcomes.

Although describing these motivations is easy enough, developmental scientists also acknowledge that studies of emergent forms are complex: Growth trajectories for different forms often intersect and interact to modify initial growth trajectories in ways that cannot be anticipated by knowledge of the phenomena prior to their interaction. Moreover, it is becoming increasingly clear that many life course outcomes thought to be associated with individual differences in specific

developmental trajectories are contingent on the outcomes of the interactions among different trajectories and/or their interactions with the physical and social contexts within which those trajectories are realized. An inevitable consequence of taking the interactions among developmental trajectories and their contexts seriously has been the recognition that current conceptual/theoretical frameworks used to describe specific developmental phenomena and to explain individual differences in developmental trajectories are, at best, incomplete and require expansion, revision, or replacement.

In this chapter, we address these issues for the two most widely accepted and empirically supported developmental frameworks that have been proposed as explanations of individual differences in socioemotional adaptation and the construction of personality, namely, attachment and temperament. In previous editions of this handbook, we have discussed the conceptual foundations of the two theoretical domains, their common (and different) aims and claims, and the results of studies focused on the nature of relations between these domains and on their joint prediction of salient life outcomes for infants and children. In the first

major section of this chapter, we reprise themes from previous editions because they ground the arguments that follow.

In the second section, we review studies published since 2007 that have examined the interaction of attachment and temperament constructs in relation to life course outcomes. Among these studies, several have tested for evidence of differential susceptibility to environmental influences. Individuals located within one region of a trait dimension may be especially vulnerable to social environments of lower quality, *but* may benefit from very high-quality social environments to a greater extent than children located at different regions of the same trait dimension. We also consider recent studies that have tested the interaction of temperament and behavioral contexts (usually parenting quality) as a predictor of children's attachment-related outcomes. We then review recent studies that have extended the scope of attachment and temperament research to health-related topics and focus on the pediatric obesity literature as an example. Unfortunately, the joint effects of attachment and temperament or their interactions were not examined in these studies. The chapter concludes with an appeal for more theory-driven research on relations between attachment and temperament domains.

Attachment and Temperament: Background

Grounding the Theories

At the core of Bowlby and Ainsworth's attachment theory are questions concerning why and how bonds between children and their primary caregivers are constructed over the early years, as well as how the shared experiences leading to and maintaining attachment relationships shape and guide children's developmental trajectories of behavior, affect, cognition, and the formation of subsequent close relationships. The theory contains both explicit and implicit assumptions concerning socioemotional development and adjustment across the lifespan; nevertheless, attachment *relationships* are social co-constructions, and the central premises of the theory concern the making, maintenance, breaking, and subjective meaning of those relationships.

By way of comparison, modern temperament theory (e.g., Rothbart, 2011) was intended to describe and explain endogenously organized

individual differences in action styles, reactivity, and regulation. Temperament theory stipulates that these differences are grounded in neurophysiological mechanisms underlying activity, affect, attention, and the regulation of these domains (e.g., Posner & Rothbart, 2009; Rothbart & Bates, 2006). Temperament dimensions are often (but not always) discussed as "core" aspects of personality (see Rothbart & Bates, 2006). Temperamental differences carry substantial implications for the quality and adaptedness of personality and social behavior over the life course, although the routes of temperamental influence(s) can be both direct and indirect (e.g., Rothbart, Posner, & Hershey, 1995). Unlike attachments, temperamental traits are not construed as products of social interactions or relationships, but some temperament traits may be modified as a result of transactions with the social environment (e.g., Braungart-Rieker, Hill-Soderlund, & Karrass, 2010; Pesonen et al., 2008).

Attachment

Bowlby (1969/1982, 1973, 1980) borrowed concepts, insights, and empirical findings from several intellectual traditions in formulating attachment theory. Psychoanalytic/object relations theory was a source of insights concerning the nature of the infant-caregiver relationship. For example, the infant-caregiver relationship was viewed as a true love relationship, with all of the emotional implications of a love relationship, and dissolution of this relationship through prolonged separations was thought to precipitate a grief reaction in the child. Moreover, the early child-caregiver relationship served as a model that influenced the ways in which a child's future intimate relationships were constructed. Finally, social and psychological adjustment was conceptualized in terms of the capacities to work, love, affiliate, and play. To the extent that attachments constructed in the context of caregiver-infant interactions constituted the foundation for learning to "love well," they constituted a cornerstone for inter- and intra-personal adjustment across a lifetime.

Ethological and comparative psychological research provided Bowlby with motivational constructs (e.g., the attachment behavioral system) and the empirical data he needed to explain a child's tendency to seek and maintain proximity to caregivers, without having to appeal to traditional behaviorist or psychoanalytic models. Bowlby (1969/1982) suggested that human infants are

equipped with a rudimentary attachment behavioral system at birth that is organized to maintain proximity to the caregiver in the first years of life, and that this behavioral system governs the expression of attachment behavior on a moment-to-moment basis. He explained the presence of this behavioral system as an evolved adaptation that increased the likelihood of infant survival in the environments inhabited by early human populations.

Properties of this behavioral system were characterized using control systems concepts (e.g., proximity to the caregiver is the system's "set-goal," and the degree of proximity is dynamically adjusted through "goal-corrected behavior" that is informed by "feedback" from sensory inputs to the system). Bowlby also coordinated his developmental schedule for the emerging attachment relationship with Piaget's periods of sensorimotor and preoperational intelligence. Like Piaget, Bowlby believed that infants and young children actively participated in their own development, and he saw active participation as a defining difference between attachment theory and both psychoanalytic and behaviorist explanations of the child-caregiver bond.

Bowlby believed that repeated activations of attachment behavior over the early years resulted in the child's constructing an internal (or mental) model of the resulting relationship. He based his concept of "internal working models" (e.g., Bowlby, 1973) on the ideas of Craik (1943), who had suggested that people construct mental models for all kinds of physical and social phenomena as heuristics for explanation of the operation and functioning of those phenomena. Bowlby found the concept attractive because it suggested both a process and a structure for preserving the child's attachment relationship in the absence of overt attachment behavior and also in the absence of the caregiver (see Bretherton & Munholland, Chapter 4, this volume).

NORMATIVE CLAIMS

From an attachment perspective, the child-caregiver bond is a special sort of relationship (i.e., a love relationship) arising from the operation of an evolved behavioral system acting to promote proximity and contact with the primary caregiver in the service of survival. As the system is activated in both normal and emergency situations (i.e., when the infant is stressed by internal or by

external stimuli) and as the set-goal is repeatedly attained (i.e., contact or proximity is achieved), the pattern of individual interactions becomes organized as a recognizable and unique relationship characterizing the child-caregiver dyad (for discussion of connections between interactions and relationships, see Hinde, 1987; Hinde & Stevenson-Hinde, 1987). This relationship is co-constructed with the caregiver over ontogenetic time in a regular, expectable sequence that parallels the growth of sensorimotor intelligence. Further activity of the behavioral system in the context of an attachment relationship provides input for the assembly of the *internal working model* of the relationship and of related models of the attachment figure and of the self. These assumptions constitute the normative, species-specific claims for attachment theory.

INDIVIDUAL-DIFFERENCE CLAIMS

Another influence on Bowlby's thinking about attachment arose from his association with Mary Ainsworth, whose research focused on the "security" construct (i.e., the feeling of safety and comfort arising from the satisfaction of basic physical and psychological needs and from the knowledge that future satisfaction of needs is not at risk). She recognized that the attachment relationship should be the primary source of security for a young child. That this relationship is a source of security can be inferred from the organization of the child's behavior with reference to the caregiver. As Ainsworth observed, for example, in 1967, the child uses the caregiver as a base for exploring the local environment in both familiar and unfamiliar settings. Furthermore, when distressed, threatened, or simply bored, proximity and contact with the caregiver generally returns the "system" to a more balanced state, allowing the child to continue exploration. She referred to the balance of attachment and exploratory behavior organized around a specific caregiver as the "secure base" and "haven of safety" phenomena (Ainsworth, Blehar, Waters, & Wall, 1978).

Although Bowlby's account of attachment co-construction was normative, he emphasized that attachment had individual-difference implications in the domains of personality and socio-emotional adaptation. Security theory provided a means for exploring those implications. Fieldwork convinced Ainsworth (1967; Ainsworth et al., 1978) that differences in the patterns of secure base

behavior characterizing different child–mother dyads reflected differences in the effectiveness of the attachment relationship as a source of security. Although differences in the organization of secure base behavior were apparent at home (e.g., Ainsworth et al., 1978; Vaughn & Waters, 1990), they were also distinguished by qualitatively distinct responses of the child to separation and reunion events in the Strange Situation procedure (Ainsworth et al., 1978). Drawing on naturalistic observations of child–mother interactions at home, Ainsworth and colleagues (1978) argued that the differences in secure base behavior seen in the Strange Situation were predictable from qualities of mother–infant interaction over the first year of life. In general, caregivers who typically respond sensitively to their child’s communicative signals have securely attached children (De Wolff & Van IJzendoorn, 1997). Thus, individual differences in attachment behavior organization reflect accommodations of the child’s attachment behavioral system to characteristic qualities of the interactive environment. Differences in experienced attachment relationships influence personality development and psychosocial adjustment by virtue of their influences on beliefs and expectations concerning the self and the self in relation to others.

Temperament

For over 15 years, the psychobiological theory of temperament articulated by Rothbart (e.g., Rothbart, Sheese, Rueda, & Posner, 2011) has dominated temperament research. Rothbart defines *temperament* as affective, motivational, and cognitive adaptations based on inherited neuroanatomical and physiological structures that may also be shaped by experience. Individual differences with respect to reactivity and regulation in the domains of attention, emotionality, and motor activity are the phenotypic expressions of temperament. Rothbart and Bates (2006) defined *reactivity* as a person’s characteristic mode of responding to changes in stimulation, including responses at behavioral, autonomic, and neuroendocrine levels. *Self-regulation* was defined as the processes operating to adjust the person’s characteristic level of reactivity across domains in response to variations in environmental demands (see Block & Block, 1980, for a similar characterization of broader personality constructs that include temperamental traits as subordinate elements, but also incorporate an individual’s life history).

Biological mechanisms associated with individual differences in reactivity are active early in life, although reactivity is expressed within motivational systems that develop as individual modules. Regulatory processes depend on maturation of the central nervous system; consequently, they develop on uneven schedules over the early years. For example, regulatory mechanisms controlling autonomic and neuroendocrine functions mature earlier than conscious regulatory processes such as “effortful control,” which are thought to modulate reactivity for motor behavior, thought, and emotions (e.g., Rothbart, Sheese, & Posner, 2007). Rothbart and Bates (2006) suggested that the consolidation of regulatory capacity could change a child’s characteristic level of reactivity between ages 3 and 6 years. Consequently, long-term rank-order stability of temperament dimensions may be expected to be modest from infancy but should increase after toddlerhood (e.g., Putnam, Rothbart, & Gartstein, 2008).

Rothbart and associates (e.g., Posner & Rothbart, 2009; Rothbart et al., 2007, 2011) have reviewed broad literatures concerning the genetic and neuroanatomical structures supporting both the reactive and the regulatory aspects of temperament. A range of brain structures and asymmetries of brain activation have also been identified as predictors of both approach and inhibitory aspects of temperament (e.g., Hane, Fox, Henderson, & Marshall, 2008; He et al., 2010), although the expected pattern of relations between asymmetry of brain activity and inhibitory temperament dimensions are sometimes counter to prediction (e.g., LoBue, Coan, Thrasher, & DeLoache, 2011).

These kinds of results offer compelling evidence that variations in human action, cognition, and emotion have a material basis, and that the central nervous system participates in these functions in a complex, transactional manner. Moreover, results of these studies support the notion that virtually every physical/physiological “structure” associated with temperamental variability has multiple functions in both development and adaptation, and that these functions may become reorganized as the environments to which the child must adjust change over ontogenetic time. Finally, these studies highlight the interactive nature of this underlying material participation in behavior, cognition, and emotion, insofar as “effects” of temperament and their underlying structures are often mediated and/or moderated by aspects of the physical and social environments (e.g., Davidson & McEwen, 2012).

NORMATIVE CLAIMS

Rothbart (2011) argues that the underlying neural and physiological structures governing motivation (e.g., approach–withdrawal, avoidance), emotion (e.g., fear, anger, joy), and their regulation are species-specific attributes of humans, and that these structures are assembled according to prescribed developmental schedules over the first years of life. These structures function in support of the organism's viability during infancy and childhood, suggesting that they are evolved adaptations. For example, emotions and affects convey information to the experiencing child about the salience and valence of the surrounding environment, in terms of that environment's support (or threat) to the experiencing infant or child's current well-being (e.g., Campos, Frankel, & Camras, 2004; Campos, Thein, & Owen, 2003), and the behavioral manifestations of affect regulate behavior in both self and others (e.g., Walle & Campos, 2012). Likewise, mechanisms regulating the experience of affects/emotions (as well as thought and action), both in terms of the intensity and duration of the experience and in terms of the frequency with which specific states are experienced, have adaptive consequences (e.g., Diamond & Aspinwall, 2003; Shin et al., 2011). Normatively then, temperament is the nexus of linkages among neuroanatomical, neuroendocrine, and physiological systems that controls the phenotypic expression of system functions at the behavioral, feeling, and mental levels.

INDIVIDUAL-DIFFERENCE CLAIMS

Of course, temperament concepts refer to individual differences within a population, and variability of phenotypic expression gives rise to notions of temperamental reactivity *dimensions* and their regulation. An infant's temperament is construed as a biological "given" or essence that is, at least potentially, present from conception forward, and it is this essential quality that defines the mode(s) of adaptation possible for a given child in the face of a variable environment.

Because temperament is an essential quality of the child, Rothbart and Bates (2006) argued that temperamental variability necessarily contributes to later variability along dimensions of personality (e.g., Grist & McCord, 2010). Moreover, temperament is linked, both directly and indirectly with adjustment (and maladjustment) over the lifespan (e.g., Bush, Lengua, & Colder,

2010; Chen, Deater-Deckard, & Bell, 2014; Mills et al., 2011; Zalewski, Lengua, Wilson, Tranick, & Bazinet, 2011).

How Attachment and Temperament Overlap

Conceptual Overlap and Distinctions

Attachment theory and Rothbart's psychobiological temperament theory are similar in several respects. In both theories, the expression of action, affect, and thought in relevant domains is grounded in neuroanatomical and physiological structures whose functions promote the immediate survival of the individual, and these structures orient the individual's trajectory of future growth and adaptation. Likewise, both describe regulatory mechanisms and processes as central aspects of the theory. In both frameworks, underlying processes related to the phenotypic expression of system function and system regulation are assumed to develop early in life. Finally, both theories propose that aspects of personality and intra- and interpersonal adjustment are influenced by the quality of adaptation within those domains. Given these metatheoretical similarities and the overlap in content between the two theories, perhaps especially with respect to affective experience, it is not surprising that the early research attempting to integrate these approaches emphasized contests over the overlapping content at both conceptual and empirical levels (see Mangelsdorf & Frosch, 1999; Vaughn & Bost, 1999; Vaughn & Shin, 2011). However, by the advent of the current millennium, it was generally accepted that neither attachment nor temperament theory could subsume the other, and researchers began to explore the interactions between domains as predictors to intra- and interpersonal adjustment outcomes (see Vaughn, Bost, & Van IJzendoorn, 2008).

Despite their similarities, attachment and temperament theories are intended to explain very different phenomena. The central problem addressed by attachment theory is the construction and maintenance of interpersonal relationships and their consequences for the developing child over the life course. As such, attachment is a social and psychological phenomenon that cannot be reduced to the activity of central nervous system structures governing proximity and contact seeking. For Bowlby (e.g., 1969/1982), the attachment behavioral system acts to promote proximity and contact between the child and caregiver, and

it is the history of experiences in which proximity and contact regulate the child's internal state (e.g., Feldman, Singer, & Zagoory, 2010) that result in the assembly of the attachment relationship. Consequently, it is a social process involving the child and caregiver that determines the outcome of attachment system activation. Temperament theory, on the other hand, assumes that reactivity and regulation of affect, attention, as well as motor activity are determined primarily by "set-points" for neuroanatomical and physiological structures that are internal to the child and variable across children (Rothbart 2011). Rothbart and Bates (2006) acknowledge that the child's characteristic degree of reactivity may be modified internally, as regulatory mechanisms and processes mature, or externally, as a consequence of experience (e.g., Blair et al., 2006), but temperament remains an essential attribute of the child that is not explicitly relational at any developmental period.

Developmental aspects of temperament theory address questions concerning the sources of age-related differences in the trajectories of reactivity and regulation within persons, whereas the developmental aspects of attachment theory address questions concerning the gradual assembly of the attachment relationship between the child and caregiver(s) over the early years. Consequently, normative questions arising from assumptions of attachment theory (e.g., Bowlby's assumption that establishing a primary attachment relationship is a normative developmental accomplishment) do not intersect with the assumptions of temperament theory. However, Rothbart and colleagues (e.g., 2011) and others have drawn attention to the developmental/organizational aspects of temperamental reactivity and the (potentially) reorganizing effects of emergent regulatory mechanisms that mature according to different timetables, as well as the potential effects of external regulators of reactivity, which might include attachment.

Empirical Overlap

Research examining both attachment and temperament domains has suggested that the caregiving environment supporting the formation of attachment relationships also influences aspects of temperament. Propper and colleagues (2008) reported that genetic risk for suboptimal vagal regulation in response to a stressor was moderated by maternal sensitivity (i.e., when a child with the "risk" allele had a mother with higher maternal sensitivity,

vagal regulation did not differ from that of children with the "low-risk" allele). Similarly, Jahromi, Putnam, and Stifter (2004) reported that maternal interventions regulated distress reactivity in 2- and 6-month-olds, and that multiple modes of intervention were more effective than any single intervention tactic. In another study, Paulussen-Hoogbeem, Stams, Hermanns, Peetsma, and van den Wittenboer (2008) found that parenting style mediated a relation between negative emotionality and internalizing problem behaviors in childhood, such that authoritative parenting style fully mediated the relation between child negative emotionality and internalizing problem behaviors. Braungart-Rieker and colleagues (2010) reported that maternal sensitivity moderated the trajectory of fear reactivity from the first to second year. Infants with more sensitive mothers showed smaller increases in fear reactivity than did infants with less sensitive mothers. Finally, Hane and Fox (2006) studied neural indicators of stress reactivity and emotionality in relation to maternal care behavior. They found elevated indicators of stress reactivity for infants of mothers who provided low-quality care. Most of these studies cannot speak to causal ordering of infant reactivity or regulatory capacity and parental behavior because assessments of both were concurrent. Nevertheless, the findings suggest that reactivity of some physiological and psychological systems underlying temperament is relatively labile during the early years. This conclusion is consistent with Rothbart and Bates's (2006) suggestion that social forces can modify initial levels of reactivity.

In the previous edition of this volume, we reviewed a handful of studies that examined interactions of attachment and temperament and/or interactions of parenting antecedents to attachment and temperament. These studies did not yield to a simple interpretation, in part because much of this research was not directed to attachment or to temperament questions per se; rather, the goals were to explain adjustment (or maladjustment) at some developmental period in terms of being predictable from temperament and attachment security and/or parenting practices. In the next section, we continue our review of studies published since 2007 that test interactions between temperament and attachment variables. We first review research addressing the direct and interactive effects of attachment and temperament on salient outcomes, then consider the question of differential susceptibility (e.g., Belsky & Pluess, 2009; Pluess & Belsky, 2010), which has become a focus of attachment

and temperament research since the previous edition of this handbook appeared.

Attachment and Temperament Interact to Predict Behavioral, Personality, and Mental Health Outcomes

Mediating and Moderating Interactions

Mediating Interactions

The notion of *mediation* has two somewhat different meanings in developmental research. The traditional meaning (Baron & Kenny, 1986) concerns causal implications of a predictor variable on an outcome that is largely indirect; that is, a predictor (A) does not directly cause the final outcome (C); rather, it is causally antecedent to an intermediate variable (B) that is the causal antecedent to the outcome (C). When C is regressed on both A and B, the intermediate variable is the primary (or only) significant predictor. Models testing this kind of mediation often measure predictors and outcomes that are temporally ordered, such that A is measured before B, which is measured before C. A second kind of statistical mediation analysis uses data collected concurrently and should not presume causal influences of predictors on outcomes. When this sort of analysis is attempted, it is prudent to test multiple models that switch the order of A and B in the prediction of C, to determine whether a mediating interpretation is justified. In our literature review, we found four published papers that tested mediating effects for attachment and temperament. In each study, tests for mediation of an attachment (A) and outcome (C) association by a temperament variable were reported. Two studies used temporally ordered measurements, and two used concurrent (or nearly so) measurements.

Drake, Belsky, and Fearon (2014) tested the hypothesis that a relation between attachment security (Strange Situation procedure classifications) and school engagement in grade 5 was mediated by temperamental regulatory capacity. Significant indirect effects were observed, but only for one (of three) regulation measures. Rispoli, McGoey, Koziol, and Schreiber (2013) tested a model predicting child social competence in kindergarten that included an indirect pathway from attachment security (using an adaptation of Waters's Attachment Q-Sort [AQS], sorted by observers)

through preschool temperament (negative emotionality) to social competence. They failed to find a temperamental mediation, although a significant indirect pathway was observed through parent emotional supportiveness. The model reported did not include direct paths from attachment to social competence, so the degree of mediation is difficult to estimate.

Two studies (i.e., Heikamp, Trommsdorff, Druet, Hübner, & von Suchadoletz, 2013; Panfile & Laible, 2012) tested for mediation effects using concurrent data. They reported that the relation between attachment (Waters's AQS sorted by mothers) and empathy was mediated by emotion regulation. The relation between attachment and empathy was not significant when the pathway from emotion regulation to empathy was included in the model. However, in the Heikamp and colleagues (2013) report, both the indirect pathway (via inhibitory control) and the direct pathway from attachment (maternal AQS sorts) were significant when predicting regulatory capacity. Neither of these studies reported the results of alternative models switching the initial and mediating predictors. Taken together, these results provide weak evidence that effects of attachment on subsequent outcomes are mediated by temperamental differences. However, this conclusion is tempered by the acknowledgment that the studies differ in important ways in terms of both attachment measures and the temperamental variable chosen for testing mediation.

Moderated Interactions

Bergman, Sarkar, Glover, and O'Connor (2008) examined relations between prenatal stress and early childhood fearfulness as a function of attachment classification category (4 categories scored using the Cassidy, Marvin, and MacArthur Working Group Strange Situation Procedure Protocol, 1992). Interaction plots suggested that the moderation effect was due to differences between the insecure-resistant (high-positive association) and insecure-avoidant cases (small-negative association), with slopes for other categories suggesting moderate positive relations between prenatal stress and fearfulness. Stevenson-Hinde, Shouldice, and Chicot (2011) also reported a moderating effect of the maternal anxiety \times child behavioral inhibition relation that was due to a difference for the insecure-resistant cases. In this instance, however, the association was signed negatively. Although both studies reported moderation, their results are con-

tradictory. In another report, Kochanska and Kim (2013) tested moderation of a relation between toddler anger proneness and subsequent parental power assertion in discipline settings (which, in turn, predicted children's later rule violation and reduced capacity to delay gratification). However, this chain of associations was observed only for insecurely attached children.

Temperamental moderation of attachment to subsequent outcome associations was reported in two studies. In a sample of toddlers (33 months old), McElwain, Holland, Engle, and Wong (2012) found that anger proneness moderated relations between attachment security and child–mother interaction patterns for children with high and low anger proneness. Attachment security (scored on a 9-point scale from the protocol by Cassidy et al., 1992) was positively associated with committed compliance (in challenge tasks) and self-assertion (in play tasks) when children scored higher on anger proneness. However, children with higher security scores engaged in more help-seeking behavior during play if they had low or moderate anger proneness scores. Troxel, Trenacosta, Forbes, and Campbell (2013) found that infant negative emotionality moderated effects of attachment (AQS by observers at 24 months) on sleep problems at 36 months. Children with higher AQS security scores were reported to have fewer sleep problems, but only if they had higher negative emotionality scores at 6 months.

Although these studies suggest that attachment and temperament domains do (sometimes) interact in the prediction of subsequent outcomes, inclusion of measures for both domains in studies of childhood adaptive functioning is relatively rare, at least in comparison to studies relating each domain separately to various outcomes. It is not easy to summarize these results succinctly. Moreover, no two studies used identical measures of attachment and temperament for children at the same ages, and the outcome domains being predicted from attachment and temperament measures varied across studies. Replication studies are sorely needed.

Differential Susceptibility to Context: Temperament and Attachment

Belsky and associates (e.g., Belsky, 1997; Belsky & Pluess, 2009; Pluess & Belsky, 2010) proposed a special sort of moderation, differential susceptibility, as an alternative to diathesis–stress theories of

risk and vulnerability. According to the diathesis–stress model, the combination of an underlying “risky” genotype *and* exposure to a specific stressor is sufficient to explain the presence of maladaptive outcomes (e.g., problem behaviors) over the life course, whereas differential susceptibility models suggest that both maladaptive and optimally adapted outcomes could be associated with the gene that was inappropriately called “risky”; that is, the combination of what had been considered to be a “risky” genotype and an environmental or social stressor was associated with poor outcomes, but when the inappropriately labeled “risky” genotype was paired with a nurturing environment, the combination would result in an especially positive outcome, making the term *risky* inappropriate (see Ellis & Boyce, 2011). The differential susceptibility hypothesis is consistent with evolutionary logic in that genotypic variability should not reach equilibrium in a population if one allele consistently imposes a great cost without also conferring substantial benefits in some circumstances. Belsky (e.g., 1997) suggested that attachment security might be one of the developmental outcomes that could be understood better if considered from the differential susceptibility perspective.

With regard to attachment security, research examining differential susceptibility has two branches. First, some studies have considered whether parental sensitivity to infant/child communicative signals predicts attachment security during infancy and early childhood equally well at different levels of some temperamental attribute (most often a composite dimension implying negative emotionality or behavioral inhibition/fear, but other dimensions related to temperamental effortful control also have been tested). From the differential susceptibility perspective, high-negative emotionality (or behavioral inhibition/fear) should be associated with insecure attachment when paired with low levels of parental sensitivity but should be positively associated with attachment security when paired with high levels of parental sensitivity. Critical tests involve contrasts between children with high scores for assessments of negative emotionality (or behavioral inhibition/fear) and those with low scores for this dimension. Differential susceptibility models demand that the high–high combination of temperamental quality and parental sensitivity differ significantly in the direction of optimality from the low–high combination of temperament and parental sensitivity, and that both types should differ significantly from the high–low combination of temperament and parenting quality.

A second group of studies has not focused on attachment security as an outcome but rather on the moderating effects of temperament on associations between attachment security and some later outcome variable (e.g., sociability with others, problem behaviors). In other studies, parenting quality and temperament dimensions are considered as predictors of outcomes that have been associated with individual differences in attachment security in the broader attachment literature (e.g., internalizing or externalizing problem behaviors, social competence), but measures of attachment security *per se* are not included in the analyses.

We summarize the results of the studies investigating attachment security as an outcome in some detail but provide a less detailed summary of representative studies examining moderating effects of temperament on attachment security (or parenting) effects for subsequent outcomes. Some studies included molecular genetics data, as well as, or in lieu of, phenotypic temperament data (see Bakermans-Kranenberg & Van IJzendoorn, Chapter 8, this volume). Only results involving the phenotypic temperament data are reviewed here.

Differential Susceptibility to Parenting Quality and Attachment Security

Belsky (1997) proposed that infants with specific underlying genotypes might be very sensitive to differences in parenting quality, such that they thrive extremely well when exposed to high-quality parenting but fare quite poorly when exposed to low-quality parenting. He suggested that the association between parenting quality and attachment security should be significant, substantial, and positive for these children. Alternatively, if infants' genotypes rendered them less sensitive to parenting quality, the association between parenting and attachment security would be less substantial and often not significant, even if positive. A number of studies have tested the effects of parenting quality on attachment security for children varying on dimensions of temperamental vulnerability/risk, but relatively few have reported all of the contrasts among groups that would provide strong support for the differential susceptibility hypothesis.

Luijk and colleagues (2011) tested whether infant capacity for stress regulation (negative emotionality) moderated the relation between maternal sensitivity and attachment security (using a continuous security scoring of infant behaviors in the Strange Situation procedure). In their analyses, the interaction of stress reactivity and mater-

nal sensitivity was a significant predictor of attachment security, and the results for children at risk for high stress reactivity conformed to the differential susceptibility hypothesis. That is, when exposed to less sensitively responsive mothers, these children tended to be less secure, but when exposed to more sensitive mothers, they tended to be more secure. For children with markers suggesting low stress reactivity (or better regulatory capacity to cope with stress), the association between maternal sensitivity and attachment security was not significant. De Schipper, Oosterman, and Schuengel (2012) also found that shy/inhibited children in foster care who were paired with more sensitive foster caregivers were more likely to be securely attached than were shy/inhibited children paired with less sensitive foster caregivers. This effect was not observed for those children who were less shy/inhibited. However, in this study, children scoring either higher or lower with respect to shyness did not differ when paired with low-sensitive foster caregivers, which is inconsistent with the differential susceptibility hypothesis.

Klein Velderman, Bakermans-Kranenburg, Juffer, and Van IJzendoorn (2006) reported on an intervention to increase maternal sensitivity in a sample at risk for low sensitivity to child communicative signals and found that mothers of highly reactive infants benefited more than other mothers from the intervention experience. More importantly, their children were more susceptible to maternal *changes* in sensitivity due to the intervention, and changes in maternal sensitivity were more strongly correlated with attachment security for high-reactive infants than for low-reactive infants whose mothers had received the intervention. However, even though the association between maternal sensitivity change and attachment security was significant for high-reactive infants in this study, the absolute levels of attachment security did not differ for high- or low-reactive infants when their mothers received intervention. It is not entirely clear whether these results support the differential susceptibility hypothesis.

Cassidy, Woodhouse, Sherman, Stupica, and Lejuez (2011) also reported on an intervention designed to increase attachment security in a sample at risk for insecure attachment as a consequence of their level of irritability during the neonatal period, and found that the intervention was more effective for infants who had been highly irritable (vs. moderately irritable) as neonates. However, highly and moderately irritable neonates did not differ in the control condition, which is contrary to the differential susceptibility

model. The researchers also tested for moderating influences of maternal attachment status (from the Experiences in Close Relationships Questionnaire; Brennan, Clark, & Shaver, 1998) on the differential susceptibility effect and found differences supporting both kinds of differential susceptibility. For highly secure mothers, infants who had been highly irritable showed the greatest benefit from the intervention, but there was no difference between irritability groups in the control condition. However, for more dismissing mothers, positive intervention effects were observed for the highly irritable infants (compared to moderately irritable infants), and highly irritable infants fared less well in the control group than did moderately irritable infants. No evidence favoring the differential susceptibility hypothesis was found for two other attachment status categories (i.e., fearful or preoccupied). These results are complicated, but they do provide support for the differential susceptibility hypothesis for some children, some of the time.

Although some support has been found for the differential susceptibility hypothesis linking attachment security to temperament via effects of parental sensitivity, other studies have failed to find such evidence. De Schipper, Tavecchio, and Van IJzendoorn (2008) tested for moderating effects of temperamental irritability on a relation between caregiving quality (with nonparental caregivers) and attachment security (using observer AQS descriptions) but failed to find a significant effect. Stevenson-Hinde and colleagues (2011) tested the joint influence of child behavioral inhibition and maternal anxiety on child attachment security ratings (based on a modified Strange Situation procedure). The interaction of behavioral inhibition and maternal anxiety was not significant, and only the maternal anxiety variable was a uniquely significant predictor of attachment security when both variables and their interaction term were simultaneously entered as predictors in a regression. Stevenson-Hinde and colleagues did not explicitly address differential susceptibility, and it may be that maternal anxiety levels are not a valid proxy for sensitive caregiving, so conclusions should be drawn cautiously.

Attachment by Temperament Interactions Suggesting Differential Susceptibility

The studies reviewed here tested the interaction of attachment security and one or another temperamental attribute as a predictor of some adap-

tive (or not) outcome. Differential susceptibility is inferred when the interaction term is significant and the association between attachment security and the outcome variable differs for children at the opposite extremes of the temperament variable's distribution. However, for some of the studies, explicit tests of the significance of differences between more temperamentally "difficult"/securely attached and less temperamentally "difficult"/securely attached children were not reported.

McElwain and colleagues (2012) tested for differential susceptibility of children high (vs. low) for temperamental anger proneness to the influence of attachment security in relation to children's behavior during mother-child interaction. In this study, child responsiveness, help seeking, self-assertion, and committed compliance were assessed across play, cleanup, and snack tasks. The authors reported significant attachment security \times temperament interactions for both self-assertion and committed compliance. Consistent with differential susceptibility hypotheses, plots of the interactions for children with low, intermediate, and high anger proneness showed that children high in anger proneness were the least self-assertive and least committed in compliance when they were less secure, and were the most self-assertive and committed in compliance when they were more secure, whereas children low in anger proneness tended to be more self-assertive when insecure but less self-assertive when securely attached.

Gilissen and associates reported two studies examining children's vagal tone (indicative of stressful arousal) to film clips during early and middle childhood in relation to temperamental fearfulness and parent-child relationship quality. Gilissen, Koolstra, Van IJzendoorn, Bakermans-Kranenburg, and van der Veer (2007) found that 4-year-olds with higher temperamental fear showed the lowest level of distress physiological reactions to fear-inducing film clips if they had a more harmonious relationship with the parent (assessed using Biringen's [2000] Emotional Availability Scales as a proxy for attachment), but they showed the highest level of fearful response to those clips if they had a less harmonious parent-child relationship. This result was replicated by Gilissen, Bakermans-Kranenburg, Van IJzendoorn, and van der Veer (2008) with 4-year-old twins and also with 7-year-old twins (attachment assessed using the Attachment Story Completion Task [Bretherton, Ridgeway, & Cassidy, 1990] for the older children) using skin conductance rather than vagal activity as the index of stress responding. The two age groups were combined for analy-

sis, with an age covariate. Again, the interaction of fearfulness and attachment quality was significant, with the highly fearful, insecure group of children exhibiting the highest level of physiological stress, whereas the highly fearful, secure group of children exhibited the lowest level of physiological stress to the film clips.

Stupica, Sherman, and Cassidy (2011) examined attachment security, neonatal irritability, and their interaction as predictors of toddlers' exploration and sociability with nonparental adults. They suggested that differential susceptibility was a plausible explanation for the sociability outcome but not for exploration (which was more consistent with the diathesis–stress interpretation).

In the Troxel and colleagues (2013) study, discussed previously, the final path model suggested a mediated moderation relation that is at least partially consistent with differential susceptibility. In their model, attachment security predicted sleep problems at 36 months, and sleep problems predicted problem behaviors at 54 months, but only for children with higher negative emotionality as infants. Thus, more negatively emotional children who were securely attached at 36 months had fewer concurrent sleep problems than did their insecurely attached counterparts, and the full indirect path from attachment to problem behaviors via sleep problems was significant for the negatively emotional children. For children low on negative emotionality, no significant pathways were observed. Because the data were not reported in a manner that tested the difference between high negatively emotional/secure children and low negatively emotional/secure children, we are cautious about claiming this study as compelling evidence for differential susceptibility. Nevertheless, the results suggest that high negatively emotional children are responsive to the quality of care they receive in a way that is not the case for low negatively emotional children with respect to sleep problems.

Failure to detect differential susceptibility when relevant analyses were reported was also found. Lickenbrock and colleagues (2013) tested temperament (negative reactivity assessed at 7 months) by attachment security (from the Strange Situation procedure with both mother and father, assessed at 12 and 14 months, respectively) interactions in relation to child compliance in cleanup and delay tasks (assessed at 20 months). Children high with respect to negative reactivity showed neither the lowest levels of compliance when they were insecure nor the highest levels of compliance

when they were secure. Tests including child security with both parents also failed to show evidence of differential susceptibility.

Parenting Quality/Sensitivity by Temperament Interactions as Predictors of Adjustment Outcomes in Early Childhood

Many studies have examined aspects of parenting quality \times temperament interactions in the prediction of a range of positively adaptive and maladaptive outcomes in early childhood (e.g., problem behaviors, self-regulation) that have also been associated with individual differences in attachment security. The results are mixed, and because these studies did not explicitly test for attachment \times temperament interactions, we only briefly summarize their results with respect to differential susceptibility. Evidence in favor of the differential susceptibility hypothesis was reported in some studies (e.g., Kim & Kochanska, 2012; Mesman et al., 2009; Pluess & Belsky, 2009; Poehlman et al., 2012). However, other investigators failed to find such evidence (e.g., Chen et al., 2014; Cipriano-Essel, Skowron, Stifter, & Teti, 2013; Kochanska & Kim, 2013). In these latter studies, the data fit more closely to the diathesis–stress or dual-risk models (i.e., low-quality care exacerbated and/or good-quality care ameliorated risk, but negative temperamental traits did not potentiate a super-optimal outcome when children were exposed to high-quality care).

Attachment, Temperament, and Somatic Health

The contributions of attachment and temperament research to children's development are primarily within the domains of relationship construction, interpersonal functioning, and mental health. However, provocative hypotheses regarding the relevance of attachment and temperament for understanding somatic health outcomes and trajectories arise from studies identifying links between social relationships, personality, and physical health (e.g., Capitanio, 2011; Pietromonaco, Uchino, & Dunkel-Schetter, 2013; Selye, 1956; see Ehrlich, Miller, Jones, & Cassidy, Chapter 9, this volume). This inquiry has been fueled by technological advances and by studies documenting mechanisms through which social experiences become biologically translated in ways that increase or decrease vulnerability for disease (e.g.,

Boyce & Ellis, 2005; Repetti, Robles, & Reynolds, 2011; Slavich & Irwin, 2014).

Although some studies have linked adult attachment—primarily self-reported attachment anxiety—and physical health and/or immune related outcomes (e.g., Jaremka et al., 2013; Maunder, Hunter, & Lancee, 2011), few studies have reported relations between early attachment and/or temperament and physical health outcomes. In this section, we explore attachment and temperament as phenomena that may influence regulatory processes associated with physical health and initiate cascades toward or away from physical illness. We briefly review literature regarding potential biological mechanisms through which attachment and temperament may affect somatic health, then turn to one illustrative example from the pediatric literature, namely, childhood obesity.

Regarding possible biological mechanisms linking attachment, temperament, and physical health, the most relevant frameworks pertain to the complex interactions among social risk, physiological stress responses, biological dysregulation (i.e., allostatic load), and immune system functioning (e.g., Boyce, Sokolowski, & Robinson, 2012; Shonkoff, Garner, & the Psychosocial Aspects of Child and Family Health Committee on Early Childhood Adoption, and Dependent Care Section on Developmental and Behavioral Pediatrics, 2012). It is thought that chronic activation or alteration of adaptive biological regulatory responses to distress result in diminished capacities to mount effective stress responses or to recover quickly from future stress responses. Increased allostatic load also leads to greater deterioration and chronic dysregulation of these biological systems. The links between allostatic processes and health outcomes involve multiple physiological systems, including the sympathetic nervous system (SNS), the HPA axis, and the immune system (e.g., Hostinar, Sullivan, & Gunnar, 2014; Irwin & Cole, 2011; Radtke, MacDonald, & Tacchini-Cottier, 2013).

Recent research on immune system functioning is noteworthy because it is thought that chronic *interpersonal* stress can result in sustained up-regulation of inflammation through proinflammatory cytokines (e.g., Slavich & Irwin, 2014). Importantly, some of the most powerful triggers that increase signaling of proinflammatory transcription control pathways involve social isolation, rejection, evaluation, and conflict (e.g., Kemeny, 2009; Taylor, 2010). Indeed, early childhood “toxic stress”, including harsh, unresponsive, and

emotionally unavailable parenting, has been associated with increases in inflammation indicative of proinflammatory immune system functioning (e.g., Danese, Pariante, Caspi, Taylor, & Poulton, 2007; Taylor, Lehman, Kiefe, & Seeman, 2006). However, consistent supportive transactions may buffer physiological stress responses, possibly by reducing proinflammatory states (Chen, Miller, Kobor, & Cole, 2011).

Given these associations between social-affective processes and inflammation, we would expect that relational experiences during the early years and biologically based tendencies influencing reactivity and regulation should influence the nature of these associations (Luecken & Lemery, 2004). Attachment system activation and caregiver responses are among the first transactions through which dyadic stress, coping, and resulting regulation of internal states occur. Over time, these experiences may become embodied through programming of neural circuitry governing physiological responses to everyday challenges. Secure attachments could support children’s flexible and adaptive biological stress response patterns that act to deter the development of a proinflammatory phenotype. Chronic insensitive parental responding or outright rejection, on the other hand, may elevate interpersonal stress reactivity in children, increase physiological dysregulation, and heighten inflammation risk (Repetti et al., 2011). Existing data demonstrate a link between attachment security and HPA axis functioning (e.g., Gunnar, Brodersen, Nachmias, Buss, & Rigatuso, 1996; Spangler & Grossmann, 1993). Similarly, internal “set-points” with respect to reactivity and regulation (i.e., temperament) could exacerbate or attenuate relations between environmental challenge and physical health through its interface with biological stress responses (Gunnar & Quevedo, 2007) and may interact with attachment quality to determine somatic health outcomes (Gunnar & Donzella, 2002; see Ehrlich, Miller, Jones, & Cassidy, Chapter 9, this volume).

Recent longitudinal data support extension of these hypotheses to somatic health domains. Puig, Englund, Simpson, and Collins (2013) reported that children classified as anxious-resistant in the Strange Situation procedure at 18 months were about six times more likely to report physical illnesses at age 32 than children classified as secure at 18 months. Anxious-avoidant children were approximately three times more likely, and anxious-resistant children were 7.5 times more likely to report *inflammation-related* illnesses at

age 32 when compared to secure children. Similar results have been reported in retrospective studies of maternal warmth (e.g., Carroll et al., 2013; Chen et al., 2011). With respect to temperament, multimethod assessments of self-control obtained over the first decade of life predicted scores on a laboratory-based physical health index, including cardiovascular, metabolic, and inflammation assessments, at age 32 (Moffitt et al., 2011). The Moffitt and colleagues (2011) and Puig and colleagues studies are, to our knowledge, the only longitudinal studies examining *early* attachment and/or temperament and *adult* physical illness or biological risk. Although more longitudinal studies like these are needed, a growing literature suggests that attachment, temperament, and aspects of physical health in childhood predict subsequent health outcomes. One such outcome is childhood obesity, to which we now turn.

Attachment/Parenting and Pediatric Obesity

Most studies examining how parents contribute to children's eating behavior and pediatric obesity have focused on general parenting and feeding styles, food access, restriction, and preferences (e.g., Davison & Birch, 2002), but a few studies document associations between attachment and obesity-related outcomes. Anderson and Whitaker (2011) used data from the Early Childhood Longitudinal Study–Birth Cohort (ECLS-B; Bethel, Green, Kalton, & Nord, 2005) to examine attachment security and obesity in preschool-age children. Attachment security at 24 months was measured with an adaptation of Waters's AQS (observer sorts), and children were classified as insecure if their scores were in the lowest quartile and secure otherwise. Children's body mass index (BMI, kg/m²) at age 4.5 years was the obesity index. Maternal responsiveness, child engagement, and *child negativity* coded from mother–child play interactions were used as covariates (as were other parenting practices related to obesity, maternal health measures, and sociodemographic characteristics), but no interactions were tested, nor was child temperament *per se* included. Logistic regressions revealed that after all the covariates were included in the model, for insecure children, the odds of obesity at 4.5 years were significantly higher than those for children with secure attachment. More recently, Anderson, Lemeshow, and Whitaker (2014) examined the relations between 9-month mother–child interaction and

obesity risk at 5.5 years of age using ECLS-B data. Mother–infant interaction quality was coded from videotapes, with scores divided into quartiles. Infant scores did not predict obesity risk, but the incidence of obesity was higher for children in the lowest quartile of maternal interaction quality scores (20.2% compared to 13.9% for children in highest quartile). However, after adjusting for maternal education, income, and race/ethnicity, maternal scores were no longer significantly associated with child obesity.

Anderson Gooze, Lemeshow, and Whitaker (2012) examined early maternal care and adolescent obesity risk using data from the National Institute of Child Health and Human Development (NICHD) Study of Early Child Care and Youth Development (SECCYD; NICHD Early Child Care Research Network, 1994). An “early maternal–child relationship quality” score was created using maternal sensitivity and child security scores at 15, 24, and 36 months. *Low maternal sensitivity* was defined as the lowest quartile for each of the time periods. With respect to child attachment, Strange Situation procedure classifications (secure vs. insecure) were used at 15 and 36 months, and AQS scores were used at 24 months (with *insecurity* defined as the lowest quartile of AQS scores, which was < .16). After adjusting for child gender and birthweight, the odds of adolescent obesity were 2.45 times higher for children with the poorest relationships compared to those with more secure relationships. The odds ratio was reduced when all sociodemographic and maternal obesity controls were entered into the model but still remained significant. Low maternal sensitivity at each time period was associated with increased odds of adolescent obesity, whereas only the 24-month insecurity (AQS observer sorts) assessment was associated with increased odds of adolescent obesity. Nevertheless, at 24 and 36 months, having both low maternal sensitivity and insecure attachment put children at significantly greater risk for adolescent obesity than if either was considered alone (Anderson et al., 2012).

Temperament and Pediatric Obesity

The focus on the role of child temperament in obesity has emerged in part from the nutrition research showing that *capacities to self-regulate eating* depend on hunger and satiety cues that operate automatically (Birch & Deysher, 1986), but are also affected by distress and emotional factors (Herman & Polivy, 2004), presumably because brain regions

governing energy balance are also implicated in emotion regulation and stress responses (Dallman, 2010). Moreover, stress responses and/or emotion dysregulation are associated with metabolic syndrome, with higher energy intake from sweet/salty foods in schoolchildren, and with children's higher BMI (Blissett, Haycraft, & Farrow, 2010; Braet & VanStrien, 1997; Faith, Allison, & Geliebter, 1997; Nguyen-Michel, Unger, & Spruijt-Metz, 2007).

Reviews of studies testing relations between temperament and pediatric obesity suggest that exploring more global self-regulation and reactivity behaviors, beyond those surrounding energy intake, is fruitful. Anzman-Frasca and colleagues (2012) reported on 18 published studies (between 1985 and 2011) examining some aspect of temperamental negative reactivity or self-regulation in infants and young children and child weight-related outcomes. In 12 of the 13 studies reviewed, *temperamental negative reactivity* was measured using a variety of scales or composites from standard parent self-report assessments of temperament (e.g., Infant Behavior Questionnaire—Revised [IBQ-R]; Children's Behavior Questionnaire [CBQ]; Revised Infant Temperament Questionnaire [RITQ]; Emotionality, Activity, and Sociability [EAS] questionnaire; Behavioral Style Questionnaire [BSQ]; Infant Characteristics Questionnaire [ICQ]). Two of the five *self-regulation* studies used behavioral assessments (e.g., inhibitory control tasks), and three used subscales from the CBQ, Colorado Childhood Temperament Inventory (CCTI), and IBQ.

With respect to negative reactivity, all three short-term longitudinal (weight gain from birth to 6 or 8 months or 6–12 months) and three of the four cross-sectional studies (sample ages ranging from birth to 8 years) found significant positive relations between temperamental negativity (especially Distress to Limitations and Negativity Reactivity/Mood) and children's weight outcomes. However, weight status in the short-term longitudinal studies was assessed prior to measures of temperament, so temporal order was an issue (e.g., Anzman-Frasca et al., 2012). The longitudinal evidence was more mixed, with four longitudinal studies having relatively small and homogenous samples reporting significant associations between negative reactivity and child weight status (i.e., Carey, Hegvik, & McDevitt, 1988; Slining, Adair, Goldman, Borja, & Bentley, 2009; Wells et al., 1997; Wu, Dixon, Dalton, Tudiver, & Liu, 2011), but failures to find evidence for such relations in large-scale cohort studies (e.g., Pryor et al., 2011).

With respect to self-regulation, Anzman-Frasca and colleagues (2012) reported that one cross-sectional study ($N = 63$) found no significant associations between inhibitory control and child BMI percentiles (Tan & Holub, 2011), but that all four longitudinal studies revealed significant negative associations between some aspect of regulation (i.e., infant soothability, observations of self-control, and delay of gratification) and subsequent child outcomes, including BMI z -scores, weight gain, obesity risk, and measured adiposity (Faith & Hittner, 2010; Francis & Susman, 2009; Graziano, Calkins, & Keane, 2010; Wells et al., 1997). Anzman-Frasca and colleagues (2012) noted that there are mixed findings with respect to soothability (e.g., positive associations with weight outcomes for girls in one sample). In contrast, behavioral assessments of emotion regulation, delay of gratification, and inhibitory control tend to show consistent (negative) associations with subsequent unhealthy weight status. Notably, in a study using NICHD SECCYD data, Francis and Susman (2009) found that children who were less able to self-regulate at age 3 and less able to delay gratification at age 5 had the highest BMI scores and the most rapid BMI gains over six time points from 3 to 12 years of age.

More recently, Rollins, Loken, Savage, and Birch (2014a) examined the interaction between girls' inhibitory control and profiles of maternal controlling feeding practices as a predictor of changes in BMI and eating in the absence of hunger (EAH) from 5 to 7 years of age. The effect of low inhibitory control on BMI and EAH depended on the maternal feeding practice. Children who had highly controlling mothers (i.e., who set limits about eating and restricted all snacks) and low inhibitory control were at the highest risk for EAH, and children of mothers at the very low end of controlling behaviors (i.e., children who had unlimited access to snacks) and low inhibitory control had the highest percent change in BMI across the 2 years (Rollins et al., 2014b). These changes were not seen for children with high inhibitory control.

Attachment/Parenting Quality, Temperament, and Pediatric Obesity

Wu and colleagues (2011) used data from the NICHD sample to examine the combined effects of child temperament and maternal sensitivity at 6 months on the development of childhood obesity

(age 2 years to sixth grade). Maternal reports of infant temperament using the Infant Temperament Questionnaire (ITQ; short version) were used to create an index of “difficultness,” which was then used to group children into difficult, average, or easy temperament categories. Maternal sensitivity was based on the composite sums for observed sensitivity to nondistress, intrusiveness (reversed), and positive regard. Mothers were grouped into sensitive or insensitive categories by a median split. Six combinations of child temperament and maternal sensitivity groupings were created, and the easy temperament/sensitive mother category served as the reference group in most analyses.

The total effect of early maternal sensitivity and child temperament on weight status was not significant in early childhood (ages 2–4 years), but was significant at school age (5–12 years). Maternal insensitivity paired with any temperament category (easy, average, and difficult) predicted increased risk for overweight or obese status across the school-age years, with children having difficult temperament *and* insensitive parenting being at greater risk for overweight or obese status in the school-age years (compared to the reference group). Children with more difficult temperaments *and* sensitive parenting, however, were not significantly more likely to be overweight/obese at school age (compared to the reference group). Only children with difficult or average temperament who experienced insensitive care had a significantly higher BMI percentile during school age (compared to the easy/sensitive group). These findings are valuable not only because they suggest that the effects of temperament on the development of pediatric obesity depend on maternal sensitivity and developmental period, but also because difficult temperament in the context of sensitive caregiving environments may result in a more optimal (child weight-related) outcome. This interpretation would be consistent with the differential susceptibility hypothesis.

In a cross-sectional study of 77 obese children (8–16 years of age) and a matched comparison group ($N = 69$), Zeller, Boles, and Reiter-Purtill (2008) examined differences in parenting style and child temperament between the two groups. A global “difficult temperament” score was created by dichotomizing each subscale of the Revised Dimensions of Temperament Survey (Parent Report) and summing across subscales (resulting in scores ranging from 0 to 6). Maternal reports of their parenting on dimensions of warmth, psychological control, and behavioral control were also used in

the analyses. Mothers of obese children (compared to mothers of nonoverweight children) reported that their children had more difficult temperaments and described their own parenting practices as being lower in behavioral control (than did mothers of nonoverweight children). Difficult temperament, lower behavioral control, and the interaction of low maternal warmth and difficult temperament significantly increased the odds that a child was obese (effect sizes small to medium based on Cohen’s d). Boles, Reiter-Purtill, and Zeller (2013) reported similar results in longitudinal data for a subsample from the Zeller and colleagues (2008) study ($N = 52$ persistently obese; 32 nonoverweight comparison cases). They showed that over a 50-month period, persistently obese adolescents who also had difficult temperaments as children were more likely to be parented with pressure to eat practices if their mothers described themselves as lower on psychological control. However, persistently obese children with less difficult temperaments (i.e., < 1 standard deviation below the mean) were parented with pressure to eat if their mothers were higher on psychological control.

In a cross-sectional study of Iranian youth (9–13 years of age) classified as obese, Bahrami, Kelishadi, Jafari, Kaveh, and Isanejad (2013) tested a model suggesting that relations between parent attachment (Inventory of Parent and Peer Attachment—Revised) and perceptions of eating control would be mediated by children’s self-reported impulsivity and general self-control. They suggested that eating control, in turn, would predict child BMI. Although the model was supported, it is difficult to draw conclusions because limited information was provided regarding the specific path coefficients and indirect effect sizes. The findings are worth mentioning, however, because Bahrami and colleagues tested potential mechanisms through which attachment and self-regulation might influence obesity-related behavior.

Summary: Attachment, Temperament, and Health

The findings reviewed here suggest that early attachments and child temperament may have important implications for our understanding of emergent biological risk markers for disease, but several recommendations can be made for further research in this area. First, more studies using early attachment assessments are needed, especially

in light of the findings reported by Puig and colleagues (2013) linking both anxious-resistant and anxious-avoidant attachment classifications to inflammation-related illnesses in adulthood, and results showing that continuity of attachment insecurity across the 12- and 18-month time periods increased subsequent physical health risks. The findings are promising, but more and better data are needed to probe further the nature of these relations with respect to anxiety and avoidance dimensions, as well as across different attachment assessments and relationships. In addition, findings from the few studies that combined attachment/parenting and temperament assessments in the prediction of child health outcomes call for more focused studies examining these interactions, especially with respect to the differential susceptibility hypothesis.

Reflections on the State of Research Relating Attachment and Temperament

Theories of attachment and temperament ground the most generative research programs on socio-emotional development during infancy and childhood. The tension between these theories and their respective research programs has stimulated substantial growth in developmental knowledge and continues to stir controversy. However, in most of the research reviewed here, there is little evidence of that controversy. Rather, most of the recent studies have simply appropriated into their own studies measures used by attachment and temperament researchers for studying infant or early childhood prediction of adaptive (or maladaptive) functioning at some later period of development. Thus, most of these studies have rather little to say about attachment or temperament theories per se. Furthermore, when both attachment and temperament measures are included in studies, investigators do not seem to attach much importance to whether one, both, or their interactions (implying mediation or moderation) become statistically significant predictors of the outcome(s) being studied. We also note that replications are rarely reported in this literature. Consequently, the generality of findings remains an open question.

The single exception to this summary statement regarding the state of research and theory about attachment and temperament is the emergence of the differential susceptibility hypothesis

and the research it has motivated. The notion that genotypic/phenotypic attributes might *either* put an infant/child “at risk” *or* confer a substantial adaptive benefit, depending on qualities of the environment to which the individual is exposed over the period of development, is provocative and may, as research findings accumulate, require important changes in the ways that development in both attachment and temperament domains are understood. Belsky (1997) suggested that parenting quality (i.e., sensitivity to infant communicative signals) could lead to very different attachment outcomes for children characterized as very emotionally reactive during infancy, depending on whether they were exposed to lower- or higher-quality (i.e., sensitive) parenting. These differences have in fact been reported in several (but not all) studies. What is most provocative, however, is that for *low* emotionally reactive children, the relation between parental sensitivity and attachment outcomes does not appear to be significant in most of these studies. This finding runs counter to most accounts of the nature of secure attachment relationships and demands an explanation. If parental sensitivity is not the foundation for attachment security for low emotionally reactive infants, what accounts for attachment differences among these infants and young children? Answering this question will be an important task for the attachment research community over the coming years.

Chapter II

Studying the Biology of Human Attachment

Amie A. Hane
Nathan A. Fox

Since the original publication of the *Handbook of Attachment* in 1999, research on the biological aspects of attachment has flourished, providing a more holistic understanding of attachment-related behavior and the physiological substrates that operate in tandem with behavior to affect social relationships. In this updated chapter, we focus specifically on infant physiological responding and expand on the literature reviewed in our chapter in the previous edition in the areas of infant autonomic and neuroendocrine correlates of behavior in the Strange Situation paradigm (Ainsworth & Wittig, 1969). We address the burgeoning enterprise of assessing the dyadic physiology of early caregiving behavior, epigenetics, and infant physiology. We also incorporate research on oxytocin and its role in the affiliative behavior of parents and infants, as well as the emerging field of parental neuroscience. Throughout this chapter, we hope to demonstrate that attachment behaviors are influenced by multiple physiological systems, and that the arbitrary distinction between “nature” and “nurture” has been replaced by a continually growing body of research showing that relationships *both influence and are influenced by* underlying biological processes. Recent work that is drawing attention to the coordination of physiological systems has added an additional layer of depth to this field, pointing to the importance of the inclusion of multiple levels of analysis

simultaneously. New research has also incorporated contextual variables to support cumulative/dual-risk models, whereby child physiological responses to relationship challenges are influenced by factors such as chronic stress and maternal depression. By reviewing the literature demonstrating that behavioral and biological systems are deeply intertwined and embedded within the larger relational ecology of relationship functioning, we hope to elucidate the rich, multisystemic complexity that underlies affiliative behavior and human attachment.

Psychophysiology

Psychophysiology is the study of how physiological processes intersect with and influence psychological processes and behavior. Psychophysiological research includes measurement of physiological systems that are correlated with observed behavioral responses; it examines how individual differences in physiological responding predispose people to certain behavioral responses. Examples of this approach are studies measuring task-elicited autonomic activity; research measuring hormones, including the activity of the hypothalamic–pituitary–adrenocortical (HPA) axis during tasks designed to provoke stress; and research on the role of oxytocin in mediating attachment-related behaviors.

In studies assessing autonomic activity, several measures provide an index of physiological arousal or enhanced sympathetic or parasympathetic activity in response to a task demand (e.g., Phillips, Carroll, Hunt, & Der, 2006). Autonomic measures have also been used to detect different states of attention. For example, heart rate (HR) change has been measured in response to visual or auditory stimuli in preverbal infants. Sustained HR deceleration is viewed as indicating sustained attention (Courage, Reynolds, & Richards, 2006). In the case of research measuring HPA axis activity, the assumption is that changes in the level of activation of the HPA axis reflect the individual's response to stress (Gunnar & Donzella, 2002). Psychologists measure cortisol change as an index of HPA activity and interpret it as an indirect measure of an individual's stress reactivity.

A psychophysiological approach differs from a neuroscience approach in several ways. First, unlike techniques that image or measure brain activity, measures of autonomic or HPA axis activity are indirect assessments of brain-behavior links. Second, the time course of autonomic or HPA axis activity is generally much slower than the time course of brain activity. Third (this is a generalization), psychophysiologicals are often more interested in the psychological processes and contextual factors that alter physiology and less interested in identifying brain circuitry underlying behaviors. The psychophysiological approach has been especially useful for studies of infants and young children because it is difficult to apply brain imaging technologies to them.

Both neuroscience and psychophysiology have been used to study the psychological states involved in attachment. In the past, most attachment research was conducted with infants and young children, and most studies involving physiological measures assessed autonomic and HPA reactivity—and these two areas of research continue to move in important new directions. The development of conceptual and methodological approaches for measuring and understanding adult attachment has provided an opportunity to use brain imaging measures. In this chapter, although we focus especially on psychophysiological measures, we review both approaches to the study of psychological states associated with attachment.

Attachment has long been viewed as a biobehavioral state in which multiple physiological and behavioral systems are organized to provide an individual with a sense of security (i.e., safety within an environment) and intimacy with sig-

nificant others (Bowlby, 1969/1982). Individual differences in the organization of certain behaviors have been well characterized by attachment classifications based on experiences in attachment relationships (Ainsworth, Blehar, Waters, & Wall, 1978). And there is empirical evidence that individual differences in attachment are associated with differences in the processing of perceptual information (Cohen & Shaver, 2004; Mikulincer & Shaver, 2007). Thus, the study of attachment can be approached from a physiological perspective by examining either (1) individual differences in arousal or hormonal changes as a function of differences in attachment classification or (2) individual differences in cognitive and affective brain circuitry associated with attachment classifications.

Psychophysiology and Attachment

In this section, we review studies of infant attachment that have included measures of either autonomic activity or activity of the HPA axis; both kinds of studies have increased in number since the previous (2008) edition of this volume. The studies can be grouped into two categories: those examining physiological responses of human infants in Ainsworth's Strange Situation paradigm (Ainsworth & Wittig, 1969), and those in which individual differences in infant physiological responses have been measured outside of the Strange Situation. The latter body of research focuses on individual differences in physiological reactivity that may be related to attachment classification or to infant behavior in the Strange Situation. We do not review the literature on correlations between infant electroencephalographic (EEG) responses and attachment in this chapter, but we encourage readers to refer to the previous *Handbook of Attachment* for a review (Fox & Hane, 2008).

We next review animal and human research demonstrating that the quality of early caregiving environments shapes individual differences in physiological and behavioral responses to stress. We then turn to the physiological effects of caregiver variables and focus specifically on two important areas of growth since the publication of the previous edition of this volume: oxytocin and neuroscience approaches to adult attachment behavior. Throughout these reviews, we hope to inform the reader about both the complexity and the

benefits of using psychophysiological and imaging methods to study different aspects of infant attachment behavior, and to highlight the most recent advances that point to a more integrated view of brain, genetic expression, physiology, and behavior that operate in tandem to produce attachment-related behavior.

It is important to raise a number of caveats concerning psychophysiological studies, particularly those measuring autonomic or HPA axis activity. The first caveat concerns the multidetermined nature of the response. Despite its simplicity of measurement, HR, for example, is complexly determined; there are both neural and extraneural influences on it. Extraneural influences include hormonal effects that are the result of sympathetic activity or metabolic effects that may be a function of somatic activity, ranging from digestion to muscle movement. There are also mechanical influences on HR, including changes in respiratory activity that affect HR via the stretch receptors in the lungs (Porges & Byrne, 1992). There are intrinsic influences on HR as well; the heart beats at a particular rate as a function of electrical discharge via pacemaker cells at the sinoatrial node. HR responds to changes in other systems, such as fluctuations in blood pressure. Most neural influence on the heart is via the vagus or 10th cranial nerve (Katona & Jih, 1985). The vagus nerve, which originates in the brainstem, has complex interconnections with neural centers regulating respiration and is linked with both afferent and efferent connections to the midbrain and cortical regions of the brain (Porges, 1995). Thus, HR (and HR change) may be the result of multiple physiological factors, only some of which directly affect or reflect psychological state.

Changes in cortisol level are also multidetermined. Cortisol, secreted by the HPA axis, is the hormone of energy; hence, it is released as a result of many aspects of an organism's interaction with its environment, including responses to novelty, appetitive behavior, sexual stimulation, and injury or illness, as well as psychological stressors (Adam, Klimes-Dougan, & Gunnar, 2007). The secretion of cortisol within the HPA system has its own circadian rhythm, and the adrenocortical system is slow to respond; thus, it may take 25–30 minutes before a change in cortisol levels as a function of environmental challenge can be detected.

The multidetermined nature of psychophysiological responses requires, at the very least, careful methodological consideration. The measurement of HR has sometimes been supplemented

with measures of somatic activity, to rule out its influences on HR. Attempts have also been made to extract from the HR signal the portion of variance that can be exclusively related to neural influence (e.g., Porges & Bohrer, 1991). Studies of cortisol response should take into account time of day for sample collection because of changes due to circadian rhythms. These precautions and concerns are critical in allowing inferences about psychophysiological responses to be made.

A second caveat regarding the measurement and interpretation of physiological responses such as autonomic and HPA axis activity is the issue of individual differences in the initial level of response. The *law of initial values* states that the initial baseline level of a physiological system will affect the degree to which that system responds to stimulus presentation. For example, people with high levels of basal cortisol and those with more normative levels may respond differently to a stressor. The notion is that there is a ceiling level above which the system usually does not operate. It is important, therefore, that individual differences in baseline level be incorporated into any analysis of phasic responses. The usual approaches include computing change scores between baseline and phasic responses or using analysis of covariance, with baseline level as the covariate.

The issue of baseline level is complicated when researchers are assessing infants and young children. Because these research participants cannot be instructed to sit quietly for a baseline recording, researchers have attempted to devise methods for recording physiological responses when infants are not responding to a strong stimulus challenge. The key is to record "baseline" in a noninvasive experimental condition that may be replicated across children. It is often necessary to record behavior during such "baseline" physiological assessments, to ensure that all children are in the same state.

Baseline differences may also speak to the underlying physiological mechanisms that affect magnitude of response. Porges, Stamps, and Walter (1974) noted, for example, that some infants do not display HR deceleration in response to a visual stimulus. These infants have relatively high HRs. When studying this issue, Porges and colleagues found that the same high-HR group also displayed low HR variability. When subjects were grouped into those displaying high versus low resting HR variability, those with high resting variability were more likely to show the supposedly normative decelerative pattern. In subsequent

work, Porges (1991, 1996; Porges, Doussard-Roosevelt, Portales, & Suess, 1994) argued that initial baseline differences in HR are due to vagal control of the heart, and that differences in the degree of this control predict HR responsiveness.

Autonomic Responding and Attachment

Autonomic Responding within the Strange Situation

The Strange Situation paradigm (Ainsworth & Wittig, 1969) was designed to assess the quality of an infant's attachment to a primary caregiver. (See Solomon & George, Chapter 18, this volume, for a detailed description of the Strange Situation paradigm.)

There are three insecure classifications: "avoidant," "resistant," and "disorganized." Avoidant infants ignore their caregivers' return after an absence and may actively avoid proximity and contact. Resistant infants display proximity- and contact-seeking behaviors, while at the same time displaying resistance to caregiver attempts to soothe distress. Disorganized infants are likely to display contradictory emotions; to appear confused, apprehensive, and hypervigilant; to make incomplete or undirected movements; and to show depressed affect and possibly behavioral stilling. Unlike the disorganized infants, the secure, avoidant, and resistant infants are viewed as having a coherent strategy for coping with separation, although the secure infants are viewed as having the most adaptive strategy.

In the Strange Situation, infants may locomote wherever they please in an unfamiliar laboratory playroom. Some infants run to the door after their caregiver leaves. Others move close to their caregiver when the unfamiliar adult enters, whereas still others play with toys and explore the room. The high mobility within the confines of the experimental setting once placed limits on researchers' ability to measure ongoing physiological activity. Recent advances in ambulatory electrocardiographic (ECG) technology have led to major advances in acquisition of ECG data during the Strange Situation. In our chapter in the previous edition of this volume (Fox & Hane, 2008), we reviewed the earlier literature on HR changes based solely on Strange Situation classification. Here we present more recent work that examines the role of additional influences, such as dyadic interactive behavior, that provide a more

nuanced snapshot of infant HR-behavior associations within the Strange Situation.

Spangler and Grossmann (1993) examined the HR of attachment-classified infants during object manipulation and play with their mothers. They found that the avoidant infants did not display HR acceleration when looking at their mothers, whereas the secure and disorganized infants did. The avoidant infants did, however, display acceleration while looking at objects or during object manipulation, whereas the disorganized and secure infants displayed HR deceleration. Because HR is a nonspecific marker of arousal, interpretation of the similar HR patterns seen in disorganized and securely attached infants is difficult. It is plausible that for disorganized infants, HR acceleration when looking to mother may represent fear arousal (Hesse & Main, 2006), whereas HR acceleration in the securely attached infant when looking to mother may represent normative separation anxiety. Spangler and Grossmann stated that "the heightened heart rate when looking to the mother [of secure infants] indicates that visual contact with mother was initiated specifically during episodes of physiological arousal" (p. 1447). In the absence of a precise linkage between measures of gaze behavior and specification of when these behaviors were coded, however, this seems to be a post hoc explanation. Given the clinical significance of disorganized attachment classifications (see Lyons-Ruth & Jacobvitz, Chapter 29, this volume), future research examining the autonomic responding of disorganized infants within the Strange Situation paradigm is an important direction; such research would elucidate both the nature of the disorganized behavior and its impact on the developing systems that underlie stress reactivity.

Bono and Stifter (1995) examined the relations between measures of HR and HR variability assessed immediately before and after the Strange Situation as a function of infant attachment classification at 18 months of age. The authors reported that infants categorized as resistant displayed faster HR and less variability in *heart period* (HP, the interval between heart beats, which is inversely related to HR) than did secure infants. These differences, however, may be due to the extreme degree of upset displayed by resistant infants and their inability to be soothed during reunion. To the extent that resistant infants display behavioral problems in regulating their affect in the Strange Situation and immediately thereafter, autonomic activity will mimic those patterns of dysregulation.

Another study examined the degree of physiological attunement between mothers and infants in a sample of low-socioeconomic-status young women (age 20 or under, $M = 17.8$; Zelenko et al., 2005). In this report, mean HR was recorded by Mini-Logger monitors that collected and stored HR signals every 10 seconds from mothers and infants as they underwent the Strange Situation paradigm. Forty-one mother–infant dyads participated, of which 23 were classified as securely attached, six were classified as insecure-avoidant, and 12 as insecure-resistant. No mean attachment group differences in HR were detected from the infants at baseline; nor were there significant differences in HR change across separation and reunion episodes between the attachment groups. All infants showed a pattern of HR acceleration during separations and deceleration upon reunion. Mothers showed no significant differences in baseline HR across the groups. However, the pattern of mean HR change for mothers of resistant infants differed significantly from that of mothers of secure and avoidant infants. For mothers of secure and avoidant infants, HR followed a pattern consistent with that of their infants—acceleration during separation and deceleration upon reunion. However, mothers of resistant infants showed HR acceleration during reunion episodes. For securely attached infants, maternal HR slowed after the successful calming of the infant, whereas the HR of mothers of resistant infants remained elevated. This inability of mothers of resistant infants to recover from the stress of separation may be a function of maternal dysregulation that contributed to the insecure attachment of the infant, a by-product of the stress associated with soothing a distress-prone infant, or a combination of these states. Although not statistically significant, the descriptive findings obtained from calculating dyadic consistency (a crude index of physiological attunement) in HR revealed that mothers and their resistant infants scored lower in dyadic consistency than securely attached dyads—an effect necessarily driven by the discrepant profile of the mothers of resistant infants, given the lack of significant HR differences among the infants across attachment groups.

Zelenko and her colleagues (2005) also assessed frequency and intensity of infant crying during the Strange Situation, and noted that resistant infants cried more than the other two attachment groups. Hence, resistant infants showed a discordance between behavioral distress and physiological arousal, which is reminiscent of

the discordance between physiological and behavioral distress of the avoidant infants studied by Spangler and Grossmann (1993), but is discrepant from Bono and Stifter's (1995) findings of increased physiological arousal in resistant infants. It is important to note that Zelenko and colleagues' sample consisted of young, poor mothers and their infants, who were probably at increased risk for poor developmental outcomes. It is unclear whether similar effects would be obtained from a more normative sample. As well, Bono and Stifter measured cardiac functioning before and after but not during the Strange Situation, whereas Zelenko and colleagues' effects were driven by changes in cardiac functioning during the procedure.

Stevenson-Hinde and Marshall (1999) examined the role of attachment security in the relation between behavioral inhibition and cardiac reactivity. Using an extreme groups approach, they selected 126 children (age 4½ years), based on level of behavioral inhibition (high, medium, or low). Behavioral inhibition was assessed via maternal report and behavioral observation in the laboratory, and children underwent the Strange Situation procedure to have their attachment security assessed while cardiac data were recorded from both the mother and the infant via telemetry. HP and HR variability (respiratory sinus arrhythmia [RSA]) was noted during four specific periods in the Strange Situation paradigm: after Episode 3 with the stranger reading a story; at the start of Episode 7, with the examiner playing a recorded story; following a structured self-esteem interview (Harter & Pike, 1984), while another excerpt from the story was played from an audiocassette; and at the end of Episode 9, as mother and child sat quietly alone. Of the children with usable cardiac data, 38 were classified as securely attached, six were classified as insecure-avoidant, and eight as insecure-resistant. No significant inhibition group or attachment group differences were found in child mean HP or RSA (aggregated across all four assessment points). A significant interaction effect indicated that children low in behavioral inhibition who were securely attached had significantly higher mean HP than did securely attached children who were high in behavioral inhibition and insecurely attached children who were low in inhibition. A similar effect was found for RSA (itself highly correlated with mean HP in this sample, $r = .80$), with low-inhibition, securely attached children showing the highest degree of RSA, although the interaction effect was not significant. Securely attached children who were not highly

inhibited showed significant increase in HP upon reunion with their mothers. Highly inhibited children, regardless of attachment status, showed no such increase, indicating that attachment security and the absence of behavioral inhibition are requisite for a significant increase in HP upon reunion. Hence, this study provides additional support for the notion that insecurely attached children and inhibited children manifest disorganization in psychophysiological responses to the challenges of the Strange Situation. Notably, this study also provides evidence for the benefit of considering temperament, attachment, and physiological reactivity in concert because there was no relation between attachment status and cardiac reactivity when inhibition was not considered.

Individual Differences in Autonomic Responding Outside of the Strange Situation Paradigm

Porges and colleagues (1994) conceptualized vagal tone as reflecting the degree to which infants will be reactive and able to self-regulate. Infants with high basal vagal tone are thought to display more mature autonomic regulation and thus may exhibit both greater reactivity and superior self-regulatory strategies. Izard and colleagues (1991) examined the relation between vagal tone measured at 3, 4½, 6, and 9 months of age and attachment status at 13 months of age in 54 infants. Forty infants were classified as securely attached, eight were classified as avoidant, and six as resistant. Measures of vagal tone, HR, and HR variance were collected at each age assessed during the first year of life. A continuous measure of security was used as the dependent measure, and vagal tone scores were computed for each of the different assessment points.

Izard and colleagues (1991) reported that measures of vagal tone measured during early infancy significantly predicted attachment insecurity at 13 months. Specifically, infants with high vagal tone at 3 months and high HR variance at 4½ months were more likely to be classified as insecure at 13 months, although there were no differences between avoidant and resistant infants. Izard and colleagues' findings seem contrary to Porges's (1991) prediction regarding the role of vagal tone in emotion regulation. Porges argues that high basal vagal tone should reflect more mature autonomic regulation and greater regulatory capacity. It is unclear why these autonomic measures at this young age differed in the direction

that they did; nor is it clear why there was a lack of differentiation at each of the other ages assessed.

Fox and colleagues conducted a series of studies aimed at examining relations among individual differences in emotion expression and emotion regulation, and measures of autonomic activity (Fox, 1989; Fox & Gelles, 1984; Stifter & Fox, 1990). Fox and Gelles (1984) found that 3-month-old infants who displayed high HR variability and low HR were more likely to express positive emotions in response to maternal bids than were infants with high HR and low HR variability. *HR variability* was defined in this study as the mean of the successive differences in HR over the recording epoch. HR variability (particularly of the mean successive differences) is highly correlated with measures of RSA, such as vagal tone. The authors reasoned that high HR variability, like vagal tone, should reflect an infant's ability to mount an organized behavioral response. This was confirmed, as they found that infants with high HR variability displayed more positive interactive behavior. In subsequent studies, Fox (1985) found that infants with high vagal tone were more reactive as young infants and also more likely to display positive social behaviors as toddlers. In contrast to Izard and colleagues' (1991) findings, but consistent with Porges's (1991) prediction, these data suggest that high vagal tone is associated with more organized social responsivity. Porges has argued that the level of vagal tone reflects the degree to which the organism will exhibit an organized response to stimulus challenge. The manner of autonomic response is reflected in organized overt behavior. Thus, infants with high vagal tone should display less dysregulated and more organized behavioral responses to novelty and challenge; infants with low vagal tone should display less organized behavioral responses to stimulation.

Fox (1985) related individual differences in HR variability to attachment status within a high-risk (premature) sample of infants. Of the 60 infants in the sample, 43 were classified at 12 months of age as secure, 16 were classified as avoidant, and only one was classified as resistant. Although there were no differences between attachment classification groups (avoidant vs. secure) on any of the autonomic measures, individual differences in behavior in the Strange Situation were related to 3-month HR variability. Specifically, infants who cried during the Strange Situation at 12 months had higher HR variability at 3 months. In addition, infants with high HR variability at 3 months displayed greater regulation at reunion during the

Strange Situation; that is, they resumed playing in a shorter period of time. Fox argued that high HR variability, like vagal tone, reflects better physiological organization, such that children with high variability are not only more reactive but also better able to self-regulate than infants with low variability.

Other evidence suggests that attachment security predicts cardiac reactivity in early childhood (Burgess, Marshall, Rubin, & Fox, 2003). In their study of 172 families, Burgess and colleagues (2003) examined relations between attachment classification at 14 months, behavioral inhibition at 24 months, social behavior at 4 years, and cardiac functioning (HP and RSA) at 14 and 24 months and at 4 years. Cardiac assessments at each age were made during the 3 minutes in which the child quietly attended to a video monitor. No significant group differences were yielded for attachment group on HP or RSA at 14 or 24 months. Also, no significant group differences as a function of inhibition (low, medium, and high) on HP or RSA at 14 or 24 months were found. However, attachment security (and not behavioral inhibition) predicted HP and RSA at 4 years. Specifically, avoidant infants showed significantly higher HP and RSA than did secure and resistant infants.

The association between 14-month attachment status and cardiac reactivity some 3 years thereafter is an impressive demonstration of the potential evocative effects of attachment security on physiological arousal. The predictive association between 14-month attachment and 4-year cardiac reactivity, and the lack of association with contemporaneous (or more proximal) assessment of cardiac reactivity and attachment security, suggest that the avoidant pattern of attachment acquired in infancy may have influenced the development of physiological reactivity. That is, infants who employed a coping strategy characterized by avoidance, or seeming indifference to maternal separation and reunion, may have acquired a generalized pattern of underarousal that continued to develop across late infancy and was not salient until early childhood. In the same study, Burgess and colleagues (2003) found that children who were classified as avoidant in infancy and who were low in inhibition at 24 months scored significantly higher than all other attachment-inhibition groups on externalizing behavior problems on the Child Behavior Checklist (CBCL; Achenbach & Edelbrock, 1991), an effect that was largely carried by high scores on the Aggression subscale of the CBCL.

Raine (1996) proposed a model of physiological underarousal in the development of antisocial behavior, which has been empirically supported (e.g., Raine, Venables, & Williams, 1990). Although three-way interactions involving attachment security, behavioral inhibition, and cardiac reactivity as determinants of childhood behavior problems were not examined in the Burgess and colleagues (2003) report, it seems plausible that avoidant infants who are also uninhibited and who acquire a cardiac profile characterized by underarousal may be at considerable risk for the development of antisocial behavior in early childhood and beyond, which is a worthy topic for future research.

Recent research has examined the physiological correlates of attachment disorganization. Tharner and colleagues (2013) proposed a dual-risk model when examining the physiological responding of disorganized infants in the Strange Situation. In their large sample of 450 mother-infant dyads enrolled in the Generation R Study, they found a significant interaction between maternal postpartum depressive symptoms and attachment disorganization on infant baseline RSA. Specifically, 14-month-olds who were classified as disorganized and whose mothers were depressed showed lower resting RSA, while the same was not true for infants who had only one such risk factor (depressed mother or disorganized attachment). In another study, physiological dysregulation was predictive of later attachment disorganization. In a study of 206 mother-infant dyads drawn from the Durham Child Health Development Study, Holowchost, Gariépy, Proper, Mills-Koonce, and Moore (2014) examined infant physiological responding during the still-face paradigm (SFP) at infant age 6 months, quality of mother-child interaction during 10 minutes of free-play at 6 months, and attachment security at 12 months. They found that infant physiological responding and maternal interactive style at 6 months jointly predicted attachment disorganization at 12 months. Infants who showed higher levels of RSA during the interactive periods of the SFP and also had mothers who showed more negative and intrusive interactions, showed higher levels of subsequent attachment disorganization in the Strange Situation (Holowchost et al., 2014). Hence, high levels of RSA during interactions that are negative and intrusive may represent a maladaptive behavioral profile that foretells behavioral disorganization under stress. Taken together, this recent evidence supports a dual-risk model for disorga-

nized attachment, whereby contextual/parenting behaviors *and* a maladaptive physiological profile, with lower resting RSA and higher reactive RSA (during stressful interactions marked by negative parenting behavior) being associated with the pattern of fear and comfort seeking seen in disorganized attachment. Future research is warranted to examine this profile.

Holochwost and colleagues (2014) failed to control for baseline RSA in assessing SFP responding, and in light of the lower basal level of RSA found by Tharner and colleagues (2013), it would be premature to draw inferences about the exact nature of the physiological profile that acts in concert with parenting factors to yield disorganized attachment. An important future direction is to examine infant vagal suppression and augmentation (in light of basal levels) under conditions of both social interaction and relationship disruption.

Cortisol and Attachment

Cortisol Responding in the Context of the Strange Situation

A number of researchers have measured the cortisol levels of infants assessed in the Strange Situation. The cortisol response takes place over a much longer time course than do other physiological systems. Thus, measuring cortisol in saliva or plasma 15–30 minutes after completion of the Strange Situation may accurately capture an infant's HPA response during the testing procedure. Gunnar, Mangelsdorf, Larson, and Hertsgaard (1989) observed 66 infants in the Strange Situation at 13 months of age. Saliva was obtained from them, first at home prior to coming to the laboratory, then immediately before and immediately after the Strange Situation procedure. Of the 66 infants, 37 were classified as secure, 10 as avoidant, 16 as resistant, and three were classified as disorganized. There were no differences among attachment groups in either cortisol level or the degree of cortisol change. In a follow-up, Gunnar, Colton, and Stansbury (1992) examined differences in salivary cortisol between 47 securely attached infants and 24 insecurely attached infants. Again, saliva was collected immediately prior to and immediately after the Strange Situation paradigm. No differences in salivary cortisol reactivity were found among infants classified as avoidant, resistant, and secure.

Spangler and Grossmann (1993), on the other hand, reported finding differences in salivary

cortisol reactivity between their infant attachment groups. In their study of 41 infants, saliva was collected immediately prior to the Strange Situation paradigm, then 15 and 30 minutes afterward. They found significant cortisol increases in infants categorized as disorganized compared to secure infants 15 minutes after the Strange Situation, as well as significant secure–insecure differences 30 minutes after it. Spangler and Grossmann argued that these data support a cortisol–coping hypothesis, with secure infants being better able than insecure infants to cope with the stress of separation in the Strange Situation. They also commented on the differences between their findings and those of the two studies conducted by Gunnar's group (Gunnar et al., 1989, 1992). They noted that these differences could have resulted from variation in the length of time after the session before saliva was collected. In the studies by Gunnar and colleagues (1989, 1992), saliva was collected 5–10 minutes after the session; in the Spangler and Grossmann study, it was collected at 15 minutes, then again at 30 minutes after the Strange Situation paradigm. Given the slow response time of cortisol, the Gunnar and colleagues data may not have reflected the full effect of the Strange Situation on the insecure infants.

In a subsequent study, Hertsgaard, Gunnar, Erickson, and Nachmias (1995) examined 38 infants from a high-risk population. Unlike other studies, this one did not control for time of day at which saliva was obtained; nor was there any pretest cortisol measurement. Of the 34 subjects with usable data, 17 were classified as secure, five were classified as avoidant, one as resistant, and 11 as disorganized. Results of the analyses revealed that the infants with disorganized classifications had more elevated cortisol levels than all of the other infants combined. Further inspection of the data revealed that the main difference in level was between the avoidant and disorganized infants. That is, avoidant infants displayed the lowest cortisol values, and disorganized infants displayed the highest. The authors argued that these data support the notion that infants categorized as disorganized may have greater vulnerability to stressful situations. It is, of course, also interesting that the infants classified as avoidant did not show elevated cortisol levels. If, in fact, avoidant infants are physiologically stressed during the Strange Situation, one would expect their cortisol levels to be higher than those of secure infants. It is also important to note that the initial level of cortisol was not assessed; therefore, it is unclear whether the

cortisol levels represent different responses to the Strange Situation or initial differences between groups in levels of cortisol.

In a subsequent study, Nachmias, Gunnar, Mangelsdorf, Parritz, and Buss (1996) examined 73 children at 18 months of age in the Strange Situation. There were 13 children classified as avoidant, 12 classified as resistant, and 48 classified as secure. Salivary samples were collected immediately prior to the Strange Situation paradigm and 45 minutes after the onset of the testing session. The children had also been observed on a previous occasion responding to several novel events presented as part of assessing behavioral inhibition. *Behavioral inhibition* was defined as the tendency to restrain or restrict one's approach to new people, places, events, and/or objects (Kagan & Snidman, 1991). Although the authors did not find a relation between inhibition and security of attachment, they did find that children with higher behavioral inhibition had higher post-session cortisol levels if they were also insecure. Secure inhibited children did not exhibit significant cortisol reactivity; nor, for that matter, did insecure infants who were low in inhibition. Thus, the degree of cortisol reactivity in response to the Strange Situation in insecure children was heightened among those with higher behavioral inhibition. These results nicely illustrate Gunnar's stress model, in which the security of attachment is viewed as a buffer against stress; in this model, infants who are securely attached should exhibit a reduced stress response. In fact, inhibited infants who were securely attached did show lower cortisol responses.

Bernard and Dozier (2010) examined change in infant cortisol in response to the stress of the Strange Situation. In order to control carefully for baseline measures in assessing change in response specifically to the Strange Situation, the order of a laboratory play task and the Strange Situation was counterbalanced and home saliva samples were collected. The range of ages in the low-risk sample of 32 mother–infant dyads ranged from 11 to 20 months ($M = 15.2$, standard deviation = 2.3). Change in cortisol before and after the free-play and Strange Situation procedures (40, 65, and 80 minutes postarrival to the laboratory) were examined in relation to attachment disorganization. Infants classified as disorganized ($n = 8$) showed a significant increase in salivary cortisol only in the Strange Situation, with no such association found for the free-play condition. As well, no such pattern was found for infants with an organized classification (A, B, or C). Though the sample is

small, the findings support the hypothesis that disorganization is associated with more acute stress in response to the Strange Situation. As well, the authors found that cortisol concentrations acquired at home prior to the laboratory visit did not significantly differ from those acquired in the laboratory before the Strange Situation paradigm began. And the comparison of cortisol change in the free play versus the Strange Situation is additionally important, revealing that for disorganized infants, cortisol reactivity to the Strange Situation is specific to the challenge of the paradigm itself.

Consistent with recent trends toward examining cumulative risk factors for physiological dysregulation and attachment, Luijk and colleagues (2010) examined maternal depression (lifetime history of depression, as reported during pregnancy) and infant cortisol responding to the Strange Situation paradigm in a sample of 369 mother–infant dyads drawn from the Generation R Study. Saliva was collected from 14-month-olds at baseline, directly after, and 15-minutes after the Strange Situation paradigm. The distribution of attachment classifications was 413 secure, 136 avoidant, and 166 resistant infants. Across the sample, 162 were classified as disorganized. Infants classified as resistant showed a significant increase in cortisol (over basal levels) relative to secure and avoidant infants, a finding that remained robust when researchers controlled for maternal depression. However, this effect was qualified by an interaction with maternal depression, with resistant children whose mothers reported higher levels of lifetime depression showing the steepest increase in cortisol reactivity. This pattern of cortisol reactivity is consistent with the behaviorally reactive profile of resistant infants, who are unable to use their caregiver as a source of comfort. Furthermore, resistant infants were more likely to show increased stress reactivity if their caregiver reported a previous diagnosis of depression.

Additional evidence in support of the dual-risk model for infant physiological regulation examined the timing of maternal depressive symptoms and infant HPA reactivity in the Strange Situation. Applying a novel approach, Laurent, Ablow, and Measelle (2011) examined infant cortisol responding in the Strange Situation. In an at-risk sample of 86 mothers, symptoms of depression were assessed via questionnaire in the third trimester of pregnancy, 5 months postnatal, and 18 months postnatal. At infant age 18 months, infant saliva samples were collected at baseline, immediately after and 15 minutes after the Strange

Situation. The data were not coded for attachment classification; however, the use of growth curve modeling to document change in cortisol in infants elucidates the nature of infant responding during the Strange Situation. Across the sample, infant cortisol data fit a curvilinear model, with levels increasing from baseline to immediately after the Strange Situation and decreasing 15 minutes later. Higher levels of maternal prenatal depression were associated with a hypo-responsive (blunted) cortisol response in infants, whereas higher depressive symptoms in both postnatal assessments of maternal depression were associated with a hyper-responsive (increased stress) cortisol response in infants. Furthermore, an increase in maternal depressive symptoms from low prenatal levels to higher postnatal levels was associated with hypercortisolism in infants, with a steeper cortisol peak immediately after the Strange Situation and lack of recovery 15 minutes after the Strange Situation. This study expands the study of the biology of attachment by providing evidence that “fetal programming” may impact the physiology underlying relationship functioning. Emergent literature on the effects of fetal programming due to maternal psychopathology (Grant et al., 2009) and teratogenic exposures (Haley, Handmaker, & Lowe, 2006) on infant cortisol responding in the SFP provide additional support for the importance of extending the examination of dual-risk models into the prenatal period. Research that integrates measures of fetal risk, infant physiology, and attachment security will be an important future direction.

Individual Differences in Cortisol Responding Outside of the Strange Situation

Longitudinal evidence indicates that attachment security foretells subsequent physiological regulation as assessed via salivary cortisol. In a comprehensive examination of biobehavioral organization, attachment security, and behavioral inhibition, Schieche and Spangler (2005) assessed 76 toddlers in the Strange Situation at 12 months; inhibited temperament at 22 months via maternal report; maternal and child behavior during a challenge task (i.e., a series of structured tasks of progressive difficulty, which culminated in the necessary involvement of the mother for successful completion) at 22 months; and salivary cortisol in infants before and 15 and 30 minutes after the challenge paradigm at 22 months. Nineteen

infants were classified as insecure-avoidant, 23 as secure, 11 as insecure-resistant, and 23 as disorganized.

Contemporaneous associations between behavior during the challenge task and cortisol showed that elevated cortisol was associated with low task orientation and low exploration in the infants, which in turn were associated with low supportive maternal presence and reduced quality of maternal assistance during the challenge task (although no significant relations between cortisol and maternal behavior during the task were revealed). Across the sample, infants showed a decline in cortisol during the challenge task, and this was particularly evident for infants who were reported by their mothers as low on behavioral inhibition. However, differential levels of cortisol were revealed for highly inhibited children depending on attachment status, with securely attached inhibited infants showing the expected decrease in cortisol from task onset to 30 minutes after the task. Avoidant infants, in contrast, showed a decrease from task onset to 15 minutes after the task, but a modest (nonsignificant) increase in cortisol 30 minutes after the task, suggesting a delayed activation of the HPA axis. This finding was complemented by behavioral findings indicating that avoidant infants manifested less effective coping and an inability to use their mothers as a source of support during the challenge task. Within-group analyses revealed that elevated cortisol was associated with low task orientation and exploration, low help-seeking behavior, and high proximity seeking for the insecure group (A, C, and D combined). No significant correlations involving cortisol within the secure group were obtained.

Recent evidence points to the importance of individual differences in infant diurnal rhythms in cortisol and attachment security. In the large sample previously described, Luijk and colleagues (2010) examined the diurnal rhythms of cortisol prior to the lab visit in which the Strange Situation paradigm was administered. The typical diurnal rhythm of cortisol is one in which cortisol is high shortly after awakening and then declines steadily across the day, though the age at which this pattern is manifest is of some dispute (e.g., see de Weerth & van Geert, 2002; Gunnar & Donzella, 2002). Chronic stress exposure, including painful procedures in the neonatal intensive care unit (Grunau et al., 2005); child maltreatment (Doom, Cicchetti, & Rogosch, 2014); and child poverty (Zalewski, Lengua, Kiff, & Fisher, 2012) are associated with blunted, or less variable, diurnal

rhythms in cortisol. Luijk and colleagues collected saliva samples from infants immediately upon awakening, and again 30 minutes later, midafternoon, late afternoon, and at bedtime. Across their large sample, 14-month-olds showed the predicted pattern of high levels at waking and a decline throughout the day. However, this healthy pattern of cortisol secretion was significantly different for infants who showed disorganized behavior in the Strange Situation; they showed a flattened slope, particularly between waking and the next collection, 30 minutes later. This finding provides physiological evidence that is consistent with the body of research linking contextual risk/chronic early-life stress to attachment disorganization.

Taken together, the research findings suggest that the association between early attachment, stress reactivity, and social behavior later in infancy is dependent on an infant's temperamental disposition and chronic stress exposure; and that for an insecurely attached or disorganized infant, physiological reactivity is associated with a corresponding behavioral profile characterized by an inability to use the mother effectively as a source of support in the face of environmental challenge.

Quality of Caregiving and Infant Physiological Arousal

Quality of maternal caregiving, particularly caregiving that is sensitive (i.e., involving prompt, contingent, and appropriate responsiveness to infant cues and signals; Ainsworth et al., 1978), is the key theoretical antecedent to infant attachment security. An exciting body of research involving both animals and humans is revealing that natural (in the case of animals) or ordinary (for humans) variations in the quality of maternal caregiving shape both neurological systems and the expression of genes that regulate stress reactions.

Meaney and his colleagues (Caldji et al., 1998; Francis, Diorio, Liu, & Meaney, 1999; Liu & Diorio, 1997) have shown that naturally occurring variations in quality of maternal caregiving behavior (MCB) among rat dams shapes the development of the neural substrates that underlie the phenotypic behavioral and endocrine responses to stress in offspring. These researchers noted that the MCB of rat dams in the postnatal period—specifically, in terms of nursing posture (arched-backed vs. lying down) and frequency of licking

and grooming behavior—is normally distributed. They created extreme groups of pups based on the quality of MCB received (low vs. high levels of licking/grooming and arched-backed nursing) and followed these offspring into adulthood. Compared with adult offspring that received high degrees of maternal licking/grooming and arched-backed nursing in the postnatal period, the adult offspring of dams that provided low degrees of maternal licking/grooming and arched-backed nursing showed a behavioral response reflective of heightened levels of stress reactivity, including higher frequencies of startle responses, less open-field exploration, and longer latencies to eat food presented in a novel environment (Caldji et al., 1998; Francis et al., 1999). These differences in behavior were accompanied by a corresponding neuroendocrine profile characteristic of heightened fearfulness (Caldji et al., 1998), such as increased plasma adrenocorticotropic hormone and corticosterone responses to restraint stress, and decreased sensitivity to the inhibitory effects of glucocorticoids during acute stress (Liu & Diorio, 1997). The behavioral differences were also associated with decreased central benzodiazepine receptor density in the central, lateral, and basolateral nuclei of the amygdala and locus ceruleus (Caldji et al., 1998).

In a study based on retrospective self-report, Pruessner, Champagne, Meaney, and Dagher (2004) found that human adults who reported extremely low-quality relationships with their parents evidenced significantly more release of dopamine in the ventral striatum and a higher increase in salivary cortisol during a stressful event than individuals who reported extremely high-quality parental relations. Such an effect suggests that early human caregiving may similarly affect the development of the systems that underlie stress reactivity.

In an effort to extend this provocative set of findings to human infants, we (Hane & Fox, 2006) examined the relation between quality of MCB and behavioral and physiological indices of stress reactivity in 9-month-old infants. The quality of MCB during routine activities in the home (e.g., feeding and changing) was assessed with Ainsworth's (1976) original global scales for rating degree of maternal sensitivity, which included ratings for acceptance, availability, appropriateness of interaction, and delight in the infant, as well as an intrusiveness scale developed by Park, Belsky, Putnam, and Crnic (1997).

We then compared the infants who received low-quality MCB to those who experienced high-

quality MCB on indices of stress reactivity, also assessed at age 9 months, and found that infants who experienced low-quality MCB displayed significantly more fearfulness during the presentation of novel stimuli and less sociability with an experimenter. In addition, the infants receiving low-quality MCB showed a pattern of right frontal EEG asymmetry. These infants were not found to differ in terms of earlier temperament from the infants who received high-quality MCB, based on degree of positive and negative reactivity to novelty assessed at age 4 months. However, infants who received low-quality MCB were more likely to express higher levels of negative affect during interactions with their mothers at age 9 months than infants in the high-quality MCB group, which may reflect the influence of infant negative disposition on MCB and/or infant negativity in response to low MCB.

In a longitudinal follow-up to Hane and Fox (2006), we examined whether the effects of the quality of MCB in infancy persist across time and influence social behavior in early childhood (Hane, Henderson, Reeb-Sutherland, & Fox, 2010). We found that, relative to children who experienced high-quality MCB as infants (high MCB children), those who received low-quality MCB (low MCB children) showed increased stress reactivity on measures that parallel those used in our earlier report, including inhibited social behavior with adults and right frontal EEG asymmetry. Low MCB children also manifested more aggression during play with a novel, same-sex peer, and mothers reported that low MCB children tended to show more internalizing problems and more proneness to anger in social situations than high MCB children. As in the 2006 study by Hane and Fox, these effects were not influenced by earlier negative reactivity to novelty.

Parent and colleagues (2005) and Zhang, Parent, Weaver, and Meaney (2004) theorized that low-quality maternal care may forecast the future and thereby prepare offspring for the ecology that is to come. The highly malleable neurobiology of young offspring is accordingly programmed by suboptimal early care, and adapts more readily by mounting defensive responses to stress across the lifespan (Parent et al., 2005; Zhang et al., 2004). One central tenet of this hypothesis is that the experience of low-quality early maternal care yields defensive/stress responding in the early rearing environment. To examine if this model may apply to human infants, Hane and Philbrook (2012) examined the direct experience of low-quality MCB on infant cortisol responding. Mothers and infants

were observed in the home, and mothers' quality of maternal care during tub bathing was coded for maternal sensitivity. Salivary cortisol was measured in infants prior to tub bathing and again 15 minutes following removal of the neonate from the bath water. Consistent with earlier MCB work and the animal models, infants of mothers who provided lower quality MCB showed a larger increase in cortisol following the experience of routine care. Hence, the experience of being in a routine, ordinary, regularly occurring care task with an insensitive caregiver is associated with elevated physiological stress responding. Such findings lend support for the notion that the experience of insensitive maternal care in humans results in defensive/stress responding. Consistent with epigenetic models of early maternal care, such elevated stress responding to normative early caregiving routines for infants of insensitive mothers may program the neonate to respond with elevated stress in the future (Hane & Philbrook, 2012).

Exposure to early and pronounced stressors that cause dysregulation of the HPA axis predispose individuals to further problems in dealing with environmental stressors, and persistent difficulty in coping with stress exacerbates risk for behavioral and health problems (Meaney, 2001). The molecular mechanism for these effects is epigenetic in nature, with maternal care leading to alterations of hippocampal glucocorticoid receptor genes (Champagne, 2013). The neuroendocrine changes associated with dysregulation of the HPA axis alter the organism's energy availability and cardiovascular health, which over time may predispose individuals to steroid-induced diabetes, hypertension, and other risk factors for heart disease (Brindley & Rolland, 1989).

Bowlby, Ainsworth, and others have contended that the importance of the quality of the mother–infant relationship is far-reaching. A body of research has documented the association between attachment security and general health outcomes (see Ehrlich, Miller, Jones, & Cassidy, Chapter 9, this volume, for discussion of attachment and psychoneuroimmunology). New evidence indicates a potential link between maternal insensitivity and poorer health. Wendland and colleagues (2014) found that low levels of maternal sensitivity in infancy (age 6 months) predicted higher body mass index in girls at age 4. Prospective longitudinal studies examining the association between maternal sensitivity and health outcomes across the lifespan are critical for identifying the long-term influence of early maternal care in humans.

The Role of Oxytocin in the Formation of Affiliative Bonds

In our chapter in the previous edition of this handbook (Fox & Hane, 2008), we reviewed the literature on physiology and adult attachment patterns. For this current chapter, we highlight advancements in research on the neuroscience of parenting and the formation of affiliative bonds, focusing on the hormone oxytocin. Using definitions that vary from those of Bowlby and Ainsworth, Feldman (2012a, p. 154) has defined affiliative bonds as “selective and enduring attachments” that are formed by the coordination of physiological and behavioral systems between partners. According to Feldman (2012b), the coordination of the biobehavioral systems underlying affiliative bonding serves as the foundation for healthy functioning in relationships. Oxytocin (OT) is a neuropeptide (neuronal signaling molecules that influence cortical activity), with the major site of genetic expression/synthesis in the magnocellular neurons of the hypothalamus, including paraventricular and supraoptic nuclei. In response to environmental cues such as infant breast feeding, childbirth, and environmental stress, processed OT is released from the posterior pituitary into circulation. OT is closely related to neuroendocrine stress responding (Gimpl & Fahrenholz, 2001). In humans, it can be measured peripherally in blood, saliva, and urine samples. The central actions of OT are numerous, including modulation of neuroendocrine responding, complex social bonds, and factors related to reproduction in both men and women. OT is of particular interest to attachment researchers because it is centrally involved in affiliative behaviors, including sexual activity (Behnia et al., 2014), social cooperation (Feng et al., in press), forgiveness (Yao et al., 2014), and empathy (Bartz et al., 2010). Although the precise mechanisms underlying the function of OT remain underspecified, there is evidence that its role in affiliative behavior may be mediated by reduction in neuroendocrine stress responding, though the anxiolytic and antistress efficacy of OT depends on the nature of the individual’s stress response profile, for example, early life stress exposure (Grimm et al., 2014), and adult attachment history and social context (Olff et al., 2013). OT has been found to increase social sensitivity under conditions of social stress (Eckstein et al., 2014); and other research indicates that OT administration allows for more flexibility in shifting attention in the face of threat (Ellenbogen, Linnen, Grumet, Cardoso, & Jooper, 2012). There is still much to learn about

the neurological underpinnings and downstream effects of OT, stress, and social behavior.

The role of OT in early parental caregiving and attachment-related behaviors is equally underspecified and complex. In animal models, administration of OT induces parental care, including higher levels of licking and grooming behavior and also aggression in rats (e.g., see Bosch & Neumann, 2012). Recent attention has also shifted to fetal programming and the role of postnatal OT exposure as a buffer against deleterious outcomes associated with prenatal stress exposure and exposure to teratogens. For example, administration of OT to offspring of prenatally stressed dams reverses social incompetence, suggesting that OT may serve a protective function for offspring exposed to high levels of antenatal stress (Lee, Brady, Shapiro, Dorsa, & Koenig, 2007). This rapidly growing animal OT literature cuts across a variety of species, examines a host of outcomes, and indicates that the effects of OT are dependent on timing of exposure and individual differences, such as sex and contextual risk.

The human attachment OT literature is also growing rapidly and reveals similar complexities. Most importantly, although this field is in its infancy, the study of OT in attachment-related behaviors has moved swiftly into integrating multiple physiological systems and behavior. One such example is Feldman’s (2012a) biobehavioral synchrony model, which highlights the multiple physiological and behavioral influences that operate in tandem, or synchronously, between the parent and child to influence relationship functioning and stress responding. This approach is holistic, but much like the aforementioned animal and social neuroscience work, poses challenges for interpretation.

Consistent with animal models, plasma OT levels in both human mothers and fathers is associated with affectionate parenting behavior. In a longitudinal study of 160 parents and their firstborn infants, patterns of parent–child interaction were observed, and plasma OT samples were collected in the home in the early neonatal period and again at infant age 6 months (Gordon, Zagoory-Sharon, Leckman, & Feldman, 2010). Plasma levels of OT for mothers and fathers increased across time, and maternal and paternal levels did not differ significantly from each other. Higher levels of maternal OT were associated with more affectionate touch, infant-directed speech, and positive facial affect. Higher levels of paternal OT were associated with an increase in playful stimulatory behavior, including touch and play with objects.

Additional evidence points to an increase in OT following mutually rewarding parent–child exchanges. Feldman, Gordon, Schneiderman, Weisman, and Zagoory-Sharon (2010) measured maternal and paternal plasma and salivary cortisol at baseline and again 15 minutes after a parent–infant play session in the laboratory when infants were 4–6 months of age. Salivary and plasma OT levels were highly interrelated for both mothers and fathers, and maternal and paternal OT were remarkably similar in their levels at both collection points. A significant increase pre- to postplay in OT was revealed only for mothers who showed high levels of affectionate interactions with their infants. For fathers, OT increased only for those who showed a high level of playful stimulation with their infants. Taken together, both studies support the role of OT in underlying caregiving-related behaviors, though this research is limited by the correlational nature of the design.

One major advantage to the use of OT is the methodology allowing for safe administration via nasal spray. This approach to administering doses of OT allows for the development of well-controlled experimental designs to examine the effect of OT on parenting behaviors. Weisman, Zagoory-Sharon, and Feldman (2012) examined whether intranasal OT administration in fathers influenced physiological and behavioral indicators of positive social engagement. In a sample of 35 fathers and 5-month-old infants, fathers were randomized to OT or placebo conditions, and saliva was collected from fathers and infants at baseline (before OT administration), and at 20 and 40 minutes following a father–child interaction, during which ECG data were acquired. Relative to fathers in the placebo condition, fathers who received OT showed increased vagal tone during interaction with their infant and promoted positive social engagement with the infant, including gaze and social reciprocity. Infants of fathers in the OT condition showed parallel increases in OT, vagal tone, and social reciprocity, despite not having any direct exposure to OT manipulation themselves.

In another study of fathers and infants, Feldman's group examined the similar patterns of physiological synchrony in father–infant interactions in terms of cortisol responding during a stress-inducing paradigm (the SFP). Fathers were randomly assigned to an OT or placebo condition, and observed with their 5-month-olds in the SFP twice, in sessions that were 1 week apart. Saliva was collected during each SFP laboratory visit, similar to that in Weisman and colleagues (2012).

Relative to fathers in the placebo group, fathers exposed to OT showed an increase in cortisol responding during the SFP, which is consistent with research showing that OT increases social sensitivity (Eckstein et al., 2014). The effects of OT exposure on infant biobehavioral responses to the SFP depended on the quality of the interaction within the dyad, such that for infants who experienced high social synchrony with fathers, paternal OT exposure was associated with elevated cortisol and increased gazing at the father during the still-face portion of the SFP. For infants embedded in a dyad characterized by asynchronous exchanges, paternal OT was associated with attenuated infant cortisol response to the SFP and less gazing in response to the “still-faced” father. This is consistent with other OT research showing that the effects of OT on stress responding and relationship functioning depend on individual-difference variables (Grimm et al., 2014), and, importantly, extends this work to individual differences in attachment-related behavior.

Neuroscience Studies of Parenting

The field of neuroimaging has exploded since publication of the previous edition of this handbook. This includes the new field of *parental neuroscience*, or research examining maternal neural responses to infant cues and attachment-related behaviors. A body of imaging research has examined patterns of neural activation in response to familiar versus unfamiliar faces, and in some instances has examined differences in women's responses to faces of their own children versus faces of unfamiliar children. For example, Nitschke and colleagues (2004) showed women photographs of their own infants, unfamiliar infants, and unfamiliar adults. Women also rated their hedonic responses to each of the photographs. Results revealed strong bilateral activation of orbitofrontal cortex when women viewed pictures of their own infants, compared to either unfamiliar infants or unfamiliar adults. Women's ratings of their hedonic response to the pictures revealed heightened positive affect to pictures of their own children versus other children. Interestingly, the brain response to their own versus unfamiliar infants diminished over time. That is, in a second block of exposures, the difference in brain response (but not in the hedonic rating) between their own and unfamiliar infants decreased. The orbitofrontal cortex is a region of

the prefrontal cortex that has been implicated in the decoding of the affective valence of a stimulus. It has been implicated in rodent and human work as a brain region that is important for reward processing (Knutson, Westdorp, Kaiser, & Hommer, 2000; Schoenbaum, Chiba, & Gallagher, 1998). Nitschke and colleagues suggest that it may also be involved in attachment-related behaviors, particularly those involved in experiencing positive affect toward an attachment figure.

In similar work, Leibenluft, Gobbini, Harrison, and Haxby (2004) examined women's neural activation while each woman viewed pictures of her own child, a friend's child, an unfamiliar child, or an unfamiliar adult. The design of the study allowed comparison of familiar versus unfamiliar children and women's own children versus familiar children to determine the neural specificity of each comparison. Results revealed that a complex set of brain networks was activated for each of the different types of stimuli. Viewing one's own child versus a familiar child activated amygdala, insula, anterior paracingulate cortex, and superior temporal sulcus. Viewing familiar versus unfamiliar children activated regions similar to those seen in prior studies in which familiar versus unfamiliar adults were viewed. The authors suggested that viewing one's own child (vs. another familiar child) activates emotional responses and cognitions that may reflect attachment, protection, and empathy. Although subjects were asked prior to scanning to rate the stimuli, the questions did not cover the psychological states that are proposed to be associated with activation of these different neural structures.

Additional support for the complexity of the neural circuitry involved in a mother's recognition of her own child, as compared with another, under conditions of distress and nondistress extend this research by adding an additional layer of context. Noriuchi, Kikuchi, and Senoo (2008) scanned mothers as they were asked to view a series of video clips of their own child versus an unfamiliar 16-month-old in both distressing (Strange Situation) and nondistressing (free play) tasks. Distinct neurological profiles of activation were found when mothers viewed their own (vs. another) child, particularly involving the orbitofrontal cortex, periaqueductal gray, anterior insula, and dorsal and ventrolateral parts of the putamen. Higher activity in the right orbitofrontal cortex was associated with increased joy in the play-viewing condition, whereas activation of the right orbitofrontal cortex was associated with anxiety while viewing

the child in the Strange Situation. The inclusion of ratings of maternal feelings marks an important extension to the neuroscience of parenting, allowing an opportunity to examine neurological responses that underlie specific affective responses related to the experience and emotions of mothering.

Another important direction is the incorporation of observed mother–infant interactive behavior and maternal neurological responding to infant distress. Musser, Kaiser-Laurent, and Ablow (2012) observed 22 mothers interacting with their 18-month-old infants and coded maternal sensitivity and intrusiveness. Mothers were later exposed to the sound of their own or another infant crying. More sensitive mothers showed greater neurological activation to their own infant's cry in the right frontal pole and inferior frontal gyrus, regions associated with emotion processing and regulation. The pattern of activation may be consistent with better recognition of their own infant's emotions and the ability to regulate their own negative emotion in order to respond sensitively. Mothers with an intrusive style of responding showed greater activation in the left anterior insula and temporal pole to their own infant's cry, regions that are associated with sensory and emotion processing and empathy, perhaps suggesting that intrusive mothers have a more reactive and acute empathic response to infant discomfort that contributes to intrusive behavior. Mothers who experienced harmonious interactions with their infant displayed greater activation in left hippocampal regions associated with memory and stress regulation. Hence, harmonious interactions may be associated with better maternal representation of the dyad's interactional history and mothers' ability to regulate stress during infant crying. The inclusion of observed mother–infant interactive behavior in the field of parental neuroscience is yet another major advancement that is providing a more complete picture of how maternal brain activation to infant cues is embedded within the larger relational ecology of the dyad.

Conclusions

Throughout this chapter, we have reviewed contemporary approaches to the study of the biology of human attachment. This vast field is expanding rapidly in new and exciting directions. Here we have focused specifically on psychophysiological and neuroscientific approaches to studying attach-

ment. Each approach involves complex technologies, with its own set of methodological issues and constraints. Current advancements in temporal precision of measurement and designs that integrate multiple biological systems along with the context of care have advanced the field considerably since the previous edition of this handbook.

Chapter 12

Toward a Neuroscience of Attachment

James A. Coan

Neurobiological studies of attachment are either abundant or scarce, depending on one's research tradition and what, precisely, one means by *attachment*. On the one hand, the past few decades have seen a great deal of nonhuman animal work detailing the neural mechanisms supporting social bonding, familiarity, affiliation, caregiving, and other behaviors that can (and often do) fall under the "attachment" rubric (see Polan & Hofer, Chapter 6, and Suomi, Chapter 7, in this volume). On the other hand, neuroscientific investigations of normative attachment in *humans* have been relatively limited. And the neural circuits supporting attachment *styles* (e.g., secure, anxious or ambivalent, and avoidant, in the social psychology tradition; autonomous, preoccupied, and dismissing, in the clinical and developmental tradition; see Crowell, Fraley, & Roisman, Chapter 27, this volume) are even more mysterious (Coan, 2010). These facts (and a cursory glance at the Contents for this volume) underscore the complexity of attachment as a domain of inquiry and suggest that, at present, any neuroscience of attachment is likely to be limited in both empirical foundation and theoretical scope.

Nevertheless, real progress is being made, and the neuroscience of attachment has much to gain from the integration of multiple research perspectives and traditions (Sokolowski, 2010). Following Bowlby (1969/1982) and Ainsworth (1989), I

consider attachment bonds to be characterized by a high frequency of close proximity to putative "attachment figures," especially during times of emotional stress. Moreover, attachment relationships serve regulatory functions, often in relation not only to basic physiological needs but also with respect to many forms of emotional responding. These regulatory functions are *social* insofar as they result from interaction with *conspecifics* (other members of the same species). Some of the regulatory functions of attachment relationships are obvious and fundamental. For example, human infants literally cannot survive without the assistance of an adult caregiver. In later childhood, however, and in adult attachment relationships, emotion may be seen as the primary target of social regulation (Mikulincer & Shaver, Chapter 24, this volume), and social relationships may even regulate primary perceptual systems that mediate emotional responses (Coan & Sbarra, 2015; Gross & Proffitt, 2013). A major interest here is the social regulation of threat vigilance and responding (Carter & DeVries, 1999; Coan, Schaefer, & Davidson, 2006; Edens, Larkin, & Abel, 1992; Hofer, 1995).

A large literature now suggests that a range of interactive social behaviors target physiological systems, temperamental dispositions, and overt behaviors associated with the stress response (DeVries, Glasper, & Detillion, 2003; Sachser, Kaiser, & Hennessy, 2013). For example, sup-

portive social behaviors attenuate stress-related activity in the autonomic nervous system (ANS) and the hypothalamic–pituitary–adrenocortical (HPA) axis (Lewis & Ramsay, 1999; Wiedenmayer, Magarinos, McEwen, & Barr, 2003). Maternal grooming behaviors affect glucocorticoid receptor gene expression underlying hippocampal and HPA axis stress reactivity in rat pups (Turecki & Meaney, 2016). In the context of a novel, mildly stressful environment, rats in the company of a familiar companion engage in more exploration and play-soliciting behavior than do rats in the company of an unfamiliar companion (Terranova, Cirulli, & Laviola, 1999).

Theorists have long argued that social bonding serves the regulatory functions of security provision and distress alleviation with respect to negative affect and arousal (Bowlby, 1973; Mikulincer, Shaver, & Pereg, 2003). Evolutionary theorists dating back to Darwin have even argued that because mammalian emotional responding evolved in a social context, emotional behavior is virtually inextricable from social behavior (Buss & Kenrick, 1998; Darwin, 1872/1998). Recent work in visual perception suggests that proximity to social resources fundamentally alters even our earliest perceptual mechanisms (Gross & Proffitt, 2013; Schnall, Harber, Stefanucci, & Proffitt, 2008). These diverse perspectives and literatures suggest that any robust conception of attachment will include multiple distributed subsystems, including (but probably not limited to) those devoted to perception, memory, emotion, motivation, emotion regulation, and social affiliation.

The promise of an “attachment neuroscience” is at once to provide critical information about how the brain supports attachment behaviors and to forge links among research traditions as diverse as the basic neurosciences, behavioral ecology, and various subdomains of psychology (e.g., developmental, social, and clinical), as well as affective science. In this chapter, the neural systems supporting emotion, motivation, emotion regulation, and social behavior are first reviewed. Following this, the social regulation of emotion and individual differences in attachment behavior are considered from the perspective of behavioral neuroscience. Based on these reviews, I describe a “social baseline” theory that integrates the study of social relationships with principles of attachment, behavioral ecology, cognitive neuroscience, and perception science. The social baseline theory borrows heavily from theoretical work on the predictive nature of the brain and the *economy of action*

built into the management of metabolic resources devoted to emotional and social behavior. Finally, recommendations are made for the development of a robust future neuroscience of attachment.

Attachment as a Neural Construct

Although attachment bonds are widely believed to result from a universal, innate “attachment behavioral system,” attempts to locate a single, dedicated attachment circuit is likely to be (to paraphrase Wittgenstein) a bit like trying to find the real artichoke by peeling away all its leaves. Almost any interpretation of the attachment behavioral system reveals it to be a higher-order construct comprising distinct behaviors about which a great deal is known, even at the neural level (see Hane & Fox, Chapter 11, and Polan & Hofer, Chapter 6, this volume). For example, many studies have addressed the neurobiology of social behaviors such as recognition and familiarity, proximity seeking, separation distress, soothing, and maternal caregiving. Thus, one of my goals in this chapter is to introduce the neuroscientific study of attachment from the perspective of what is currently known about its social and emotional *constituents*.

A corollary goal is to move toward bridging two broad, rigorous, productive, and unfortunately disparate literatures. One is a thriving animal literature dedicated to what is variously termed “social bonding,” “pair bonding,” and “attachment bonding.” The other contains a vast body of research on human attachment behavior, including studies of individual differences in internal working models of attachment (reviewed in Mikulincer & Shaver, 2007; Chapter 24, this volume; also see J. A. Feeney, Chapter 21, this volume). These two worlds have had little to say to each other—a reflection of their starkly different assumptions and research strategies as much as their different subject populations. Animal models emphasize discrete social processes in terms of specific causal neural structures, circuits, neurotransmitters, neuropeptides, pheromones, or hormones. Attachment relationships are defined observationally, by the presence of separation distress or physiological soothing as a function of close proximity. By contrast, social, clinical, and developmental psychologists often focus their efforts on assumed “behavioral systems,” seeking to understand how humans behave in—and, importantly, what they have to say about—relational contexts.

This is not to say that research on attachment in humans has not utilized physiological measurement. On the contrary, attachment researchers have used measures of ANS physiology, electroencephalography (EEG), glucocorticoid levels, and more recently, functional magnetic resonance imaging (fMRI). These measures have provided valuable insights into human social behavior, but they are rarely capable of identifying causal brain-behavior relationships (Norris, Coan, & Johnstone, 2007), and their frequent dependence on self-report measures (including coded interviews) may result in neurobiological correlates that are quite distinct from those of behaviorally defined animal models (Williamson, 2006).

Yet another difficulty presents itself in bridging these literatures. Even if the definitions of attachment were perfectly matched, and if the neural measures applied to humans and nonhuman animals were identical, the neural processes associated with attachment behaviors in nonhuman animals may not generalize perfectly to those in humans. Work on the social communication value of pheromones provides an excellent example of this point. *Pheromones* are chemical substances that convey information between members of the same species (Beny & Kimchi, 2014). It is certain that nearly all animals, including humans, show at least some evidence of two distinct olfactory systems (Shipley, Ennis, & Puche, 2003). The *primary olfactory system* is dedicated to the detection of odors that convey information about food or the presence of predators, and this system is most commonly associated with the sense of smell. By contrast, the *accessory olfactory system* is, in many species, dedicated to the detection of specific pheromonal information. This accessory olfactory system consists of the vomeronasal organ (VNO) and the accessory olfactory bulb (AOB). Pheromones make contact with the VNO, exciting pheromone-specific sensory neurons projecting to the AOB.

In a wide variety of species, this system is capable of providing rapid and powerful information about sex, reproductive capacity, mate location, territorial boundaries, and even social status (Beny & Kimchi, 2014; Insel & Fernald, 2004). Nevertheless, the strongest of these findings derive exclusively from studies of nonprimate animals. After a great deal of initial excitement about the possibility of a human pheromone system, enthusiasm has waned significantly amid evidence that although there does appear to be a human VNO, (1) there is no obvious pheromone-specific sensory

neuron associated with it; (2) vomeronasal receptor genes present in the human genome appear to be *pseudogenes* (genes that have lost their protein-coding ability); and (3) the AOB does not appear to exist at all in the brains of adult humans (Meredith, 2001; Smith, Laitman, & Bhatnagar, 2014). In other words, the VNO—the primary and best-understood mechanism of socially critical pheromonal communication in animals—appears to be vestigial in humans.

Despite these cautions, it is clear that research on animals has yielded invaluable information about the neurobiology of attachment, without which any understanding of human attachment would, at the neural level, be severely impoverished. Moreover, advanced neuroimaging techniques such as EEG, positron emission tomography (PET), transcranial magnetic stimulation (TMS), and fMRI promise access to human neural processes at a level of detail undreamed of until the very end of the 20th century. Hence, the potential for building bridges between animal and human attachment literatures is higher than it has ever been. fMRI studies in particular, by virtue of their rapid proliferation and relative lack of invasiveness, are beginning to supply pieces of the human social-bonding puzzle that will complement anatomical and molecular work in animals. Such advances promise the formation of a more comprehensive neuroscience of attachment.

The Neural Constituents of Attachment

Neural systems supporting attachment are likely to include, at a minimum, those underlying incentive motivation, emotional responding, emotion regulation, and discrete social behaviors, such as the establishment of familiarity and preference, proximity seeking, separation distress, and social affect regulation. This chapter does not provide an exhaustive treatment of all possible constituent systems underlying attachment. In truth, because so many neural structures are involved one way or another in attachment behavior, it is possible to think of the entire human brain as an attachment system. Auditory, olfactory, and visual sensory systems are heavily implicated for obvious reasons. Memory processes—involving, for example, long-term memory consolidation and retrieval in the hippocampus—underlie familiarity, recognition, and the maintenance of shared histories.

Many different regulatory needs affected by attachment relationships are likely to be related to activity in the hypothalamus. Conflict-monitoring demands will be made on the anterior cingulate cortex (ACC). Each of these systems and more contribute to attachment in a variety of ways. In this chapter, however, I review a smaller number of putatively basic elements.

Preliminary Considerations

Behavioral versus Neural Systems

I should first distinguish between what ethologists call “behavioral systems” and what neuroscientists call “neural systems.” A *behavioral system* is a set of behaviors associated with a common causal antecedent and resulting, once activated, in a common consequence, which in turn deactivates the system. Bowlby (1969/1982) described several behavioral systems associated with social behavior. When discussing behavioral systems such as these, there is a great temptation to view the behavioral system as having a one-to-one relationship with some underlying neural system. But such tidy correspondences are rare. *Neural systems* are coordinated neural inputs and signaling targets among populations of neurons that form a circuit. Neural systems can be tightly organized in close physical proximity or distributed throughout the brain. The problem is that similar behaviors may be caused by dissimilar neural systems. Moreover, similar neural activations can result in quite distinct behaviors. So the search for specific neural circuits associated with observationally defined behavioral systems is fraught with theoretical and empirical difficulty.

Bottom-Up versus Top-Down Processing

Although the terms *bottom-up* and *top-down processing* are frequently used in the cognitive neurosciences (and throughout the remainder of this chapter), their meanings may not be immediately obvious. Bottom-up processes begin, more or less, with sensory information, usually within subcortical brain structures, working “up” to more integrative areas within the cortex. The process of receiving sensory inputs from the environment and converting those inputs into neural pulses that are relayed to cortical structures as consciously perceived information about one’s surroundings would be an example of this. Top-down processes are essentially the opposite. In this case, integrative,

cortically mediated information is sent “down” to more sensory-oriented subcortical structures, often for some regulatory purpose. One example of a top-down process might be the brain’s tendency to impute information from memory and experience into stimuli in the periphery of the visual field, thereby imposing “best guesses” on ambiguous visual information. These distinctions are necessarily simplified, but not unreasonably so. Exceptions and ambiguities are legion, but the difference between top-down and bottom-up processing retains its pragmatic utility both neuroanatomically and conceptually.

Emotional and Motivational Elements

Incentive Motivation, Reward, and the Dopamine System

Incentive motivation involves the acquisition of rewarding stimuli. The intensity of incentive motivation varies as a function of the state of the individual and the magnitude of the reward. For example, if a typical Westerner is mildly hungry and is offered a kind of food that is normally undesirable—*uni* (raw sea urchin), for example—there will be little incentive motivation to eat the food. If the individual is extremely hungry, however, the incentive motivation to eat the *uni* will be high. Similarly, if the same individual is again only mildly hungry, but is given a food item that is deemed highly desirable—say, a piece of chocolate cake—the incentive motivation to eat the cake will be high.

Incentive motivation plays a key role in a number of attachment-related processes (e.g., proximity seeking) and is tightly linked to the dopamine projection system of the ventral tegmental area (VTA). Dopamine is produced in the VTA and substantia nigra, and is projected to a variety of distinct networks (Lammel, Lim, & Malenka, 2014). This dopaminergic activity represents a neural substrate for the facilitation of goal-directed behavior (Berridge, 2007; Depue & Collins, 1999). Strongly implicated in this function is the nucleus accumbens, which is a major terminus of dopaminergic projections from the VTA (Tzschenke & Schmidt, 2000). Dopaminergic activity within the VTA and nucleus accumbens has been repeatedly associated with reinforcing stimuli and the experience of pleasure. For example, rats capable of directly stimulating these circuits with a lever press will repeatedly do so, even in lieu of access

to food, water, and sex. This preference for lever pressing over food and water will continue even to the point of death (Bozarth & Wise, 1996).

Dopaminergic cells in the VTA are highly responsive to conditioning (Depue & Collins, 1999), especially to cues that predict the receipt of reward (Schultz, Dayan, & Montague, 1997). Importantly, the VTA is also responsive to stimuli that are *unconditioned* (Rolls, 2007). *Unconditioned stimuli* are those that naturally, automatically, and unconditionally trigger a response in an organism. *Positive unconditioned stimuli* act as reinforcers, and include certain flavors, water, sleep, touch, and a variety of social cues. *Negative unconditioned stimuli* act as punishers or negative reinforcers, and include pain, social deprivation, and putrefying odors (Rolls, 2007). With repeated exposure to unconditional reinforcers, dopaminergic neurons in the VTA become sensitive to sensory cues associated with those stimuli. In this way, the VTA begins to activate the nucleus accumbens earlier and earlier in a “chain of cues” that increase the probability of coming into contact with the original unconditioned reinforcer (e.g., an attractive potential mate). Conditioned associations between cues related to desirable unconditioned stimuli and dopaminergic activity in the VTA increase the predictability of those unconditioned stimuli, and hence the opportunities for obtaining them (Depue & Collins, 1999).

The Amygdala and Hippocampus in Affect and Memory

The amygdala is now one of the most widely recognized brain structures associated with emotion (Johansen, Cain, Ostroff, & LeDoux, 2011). Far from a unitary structure, the amygdala contains many subnuclei, accounting for its involvement in a vast array of emotional responses (Davis & Whalen, 2001). A large body of research now supports the notion that the amygdala is sensitive to both conditioned and unconditioned signs of threat. Moreover, at least two pathways to amygdala activation associated with visual stimuli exist, both of which can mediate fear learning. One is a very rapid and direct route through the thalamus (the thalamoamygdala pathway) that processes obvious or highly specific sensory information (Öhman, 2005; Phelps & LeDoux, 2005). Another pathway processes slower and more complex information in the visual cortex before activating the amygdala. When paired with unconditioned aversive stimuli

(e.g., a loud noise, pain), otherwise meaningless stimuli are quickly associated with the presence of a threat—conditioning dependent to a large degree on the amygdala. The amygdala is also exquisitely sensitive to social signals expressed on the face (Benuzzi et al., 2007; Rolls, 2007). Fearful faces, in particular, reliably activate the amygdala in normal human subjects (Thomas et al., 2001; Whalen et al., 2004). And human patients with impaired amygdala functioning have difficulty processing emotional facial expressions, especially those communicating social emotions (Adolphs, Baron-Cohen, & Tranel, 2002).

The amygdala also plays a major role in the consolidation of long-term memories. Amygdala activity during memory encoding is associated with the recall of emotionally salient information even weeks after testing (Hamann, Ely, Grafton, & Kilts, 1999). The amygdala “tags” sensory experiences as significant or salient, and this tagging is prominently represented in long-term memory consolidation. Importantly, the hippocampus appears to support the formation, storage, and consolidation of associations between internal states and spatial or contextual environmental stimuli (Brasted, Bussey, Murray, & Wise, 2003). Ultimately, both the amygdala and the hippocampus are likely to underlie the identification and consolidation of significant interactions between attachment figures and emotionally salient situations. The amygdala will tag emotionally salient stimuli and will participate, along with the hippocampus, in the consolidation of contextual cues associated with those stimuli in long-term memory. Among those cues will be the behavior of attachment figures.

Threat Responding, Social Soothing, and the Hypothalamus

The hypothalamus regulates a variety of metabolic and autonomic processes, as well as linking the central nervous system to the endocrine system, most famously in the case of cortisol release via the HPA axis (Dickerson & Kemeny, 2004). The hypothalamus receives inputs from a wide variety of structures implicated in social behavior, emotion, stress, and attachment, including the amygdala, prefrontal cortex (PFC), and hippocampus (McEwen, 2007). The periventricular nucleus of the hypothalamus is capable of synthesizing corticotropin-releasing hormone (CRH) (Aguilera & Liu, 2012). In threat responding, CRH released

by the hypothalamus stimulates the release of adrenocorticotrophic hormone (ACTH) in the pituitary gland. ACTH causes increased production of cortisol and catecholamines (e.g., epinephrine and norepinephrine) in the adrenal cortex. This cortisol is circulated throughout the body, including the brain. Critically, circulating cortisol in the brain is capable of activating glucocorticoid receptors in the hippocampus that feed back to inhibit the HPA axis (Kemeny, 2003).

Importantly, the hypothalamus is one of the key structures implicated in the regulatory effects of social soothing on neural threat responding, including interactions with attachment figures (Coan, Schaefer, & Davidson, 2006; Conner et al., 2012). The precise mechanisms by which social soothing down-regulates HPA axis activity are unknown, but the hypothalamus is known to coordinate the activity of many behavioral and physiological systems, including those involved in maternal behavior and pair bonding (Kim et al., 2011). Moreover, maternal and pair-bonding behaviors are strongly associated with oxytocin and vasopressin—neuropeptides (reviewed below) that the hypothalamus is capable of synthesizing in abundance (Carter, 1995; Gainer & Wray, 1994).

The PFC, Emotion, and Emotion Regulation

Many regions of the PFC are implicated in emotion, motivation, and emotion regulation (Coan & Allen, 2004; Ray & Zald, 2012). Indeed, portions of the PFC are strongly connected to the dopaminergic projection system (e.g., nucleus accumbens and VTA), and the PFC shares numerous connections with the amygdala, hippocampus, and hypothalamus. For example, the orbitofrontal region of the PFC assists the amygdala and hippocampus in linking the emotional value of secondary sensory information (e.g., place cues) to primary reinforcers, such as food, water, and social contact (Rolls, 2007).

One of the major functions of the PFC is the regulation of emotion. Prefrontal regions may bias brain circuits responsible for appraising the emotional content of sensory stimuli and instantiating behavior directed toward approach- or avoidance-related goals (Davidson & Irwin, 1999). Different portions of the PFC underlie different emotion regulation strategies (Ochsner, Silvers, & Buhle, 2012). These can include “automatic” forms of emotion regulation, as well as effortful forms related to the cognitive control of attention or stimulus

appraisal (Ellenbogen, Schwartzman, Stewart, & Walker, 2006). Some automatic forms of emotion regulation are conditioning and extinction learning, including instrumental avoidance. These rapid and automatic regulatory functions (especially extinction learning) have been associated with the ventromedial and medial orbital PFC (Milad et al., 2005; Quirk & Beer, 2006; Sierra-Mercado, Corcoran, Lebrón-Milad, & Quirk, 2006). More “effortful” forms of regulation require attention, working memory, and other cognitive operations (Sheppes, Catran, & Meiran, 2009). For example, cognitive reappraisals have been used to alter the meaning of a stimulus, and attentional practices (e.g., meditation) have been used to alter attentional foci associated with affective stimuli. These processes have been associated with more lateral, especially dorsolateral, portions of the PFC—regions also known to support working memory, language, and action planning operations (Kanske, Heissler, Schönfelder, Bongers, & Wessa, 2010).

Thus, the PFC may be associated with attachment processes in at least two ways. First, over time, medial orbital circuits may encode conditioned or “automatic” responses to attachment figures related to excitatory or inhibitory responses to threat cues. Second, dorsolateral circuits may modulate cognitive operations associated with attachment figures in reflective, working memory. In truth, these distinctions are not likely to be as discrete as the previous formulation suggests, but the distinction between medial orbital and dorsolateral circuits of the PFC offers a useful neural heuristic for thinking about the regulatory influences of attachment figures in automatic versus explicit terms, respectively.

Emotional Constituents in Combination

Because all of the previously described constituent systems are linked, it is possible for them to coordinate in important ways. For example, dopaminergic neurons in the VTA share connections with many regions other than the nucleus accumbens, including the amygdala (in various nuclei, as well as the extended amygdala), the hippocampus, the hypothalamus, and the PFC. In this way, these structures form their own distributed networks of often reciprocal influence. To understand how such a network may function, consider the distribution of activity following an encounter with an unconditionally rewarding stimulus. Dopamine is released from the VTA,

which stimulates dopaminergic activity in the nucleus accumbens associated with anticipatory pleasure. The amygdala “tags” sensory properties of the stimulus as significant during the process of long-term memory consolidation via the hippocampus, which also encodes contextual information as part of the consolidation process. The PFC uses this information to effect action plans and regulate subsequent behavior relevant to the stimulus. As experience with the rewarding stimulus increases in frequency (partly as a function of successful regulation and action planning activity in the PFC), the affective “tagging” of cues associated with it proceeds down a “chain of cues,” increasing the probability that the rewarding stimulus will be accessed (or avoided in the case of unconditionally negative reinforcers).

More concretely, consider an encounter with an attractive potential mate. In many species, including humans, such an encounter is unconditionally reinforcing. The encounter initially elicits pleasurable feelings and an increase in incentive motivation associated with the partner. The amygdala tags sensory features of the encounter as salient during the process of memory consolidation, in cooperation with the hippocampus; the VTA becomes conditioned to cues associated with (and predictive of) the potential mate, thereby activating incentive motivation circuits early in the “chain of cues” that will increase the likelihood of encountering the potential mate again. With repeated exposures, and a bit of luck, the potential mate may even respond in kind. With this, the complex process of attachment bonding has begun (see Zeifman & Hazan, Chapter 20, this volume). During the attachment bonding process, the PFC utilizes information about the potential mate to adjust its emotion regulation activities, opting in many cases to cede some level of regulatory effort to the potential mate, as discussed below.

Social Elements

Familiarity and Preference

A bedrock feature of any social species (as well as any conception of attachment) is the ability to distinguish individuals who are familiar from those who are not—an ability that in turn is yoked to a preference for the familiar. Indeed, the establishment and maintenance of preferences for familiar others (caregivers, peers, one’s mate, etc.) form the first necessary condition of attachment bonds. Throughout evolutionary time, familiarity was probably a matter of survival, and so it remains

in the case of infants and their caregivers. One of the striking things about humans (and many other mammals) is how well *designed* we are for affiliation (Depue & Morrone-Strupinsky, 2005). Many stereotyped behaviors, including facial expressions, vocalization, bodily gestures, and so forth, are calibrated to signal social closeness and/or discomfort. These signals are readily recognized by most humans and may in many cases be innate (Laird & Strout, 2007; Rolls, 2007).

More than 40 years ago, Bowlby (1969/1982) suggested that infant–mother bonds, characterized by both the ability to distinguish the caregiver from others and a strong preference for the caregiver, formed very rapidly. This is true of many species (Rilling & Young, 2014). Most researchers who study infants agree that the development of attachment bonds is critical because infants often must survive long periods of early development totally dependent upon their caregivers, even when those caregivers are neglectful or abusive (Simpson & Belsky, Chapter 5, this volume).

Among social species, the most common manifestation of the attachment bond is that between an infant and its mother. Human infants can distinguish their mothers from others within hours after birth (DeCasper & Fifer, 1980). But attachment bonding is a generalized capacity only *very frequently* applied to the actual mother. For example, many birds become bonded within hours to the first moving object they encounter. Interestingly, Lorenz (1935) observed that the geese he reared not only bonded to him (and followed him) as if he was the parent, but also that they “courted” him upon reaching sexual maturity, preferring him even to other geese. These observations raise important questions about the degree to which early sensory objects associated with a caregiver are “etched” into the developing brain, how such a thing could occur, and whether a critical period for bonding formation exists in early development.

Filial Bonding, the Locus Ceruleus, and the Amygdala

Filial bonds are those concerning an offspring and a parent. In humans, strong attachment to the caregiver usually develops by 6 months of age, but behaviors resembling filial bonding appear from birth. Filial bonds may differ from adult affiliation behaviors in important ways, due to the dependent nature of the offspring–parent relationship. Many offspring of social species are totally dependent on a caregiver for survival, and attachments

are imperative regardless of the quality of the care (Hofer & Sullivan, 2001). Indeed, nonhuman primates form strong attachments to their mothers even when the mothers are abusive, and this pattern extends to human children (Moriceau & Sullivan, 2005). Rat pups have been observed to form preferences even to stimuli paired with electric shock. This seemingly paradoxical effect prevents pups from aversion learning while being handled roughly by the mother (Hofer, 2006)—an unfortunate predicament, but better than being abandoned. Ultimately, filial bonds form in a context of significant dependence, at least early in development, which may also explain why they occur so rapidly and unconditionally by comparison with attachment formation in adulthood.

Filial bonding also occurs in a context of significant neural development. The human brain grows exponentially during the first year of life and continues to develop rapidly into the second year (Franceschini et al., 2007). Glucose metabolism rises gradually until about the fourth year and, on average, the level of brain glucose metabolism is more than double that of adults until about age 10 (Chugani, 1998). The production of *neurotrophins* (proteins that support neuron survival) depends on neuronal activity and, by extension, environmental stimuli (Berardi & Maffei, 1999; Cancedda et al., 2004). Within the first 2 years of development in humans, the brain's production of axons, dendrites, and synapses far exceeds its needs. Synaptic connections are then "pruned" throughout childhood by lack of use; that is, synaptic connections that go unused are discarded (Reichardt, 2006). In this way, the environment exerts its influence on the otherwise genetically determined development of the brain. At a systems level, neural organization tends to follow functioning—repetitive and patterned activation—during development (Hebb, 1949; Posner & Rothbart, 2007).

During the earliest stages of this process, at least two brain structures, the locus ceruleus and the amygdala, interact to facilitate filial bonding. Although in adults norepinephrine *moderates* memory consolidation and learning (Cahill, Prins, Weber, & McGaugh, 1994), norepinephrine from the locus ceruleus appears to be both necessary and sufficient for learning in human and animal neonates (Sullivan, 2003). And the neonate locus ceruleus releases large amounts of norepinephrine early in development (Nakamura & Sakaguchi, 1990). Combined with the look, sound, and smell of a caregiver, familiarity with that caregiver occurs rapidly. Importantly, this learning is occurring alongside a neonatal amygdala that is not yet fully

functional, making it difficult or impossible for aversive conditioning to occur (Sullivan, 2003). Thus, because the amygdala is immature during early neonatal development, it may not be capable of associating aversive stimuli with alarm or avoidance behavior, which may leave virtually all stimuli to be simply encoded as "familiar" or not."

During this developmental period, neural pathways linking amygdala to hippocampus are similarly underdeveloped, as are many regions within the PFC (Herschkowitz, 2000). This suggests that learning in neonates may not involve the PFC, or may do so only in limited ways. In either case, these systems begin to develop rapidly in infancy, leading many to refer to this developmental time as a "critical" or "sensitive" period for neural development. Sensitive periods have been studied extensively in terms of the brain's sensory systems. For example, temporary blockage of visual input to one eye in cats during early development causes irreversible impairment in the visual cortex (Hubel & Wiesel, 1970). Similarly, children born deaf have been observed to cease vocalizations in late infancy, probably due to a lack of auditory stimuli (Schauwers et al., 2004). Interestingly, environments rich in social and cognitive complexity are associated with significantly more synapses per neuron throughout the visual cortex than are simple socially paired housing and individual housing (Briones, Klintsova, & Greenough, 2004). These effects remain even after later environments are changed or reversed, suggesting that plastic changes associated with early experiences are persistent.

In combination, these findings suggest that filial bonding occurs rapidly and unconditionally. Moreover, the filial bond develops in a context of rapid neural development, during what appears to be a sensitive period of learning. As discussed in greater detail below, this process (especially to the extent that it involves developing links between the PFC and affective structures such as the amygdala and nucleus accumbens) may result in the development of different reflexive "assumptions" about the nature of the social world, including the world as it will be encountered in the future. This may set the stage for different broad strategies for engaging (or avoiding) social stimuli, perhaps especially during emotional situations. Indeed, conditions under which the filial bond forms and develops may constitute a kind of rudimentary "preworking model" of interdependence and affect regulation—of attachment—that is either altered or reinforced during the course of development throughout childhood.

Adult Affiliation, Nucleus Accumbens, and the Social Neuropeptides

Of course, attachment bonds characterized by interdependence and affect regulation extend far beyond the prototypic mother–infant relationship. Adult attachments occur in the context of romantic relationships, especially monogamous ones—but adult attachment is probably not restricted to this. Indeed, relationships that meet attachment criteria have by now been documented between pairs of individuals as diverse as adult romantic partners (Fraley & Shaver, 2000), captive chimpanzee cagemates (Bard, 1983), chimpanzees and their human caretakers (Miller, Bard, Juno, & Nadler, 1990), and domesticated dogs and their owners (Topal, Miklosi, Csanyi, & Doka, 1998). Aspects of attachment seem to occur even between organization members and their leaders (Davidovitz, Mikulincer, Shaver, Ijzak, & Popper, 2007).

Of interest here are neural circuits that support the establishment and maintenance of attachment bonds in later childhood and adulthood. How does the brain facilitate movement from a first encounter through simple familiarity to an attachment bond? A reasonable first step consists of positive, possibly unconditioned social affiliation behaviors (e.g., eye gaze, soothing vocalizations, nonthreatening facial and bodily behaviors). It is clear that some social cues are unconditionally capable of activating neural structures supporting incentive or reward motivation, especially the nucleus accumbens and the VTA (Young & Wang, 2004). Even passively viewed images of female faces activate the VTA and nucleus accumbens unconditionally in heterosexual men (Aharon et al., 2001). In rats, maternal females show an increase in dopamine release in the nucleus accumbens when exposed to pups (Hansen, Bergvall, & Nyiredi, 1993). Depletion of dopamine in the VTA and nucleus accumbens via lesions or dopamine antagonists virtually eliminates rat maternal behavior (Hansen, Harthorn, Wallin, Löfberg, & Svensson, 1991). Interestingly, maternal behaviors not directly associated with caregiving, such as nest building, passive nursing, and aggression, are virtually unaffected by these manipulations. Other studies have linked dopamine release in the nucleus accumbens and VTA to the spontaneous establishment of partner preferences (Aragona et al., 2006).

Mating behavior in the absence of partner preference is also associated with dopamine in

the nucleus accumbens (Balfour, Yu, & Coolen, 2004), however, suggesting that dopaminergic activity in the nucleus accumbens is insufficient in itself for the establishment of partner preferences. This raises the question of how partner preference is “linked up” to the dopaminergic incentive motivation system. Here the neuropeptides oxytocin and vasopressin appear to play major roles (Depue & Morrone-Strupinsky, 2005; Young & Wang, 2004). Both have been associated with the formation of partner preference regardless of mating behavior, and both, but especially oxytocin, are elicited by positive social behaviors (Carter, 2014). Moreover, both are capable of potentiating dopaminergic activity in the VTA and nucleus accumbens in response to social cues (Shahrokh, Zhang, Diorio, Gratton, & Meaney, 2010).

Perhaps the most celebrated example of the function of these neuropeptides derives from work on pair bonding within monogamous prairie voles (Carter, 1995; Insel & Fernald, 2004; Young & Wang, 2004). When these animals forge a pair bond, they mate, share nests and territory, cooperate in the care of their young, and forcefully reject intruders of either sex. Unlike in nonmonogamous animals—including other variants of voles—the nucleus accumbens in these animals is rich in oxytocin receptors. Moreover, structures such as the VTA and ventral pallidum are rich in receptors for vasopressin (Lim & Young, 2006).

These findings offer clues as to how social cues activate incentive motives associated with dopaminergic activity and in turn the formation of partner preferences and proximity-seeking behavior. Socially sensitive oxytocin and vasopressin synthesized within the medial preoptic area of the hypothalamus project to circuits in the VTA, nucleus accumbens, and ventral pallidum, and probably stimulate dopaminergic activity linked to social incentives. Because activation of this dopaminergic system is frequently associated with positive affect and reward, the degree of oxytocin and vasopressin activity may determine the degree to which a social experience is rewarding, by virtue of the dopaminergic cascade that follows it.

Proximity Seeking, the Dopamine System, and Endogenous Opioids

One of the natural consequences of familiarity, preference, and bonding is *proximity seeking*, a characteristic of social behavior strongly associated with attachment. Proximity seeking is

likely to be an extension of motivational circuits associated with reward and partner preference. Of course, individuals can seek close proximity both as a function of positive affect and reward, and in response to cues of punishment, where the goal is the provision of safety (Depue & Morrone-Strupinsky, 2005). In the case of positive affect, proximity is sought because the attachment figure has become associated with rewarding feelings of pleasure, and close proximity increases the frequency or intensity of these feelings. In the case of negative affect, the attachment figure may serve as a safety cue, eliciting approach behaviors oriented toward the acquisition of security (Beckes, Coan, & Morris, 2013). In this way, proximity seeking can involve both reward-related approach behaviors and approach behaviors associated with active avoidance.

Behaviorally, these motivations may appear to be identical, but they are likely to involve both shared and distinct neural circuits. Moreover, although attachment theory emphasizes the emotion regulation function of proximity seeking due to the need for security, it may be counterproductive to downplay the role of proximity seeking due to reward processes. In addition to the reinforcing nature of dopaminergic activation, for example, consummatory pleasure may play a role in rewarding social interaction. After all, positive social experiences are characterized in everything from semistructured scientific interviews to ancient literature as involving feelings of warmth, closeness, love, affection, and pleasure. Depue and Morrone-Strupinsky (2005) have argued that feelings of consummatory pleasure promote the development of contextual associative memory networks that help both to establish and to maintain social bonds, and that are ultimately responsible for many of the *regulatory* effects associated with the soothing and security provided by attachment relationships. The critical substrate for these feelings, and perhaps for the socioaffective regulatory effects that accompany them, may be the release of endogenous opioids that often follows activation of oxytocin receptors—not only in structures such as the nucleus accumbens and VTA but also within the anterior cingulate cortex and elsewhere.

There is abundant evidence for the role of endogenous opioids in a wide variety of social behaviors (Loseth, Ellingsen, & Leknes, 2014). In humans and other animals, these opioids are released during childbirth, nursing, maternal caregiving, sexual activity, and many modes of tactile stimulation, including grooming and play behavior

(Carter & Keverne, 2002; Keverne, Martensz, & Tuite, 1989). This release may mediate the reward associations that are forged between infants and mothers, as well as between romantic partners and even platonic friends. For example, morphine, an opioid receptor agonist, increases the reinforcing effects of a host of maternal behaviors, mother–infant bonding, time spent by juveniles (rats) with their mothers after a brief separation, grooming, and juvenile play behavior (Agmo, Barreau, & Le-maire, 1997; Nocjar & Panksepp, 2007; Panksepp, Nelson, & Siviy, 1994; Vanderschuren, Niesink, & Van Pee, 1997). By contrast, opioid receptor antagonists such as naltrexone reduce the reward-conditioning effects associated with each of these forms of social contact (Graves, Wallen, & Maestripieri, 2002; Holloway, Cornil, & Balthazart, 2004). In humans, the administration of the opioid antagonist naltrexone was associated with increased voluntary isolation from friends, as well as decreased levels of enjoyment in the company of others (Jamner & Leigh, 1999).

Importantly, tactile stimulation appears to play a particularly powerful role in the activation of affiliative reward conditioning (Melo et al., 2006). In some animals, the affiliative conditioning associated with maternal behavior is attenuated in the absence of tactile stimulation.

Attachment and Social Affect Regulation

Many evolutionary accounts of the reproductive advantages of infant–caregiver bonds have been proposed, but similar accounts of adult attachment bonds are relatively recent (see Simpson & Belsky, Chapter 5, and Zeifman & Hazan, Chapter 20, this volume). Fraley and Shaver (2000) have proposed that adult attachments represent homologies of the infant–caregiver bond coopted by natural selection to facilitate pair bonding. By this account, adult and infant–caregiver attachment systems entail similar goals (the survival of offspring) and operate according to similar conditions of activation (e.g., presence of a threat) and termination (e.g., regulation of threat responding by the attachment figure). Evolutionary perspectives such as these address *ultimate* functions, in the sense of explaining why attachment bonds and capabilities persist among so many species.

Function can be considered in a more proximal, ontogenetic sense as well, and it is at this level

that the regulation of affect may take center stage. Proximal functions of the attachment system are thought primarily to reflect social regulation of emotional responding. Bowlby (1969/1982), following along with Ainsworth, Blehar, Waters, and Wall (1978), argued that a critical function of attachment figures is the provision of a “secure base” from which infants can explore their worlds relatively free of anxiety, and a “safe haven” to which the infants can return when distressed. It was proposed, for example, that the base from which an infant can explore his or her world is secure to the extent that the caregiver is responsive to the infant’s distress. Many have since proposed that the quality of the caregiver–infant attachment bond—especially of the caregiver’s status as a secure base—holds consequences for child and adult emotional functioning, including styles of interpersonal relating and emotion regulation capabilities. A very large behavioral database now supports this notion with respect to both childhood and adulthood (Beckes & Coan, 2015).

Throughout childhood, and certainly by adulthood, the regulatory effects of attachment relationships are likely to be felt in two broad ways (Coan, 2011). The first is immediate, such as when the attachment figure *mediates* a decrease in emotional responding “online.” An example of this may be when a caregiver holds a child’s hand during a blood draw at the doctor’s office, thus actively soothing the child’s anxiety as it occurs. The second is more generalized, where the attachment figure *moderates* the degree of emotional responding through, for example, a “mental representation.” These social regulatory moderators may manifest either as internal working models based on procedural and semantic memory, or as declarative, explicitly recalled mental images. Indeed, online regulation experiences are likely to condition mental representations in both implicit and declarative memory. In the sections that follow, immediate, online regulation is considered in contrast to mental representations of a putative attachment figure, often referred to as *internal working models*, that may serve to preempt the level of distress an individual experiences in the face of a potential threat.

Socially Mediated Regulation

The psychological and physiological impact of everyday stress is offset in part by social buffering (Cohen & Wills, 1985). This social buffering occurs at all levels (e.g., group, caregiver, famil-

iar conspecific), but familiarity, physical contact, and attachment are associated with the strength of social regulation effects (Cohen, 2004; Cohen, Janicki-Deverts, Turner, & Doyle, in press). Even in rats, the presence of familiar conspecifics increases exploration and attenuates HPA axis activity under conditions of threat (Kiyokawa, Kikusui, Takeuchi, & Mori, 2004; Ruis et al., 1999). Familiar conspecifics attenuate emotional stress responding in nonhuman primates during new social group formation and social conflict (Gust, Gordon, Brodie, & McClure, 1996; Weaver & de Waal, 2003). These effects are widely believed to derive from the activity of oxytocin, vasopressin, and endogenous opioids in the VTA, ventral pallidum, nucleus accumbens, anterior cingulate, insular cortex, and portions of the ventromedial PFC (Carter & DeVries, 1999; Kosfeld, Heinrichs, Zak, Fischbacher, & Fehr, 2005; Loseth et al., 2014; Nocjar & Panksepp, 2007).

Increasingly, researchers have sought to identify how neural circuits associated with social affiliation and emotion function in contexts that combine some form of social interaction with externally generated emotional stress. For example, my colleagues and I have collected functional brain images from married women (Coan, Schaefer, & Davidson, 2006) and both male and female platonic friends (Coan, Beckes, & Allen, 2013), as they were subjected to the threat of mild electric shock while alone, and while holding hands with either a relational partner (spouse or friend) or anonymous experimenter. Our results suggest that supportive touch even from strangers can attenuate threat-related neural activity, and that these regulatory effects are moderated in important ways. Higher current relationship quality, for example, corresponds with greater regulation of threat-related neural activity in the right anterior insula, superior frontal gyrus, and hypothalamus during spousal, but not stranger, hand holding (Coan, Schaefer, & Davidson, 2006). And greater perceived *mutuality*—a measure of shared feelings, goals and interests—is associated with less threat-related activation of the lateral prefrontal cortex and supplementary motor cortex whether the relational partner is present or not (Coan, Kasle, Jackson, Schaefer, & Davidson, 2013).

Other work is converging on similar results. For example, in the presence of their mother, the brains of high-anxious children respond to anxiety-provoking words indistinguishably from those of low-anxious children, but high-anxious children show increased threat-related activa-

tion of the ventromedial PFC and hypothalamus while alone (Conner et al., 2012). Individuals show reduced pain and pain-related activation of the anterior insula and dorsal ACC when viewing images of a loved one (Eisenberger et al., 2011; Younger, Aron, Parke, Chatterjee, & Mackey, 2010). Indeed, the social regulation of pain is by now a well documented phenomenon (Krahé, Springer, Weinman, & Fotopoulou, 2013), with attachment style emerging as an important moderator (Sambo, Howard, Kopelman, Williams, & Fotopoulou, 2010; Wilson & Ruben, 2011). Even simple reminders of secure attachments reduce activation in the ventral ACC, PFC (lateral and medial), and hypothalamus during threat of social exclusion (Karremans, Heslenfeld, van Dillen, & Van Lange, 2011).

Socially Moderated Regulation

Thus far, we have primarily considered basic systems supporting “normative” manifestations of attachment behavior, as well as concrete examples of regulatory functions of the attachment system. However, the regulatory effects of caregiving experiences, such as those between infants and caregivers, or even between romantic partners, are likely to extend far beyond online moments of soothing and security provision. Bowlby (1979) thought that early attachment experiences held implications for interpersonal and emotional functioning “from the cradle to the grave” (p. 129), and in the past several decades many researchers have adopted this idea as one way to understand adult interpersonal functioning (Mikulincer & Shaver, 2007).

Unfortunately, much of what is known about links among early social experience, neural development, and subsequent emotional behavior has been derived from studies of low social status, abuse, and neglect. For example, low status, neglectful, or abusive early social environments are associated with risks for heightened stress reactivity, anxiety, depression, and social deviance that extend well into adulthood (Gonzalez, Beckes, Chango, Allen, & Coan, 2015; Teicher, Samson, Polcari, & McGreenery, 2006). In one study, children who had experienced social deprivation and neglect in Romanian orphanages were observed to have lower overall levels of vasopressin, as well as blunted oxytocin responses to physical contact with their caregivers, relative to family-reared children (Wismer-Fries, Ziegler, Kurian, Jacoris, &

Pollak, 2005). Social isolation, generally, is a well-known risk factor for a number of neurodevelopmental, physiological, and psychosocial problems, ranging from anxiety and depression to increased risk of suicide, family discord, poor health behavior, cognitive decline, cardiovascular disease, stress-related dwarfism, increased vulnerability to trauma, and even all-cause death (Barber, Eccles, & Stone, 2001; Cacioppo & Cacioppo, 2014; Henriksen, Torsheim, & Thuen, 2014; House, Landis, & Umberson, 1988; Kawachi & Berkman, 2001; Knox & Uvnäs-Moberg, 1998; Newcomb & Bentler, 1988; Norman, Hawkey, Ball, Berntson, & Cacioppo, 2013; Skuse, Albanese, Stanhope, Gilmour, & Voss, 1996). In nonhuman primates, frequent or prolonged separation of offspring from caregivers (primarily mothers) can result in socially deviant behavior and dysregulated physiology later in life (Mineka & Suomi, 1978; Suomi, Chapter 7, this volume). Among brown capuchin monkeys, patterns of mother-offspring behavior partially determine the postconflict reconciliation styles of offspring during later interactions with nonfamilial conspecifics (Weaver & de Waal, 2003).

Neural Mechanisms

Researchers have begun to identify neural mechanisms linking early parental care to trait-like individual differences in threat responding over the lifespan (Sachser et al., 2013; Weaver, Diorio, Seckl, Szyf, & Meaney, 2004). For example, in rats, grooming behavior by the mother “sets” or “programs” the degree to which her offspring react to threat cues throughout their lives. This modulation of threat reactivity has been observed both in behavior and in HPA axis activity. Moreover, associations between maternal grooming and offspring threat reactivity have been linked to the molecular regulation of genes that moderate HPA axis functioning. As reviewed earlier, the HPA axis has its own built-in regulatory mechanism in the hippocampus, whereby circulating cortisol activates hippocampal glucocorticoid receptors, which in turn down-regulate the production of CRH in the hypothalamus. Grooming attenuates the methylation of genes that encode for glucocorticoid receptors in the hippocampus, thus enhancing their expression and making the hippocampus more sensitive to circulating cortisol (Meaney & Szyf, 2005). Cross-fostering studies by Meaney and colleagues suggest that lifelong stress reactivity—

and even the subsequent maternal behavior of female rat pups—is attributable more to the degree of postnatal maternal grooming than to genetic inheritance (Weaver et al., 2004). More recent studies suggest that similar patterns may soon be found with regard to the methylation of genes that encode for oxytocin receptors (Jack, Connelly, & Morris, 2012; Kumsta, Hummel, Chen, & Heinrichs, 2013; Puglia, Lillard, Morris, & Connelly, 2015).

Attachment and Internal Working Models

According to attachment theory (Bowlby, 1969/1982, 1973; Mikulincer & Shaver, 2007), threat detection capabilities may have coevolved with the attachment behavioral system, thus increasing the likelihood that humans will seek out and maintain proximity to attachment figures from infancy onward. From this perspective, distress alleviation could be considered a vital mechanism through which attachments are formed (Beckes & Coan, 2015), and the attachment system could be considered a dedicated component of the brain's overall stress response (Taylor et al., 2000, 2004). Indeed, evidence suggests that even subliminally presented threats increase access to attachment-related cognitions and bias attention toward recognizing individuals who could be considered more responsive to distress (Beckes et al., 2013; Beckes, Simpson, & Erickson, 2010). Moderating the degree to which proximity to attachment figures is sought in the context of a threat is “attachment security,” which is presumed to be the product of many attachment-related experiences involving both threats and attachment figures. These experiences shape “internal working models” of attachment that guide emotion regulation throughout life (see Cassidy, 1994; Bretherton & Munholland, Chapter 4, this volume). According to Bowlby (1969/1982), internal working models are mental representations of the responsiveness and practical utility of attachment figures when threats arise, and of the self in relationship with these figures.

Indeed, Hofer (2006) has described a process by which very early developmental experiences in interactions with a caregiver may plausibly proceed from the online regulation of fundamental neural systems supporting sensorimotor, thermal, and nutritional functions to the shaping of internal working models of attachment security. In this model, in early development, access to primary reinforcers (e.g., food, water, warmth, touch) is dependent on

(1) caregiver support and (2) brain circuitry used to solicit caregiver support via expressed affect. Over the course of development, what begins as the regulation of physiological needs via affect becomes the regulation of affect per se (Hofer, 2006). Throughout this process, the regulatory behavior of the attachment figure (e.g., the provision of security, the alleviation of distress) is likely to set expectations about the availability of attachment figures during times of stress—the internal working models reflecting attachment security.

Thus, internal working models are likely to reflect conditioned associations between proximity to attachment figures and both internal needs and external signs of threat, mediated through the amygdala, nucleus accumbens, and hippocampus, as well as portions of the PFC. These conditioned associations may remain stable for long periods of time, especially to the extent that they continue to be reinforced by internal feelings of security, prevailing social contingencies, or both. This process probably allows individuals to adapt themselves to a variety of environmental conditions (e.g., security-restoring or security-enhancing experiences with attachment figures, frequent or lengthy absence of the caregiver, abuse by the caregiver, excessive caregiving). Such adaptations are referred to in various research traditions as “attachment patterns,” “attachment styles,” or “attachment states of mind” (e.g., secure, anxious or ambivalent, avoidant, preoccupied). These adaptations are thought to be relatively stable when the individual remains in a stable environment, and can be measured by observations, self-report questionnaires, and structured interviews (e.g., in this volume, see Crowell, Fraley, & Roisman, Chapter 27; Kerns & Brumariu, Chapter 17; Solomon & George, Chapter 18).

Behavioral research on the effects of different adult attachment styles suggests the presence of two relatively independent axes regarding attachment insecurity—*anxiety* and *avoidance*—along which individuals can vary (J. A. Feeney, Chapter 21 this volume; Mikulincer & Shaver, 2007). Moreover, different combinations of scores along these dimensions can result in particular styles of interpersonal relating. For example, individuals low in attachment anxiety and in attachment avoidance are considered generally secure in their attachments to others. Individuals high in both avoidance and anxiety are thought to avoid attachment relationships out of fear, while those high in avoidance but low in anxiety are thought to be dismissing of attachments, compulsively

self-reliant, and unlikely to seek proximity to attachment figures under stress (Bartholomew & Horowitz, 1991; Brennan, Clark, & Shaver, 1998). Finally, individuals low in avoidance but high in anxiety are thought to be preoccupied with the status of their attachment relationships and the availability of attachment figures.

Although a number of researchers are now examining associations between attachment style and neural activity, dedicated circuits that are causally responsible for attachment style remain mysterious, if indeed there are any. In most cases, attachment styles manifest as individual differences in responses among neural circuits that otherwise generally support emotion, emotion regulation, threat vigilance, and social cognition (Vrtička & Vuilleumier, 2012). Early studies suggested that insecurely attached infants of depressed mothers were more likely to show PFC asymmetries lateralized to the right (Dawson et al., 2001). EEG asymmetries in alpha power (8–13 Hz) correspond with emotional reactivity and regulation, with relatively greater left PFC activity indexing an increased probability of approach behavior, and relatively greater right PFC activity indexing an increased probability of avoidance (Coan & Allen, 2004; Coan, Allen, & McKnight, 2006; Steiner & Coan, 2011). Thus, according to Dawson and colleagues (2001), insecurely attached infants of depressed mothers have a trait-like propensity to engage in avoidance behavior. This is consistent with recent observations of greater amygdala volumes in adults who were identified as insecurely attached a full 22 years earlier (Moutsiana et al., 2015). Moreover, individuals who score high in attachment avoidance may have lower cell density within the hippocampus—a condition also associated with clinical conditions such as posttraumatic stress disorder (PTSD) (Quirin, Gillath, Pruessner, & Eggert, 2010). At the genetic level, attachment anxiety and avoidance are associated with polymorphisms in dopaminergic and serotonergic receptor genes, respectively (Gillath, Shaver, Baek, & Chun, 2008), suggesting that insecurity is influenced in part by genetic vulnerabilities to social dysfunction and emotional dysregulation.

Securely attached individuals may be generally less reactive to distress, even in very early attentional processing (Nash, Prentice, Hirsh, McGregor, & Inzlicht, 2014), though security primes have also been associated with *increased* prefrontal, striatal, and parahippocampal activity, probably reflecting increments in self-regulatory motivation and capability (Canterberry & Gillath, 2013;

Eisenberger et al., 2011; Younger et al., 2010). Insecure attachment, by contrast, has been associated with elevated neural activity throughout the brain under conditions of threat, stress, and pain. Indeed, avoidant attachment has been associated with more, not less, activation of prefrontal systems associated with emotion regulation, suggesting that insecure attachment may entail increased regulatory activity attributable either to diminished regulatory efficiency or greater emotional burden (Vrtička, Bondolfi, Sander, & Vuilleumier, 2012), with heightened emotional burden being the most likely explanation. For example, high attachment avoidance is associated with greater laser-evoked N2 and P2 amplitudes—putative EEG measures of threat salience—in the presence of romantic partners (Krahé et al., 2015). This suggests that attachment-related avoidance renders potentially threatening stimuli even more threatening, at least when other people are present. This also raises interesting questions about the function of this kind of avoidance, which may include a desire to avoid additional burdens associated with close relationships. Under ordinary circumstances, time with relational partners may be enjoyable and even relaxing, but for avoidant individuals, stress entails dealing with not only the stressor but also the relational partner. Partners in this case are costs rather than resources. Thus, for such people, it may be best to be alone when stressed.

Attachment anxiety has also been associated with a variety of threat- and pain-related processes in the brain. For example, individuals high in attachment anxiety show increased responding in the dorsal anterior cingulate cortex (dACC)—a region associated with identifying salience and incongruities with expected outcomes—in addition to the right amygdala and parahippocampal areas (Buchheim et al., 2006; DeWall et al., 2012; Gillath, Bunge, Shaver, Wendelken, & Mikulincer, 2005; Vrtička et al., 2012). Importantly, while considering negative relationship scenarios, higher attachment anxiety scores correspond with increased activation within the temporal pole on the one hand and diminished orbitofrontal activity on the other (Gillath et al., 2005). This suggests that individuals high in attachment anxiety have trouble engaging regulatory systems when signs of relationship trouble are present. In summary, these studies suggest that individuals high in attachment anxiety may suffer from greater emotional reactivity, mediated through heightened vigilance for potential threats, especially because of an insecurity about the availability of social resources.

Social Baseline Theory

Social affect regulation, within the context of attachment theory, can be viewed as a core function of attachment relationships. Social influences on the regulation of affect are sufficiently powerful and unconditioned to suggest that the brain's first and most effective approach to affect regulation is via social proximity and interaction. This is most obvious during infancy, in which very basic physiological needs are regulated first via affect expression, leading to a dynamic of regulating affect *per se* (Hofer, 2006). For the infant, this is occurring in a context of rapid and expansive neural development—possibly a “critical period” during which a number of expectations about the nature of the infant's future environment are formed. Much of this development is occurring in the PFC, a region of the brain powerfully implicated, among many other things, in affect regulation. Because the PFC is underdeveloped in infancy, the caregiver effectively serves as a kind of surrogate PFC (Gee et al., 2013)—a function that may hold a number of neurodevelopmental consequences for emotion reactivity and regulation throughout life (Gee et al., 2014; Tottenham, 2012).

Social baseline theory (Beckes & Coan, 2011; Coan & Sbarra, 2015) suggests that social affect regulation was long ago adopted as an efficient and cost-effective means of regulating affect. It draws on the “economy of action” principle built into biological systems that requires organisms to consume more energy than they expend if they are to survive to reproduce (Proffitt, 2006). Because all bodily activities (including neural activities) expend energy, energy expenditure must be managed. Proffitt has proposed that one of the ways in which the brain manages energy expenditure is via changes in sensory perception that aid in decision making about the deployment of an organism's resources. For example, Proffitt has observed that donning a heavy backpack causes hills to appear steeper and objects to appear farther away, thus discouraging individuals from using their resources to climb those hills or approach those objects. In this way, the brain can be thought of as a “Bayesian machine,” making “bets” at any given time about what resources to deploy and at what level of effort (Clark, 2013; Friston, 2010).

Social baseline theory draws on this Bayesian view of the brain to propose that social species in fact *assume* relatively close proximity to conspecifics because they have adopted social proximity and interaction as an environmental niche (Beckes &

Coan, 2011). For humans especially, social proximity and interaction are strategies for economizing energy expenditure in everything from raising children (Burkart, Hrdy, & Van Schaik, 2009) to regulating basal metabolic rates and core body temperatures (Nuñez-Villegas, Bozinovic, & Sabat, 2014). This implies that the absence or loss of conspecifics, in defying this baseline assumption, functionally adds to the perceived cost of interacting with the environment—especially in (but not limited to) threatening contexts (Coan & Sbarra, 2015). Bowlby (1969/1982) held an explicitly similar view of human adaptation, also detailing the emotional damage wrought by a relational partner (parent, romantic partner, friend, even a stranger) who is simply unresponsive in times of need (Beckes & Coan, 2015). Ultimately, both attachment theory and social baseline theory propose that social isolation is, for a social organism, akin to donning a heavy backpack: It alters both the real and perceived costs of survival. In proposing social baseline theory, I do not intend to invalidate or supplant attachment theory. Rather, my interest in social baseline theory is to describe a more generalized and abstracted set of neural and ecological principles—principles that may shed light on mechanisms underlying the attachment dynamics described by Bowlby almost half a century ago. To this end, social baseline theory starts with at least two ways in which the presence of conspecifics may reduce, for social organisms, the actual and perceived cost of engagement with the environment. I call these strategies “risk distribution” and “load sharing.”

Risk Distribution

The first way in which social species, including humans, benefit from close social proximity is via the simple distribution of risk in the environment—colloquially, through safety in numbers. Many species benefit from living in groups, and simple risk distribution strategies are likely to be *plesiomorphic*, or relatively ancient, in evolutionary terms. Although group living incurs resource consumption costs, the benefits may outweigh those costs sufficiently to create conditions under which group cohesion ultimately promotes the survival of each individual in the group. Risk distribution speaks to the amount of risk a given individual carries as a function of the degree to which he or she is alone, and it can manifest in many ways (Davies, Krebs, & West, 2012). For example, any given individual is at substantially reduced risk of personal danger

(e.g., predation) when group size increases. Among many species there is a thermal advantage of huddling, a process known as *social thermoregulation* (Canals, Rosenmann, & Bozinovic, 1989). Some social species utilize group size to maximize their performance as predators; this too can be a form of risk distribution, for if contact with prey is maximized by groups of predators, the risk that any one predator will perish from starvation is minimized.

Social species are capable of assessing the distribution of risk and making Bayesian decisions about the cost-effectiveness of a variety of behaviors at any given time. Practically speaking, the presence or absence of conspecifics provides, at the lowest level of social proximity, a heuristic for deploying potentially costly resources. For example, in the presence of conspecifics, ostriches are less vigilant for predators. Indeed, the degree to which ostriches engage in vigilance behavior while searching for food decreases steadily as group members are added—even as the overall vigilance each ostrich benefits from does not change (Bertram, 1980). Insofar as activities such as threat vigilance are effortful—are yoked to perceived bodily resources or opportunity costs—they are deployed only as needed. Resources that are saved by social proximity are either conserved or applied to other valuable purposes.

Load Sharing

Risk distribution is likely to influence attention—particularly vigilance for potential danger—and this may bring wider implications for cognitive and affective activities that either share attentional circuitry or compete with that circuitry for metabolic resources carried in the blood (see Dietrich, 2009). But the impact of risk distribution on a host of other cortical and behavioral activities is likely to be more limited. This is especially true of prefrontal regions supporting working memory and inhibitory control—including the self-regulation of emotional responses. Interestingly, such prefrontally mediated activities are thought to be particularly costly to deploy for long periods of time, either because they compete with other regions for blood or entail an opportunity cost by limiting other vital functions mediated through the same regions (Dietrich, 2004, 2009; Kurzban, Duckworth, Kable, & Myers, 2013). Evidence for this derives in part from studies of “ego depletion” as a consequence of effortful attention, working memory, and self-control. In this work, individuals who are asked to engage in tasks re-

quiring self-regulation are commonly less capable of similar tasks later on. Importantly, these and similar depletion effects are likely attributable to the way the brain “budgets” its available resources as a function of expected future demands, rather than the literal depletion of currently available fuel within the brain (Job, Dweck, & Walton, 2010; Kurzban, 2010).

Social baseline theory predicts that the PFC and many of the regulatory processes it supports may be particularly affected by the presence of an attachment figure, especially in, but not limited to, the context of a threat. Here the advantage of close proximity extends far beyond simple models of risk distribution: Over and above the probabilistic dilution of risk, a trusted and interdependent associate can be counted on to engage in a number of health- and safety-enhancing behaviors on one’s behalf. Such behaviors may include the identification and acquisition of resources, vigilance for future environmental threats, caring for one’s needs, and nurturing of one’s offspring. These allegiances—these attachments—serve to distribute the cost of many of life’s metabolically expensive activities, not least being the regulation of one’s own negative affect. Simply put, affect regulation is possible, but more difficult, in isolation. I refer to this second level of social regulation as “load sharing,” and I believe it is an essential component of attachment relationships throughout the lifespan. Load sharing is likely to be relatively *apomorphic*, or more specific to social animals, particularly humans. Human brains are highly sensitive to the load-sharing significance of close attachment bonds and adjust their efforts accordingly. For example, individuals in close, trusted relationships will invest less effort in down-regulating their negative affect, leaving them less responsive to threat cues and other signs of possible harm (Coan, Schaefer, & Davidson, 2006; Coan et al., 2013; Edens et al., 1992; Mikulincer & Florian, 1998; Robles & Kiecolt-Glaser, 2003). Indeed, humans will spontaneously down-regulate their efforts in the presence even of strangers if all are engaged in a shared goal (Ingham, Levinger, Graves, & Peckham, 1974). And humans just as spontaneously engage in goal and intention sharing (Tomasello, Carpenter, Call, Behne, & Moll, 2005; Warneken & Tomasello, 2009). Thus, the social brain may be designed to distribute both physical and cognitive effort across social networks as a function of common goal pursuit, and this may be a key process in how attachment relationships facilitate successful affect regulation.

Unlike risk distribution strategies, which are primarily sensitive to numbers alone, load sharing is likely to develop as the brains of individuals in a relationship become familiar with one another, especially in the context of coping with adversity or sharing goals. Over time, individuals in attachment relationships may literally become part of each other's emotional response and regulation strategy. This is not metaphorical, but literal, even at the neural level. For example, we have observed that the brain encodes threats to familiar friends almost as if those threats were directed at the self, but also that threats directed at strangers are encoded quite differently (Beckes, Coan, & Hasselmo, 2013). We, and others before us (most notably Aron and colleagues; cf. Aron & Aron, 1996; Aron & Fraley, 1999; Mashek, Aron, & Boncimino, 2003), have suggested that this reflects an incorporation of the familiar other into the neural representation of the self—that, indeed, this may well be what the subjective feeling of familiarity is at the neural level. The self is, after all, not something the brain has so much as *does*. Being a collection of neural circuits tasked with a job, the “self” is likely to be quite flexible, indeed both expandable and collapsible, with implications for how the brain budgets its bioenergetic resources, and always with the corollary goal of economizing those resources if possible. As applied to affect regulation and attachment theory, a man who has been alone for a long period of time may learn to depend heavily on his own prefrontally mediated emotion regulation capabilities, but upon establishing an attachment relationship, the degree to which he perceives his environment to be threatening may diminish in proportion to the perceived increase in resources brought to bear by the attachment figure, and, in turn, his emotion regulatory burden will lighten. The effect should literally reduce the frequency with which he exercises his PFC in the service of emotion regulation. With sufficient experience in the relationship, the level of interdependence associated with emotion regulation needs can become strong. Indeed, a grim reminder of this occurs when one or the other member of an attached pair is suddenly absent due to death or divorce, leaving the partner severely dysregulated (Krietsch, Mason, & Sbarra, 2014; O'Connor & Arizmendi, 2014; Sbarra, Law, & Portley, 2011; Schultze-Florey et al., 2012).

As mentioned above, we have observed this dynamic in vivo using a paradigm that combines supportive touch with the threat of electric shock, all during fMRI. In the first of these studies (Coan,

Schaefer, & Davidson, 2006), married women in an MRI scanner were confronted with the threat of a mild electric shock under each of three conditions: while alone, while holding a stranger's hand, and while holding their spouse's hand. Women in the highest-quality relationships showed the lowest degree of threat-related brain activation, limiting their response to relatively automatic regulation of threat perception via structures such as the ventromedial PFC. When a marital relationship was of relatively poor quality, however, the number of problems confronting a woman's brain under threat increased to include attention to bodily sensory afferents, presumably related to the threat of shock (right anterior insula), task salience (superior frontal gyrus), and release of regulatory stress hormones (hypothalamus). As the hand-holding partner switched from attachment figure to stranger, however, yet more problems presented themselves, with additional threat-related brain activations triggered to solve them. For example, threat-related vigilance increased (e.g., via the superior colliculus); effortful emotion regulation strategies were employed (e.g., via the right dorsolateral PFC); and areas were recruited that indicated increased threat-related avoidance motivation (e.g., the caudate and nucleus accumbens). But when facing the threat alone, the brain appeared to perceive yet more problems requiring attention, adding—to the already enumerated threat responses—increasing bodily arousal (e.g., through the ventral ACC) and the coordination of visceral and musculoskeletal responses (e.g., via the posterior cingulate, supramarginal gyrus, and postcentral gyrus). Since then, we have observed a similar pattern of results when the relational partner was a platonic friend (Coan et al., 2013), and among couples suffering from relationship distress *after*, but not before, 20 weeks of attachment-related emotionally focused couple therapy supervised by Susan Johnson (Johnson et al., 2013; Brassard & Johnson, Chapter 35, this volume).

Importantly, the social affect regulation observed in these studies appears to be a mediated through a relatively bottom-up process, as opposed to solo affect regulation, which is more top-down. When engaging in self-regulation, a person is likely to engage in costly, effortful cognitive and attentional strategies in the service of inhibiting either somatic responses or neural activity supporting the identification of threats. This effortful regulation of affect relies to a great degree on the PFC. In this way, self-regulation frequently occurs in the context of an affective response that

has already transpired. By contrast, social affect regulation may be mediated through early perception, decreasing threat sensitivity and obviating the need for any self-regulatory effort at all. Thus, social affect regulation could be characterized as more efficient, or less costly, than self-regulation strategies (cf. Gross & Thompson, 2007) such as the suppression of emotional responses, cognitive reappraisal, or mindfulness meditation. The extent to which this is true awaits further investigation.

Attachment Styles as Bayesian Priors

Of course, the preceding discussion offers only a simplified, normative, idealized model of social affect regulation. It is likely that superimposed on all of the processes described earlier are trait-like, and to some extent experience-based, assumptions about the function and metabolic cost of social factors in regulating the perception of threats, and hence of affect (Bar-Kalifa & Rafaeli, 2015). Accordingly, one way to conceptualize attachment styles and internal working models is as prior probabilities in a Bayesian decision-making process (Clark, 2013; Friston, 2010), in which the goal is to predict the regulatory cost-effectiveness of potential attachment figures (Coan, 2010). In this way, attachment styles represent strategies, based on prior experience, for making decisions about how to utilize one's own neural resources in the presence or absence of strangers and attachment figures. Indeed, we have observed that individuals who experienced higher levels of (behaviorally coded) maternal support in early adolescence were—12 years later—also less responsive to threat cues in the insula and PFC during supportive hand holding by a friend. Individuals whose childhood neighborhoods were characterized by low social capital and high crime showed the opposite pattern, with supportive hand holding having less of a regulatory effect (Coan et al., 2013).

A secure attachment style presumably disposes a person to make bets closely in accordance with the idealized picture described earlier. By contrast, avoidant and anxious strategies may encourage individuals to make greater use of their own resources even in the presence of social support, or to place themselves outside the reach of social support in the hopes of avoiding additional costs (e.g., having to regulate others as well as self), thus, again, requiring them to rely on their own emotion regulation strategies. At present, this Bayesian conceptualization of attachment style is

predominantly a matter of conjecture. I expect that future neuroscientific studies of attachment will provide additional clues to the nature of social affect regulation in the brain.

Recommendations and Conclusions

In this chapter, I have sought (1) to synthesize a broad array of studies in the service of introducing the reader to the current state of the neurosciences as they pertain to research on attachment, and (2) to propose a plausible model of how what is known about the social brain and affect regulation may eventually be combined with attachment theory. This effort has necessarily included discussions of the neural constituents of attachment, from neural systems supporting emotion and motivation to those supporting emotion regulation, filial bonding, familiarity, proximity seeking, and individual differences in attachment style. What follows is a partial list of recommendations for researchers excited about pursuing the neuroscience of attachment. (Other models and suggestions can be found in other chapters in this volume, especially Simpson & Belsky, Chapter 5; Hane & Fox, Chapter 11; and Polan & Hofer, Chapter 6.)

- *Expand the cognitive and emotional repertoire in laboratory challenges.* Studies of the neural systems underlying attachment should combine the presence or absence of attachment cues (e.g., proximity to attachment figures) with laboratory situations that elicit a range of emotional responses—not only threats but also potential rewards, losses, and even effortful cognitive activity that may be affectively ambiguous (Coan & Maresh, 2014). Many theorists have proposed that the attachment behavioral system is activated during threats to the individual or to the individual's attachment bond, but few researchers of attachment processes at the neural level have actually designed studies with this in mind. Fewer still have sought to identify how social contact influences neural responses to positive affect elicitation. Social baseline theory suggests that attachment figures may offset the cognitive (and indeed physiological) costs of a wide variety of activities (Coan & Sbarra, 2015), and the full range ought to be explored. In my view, much recent work points to the regulatory impact of social relationships in ways that have yet to be framed from the perspective of attach-

ment theory. For example, proximity to social resources may alter visual sensory perception (Gross & Proffitt, 2013), the frequency of supportive interpersonal touch may affect athletic performance (Kraus, Huang, & Keltner, 2010), and collective IQ (the IQ score of a group) may increase more as a function of sensitivity to interpersonal social cues than of individual intelligence (Woolley, Chabris, Pentland, Hashmi, & Malone, 2010). Moreover, the increasing sensitivity and even portability of modern neuroimaging techniques (e.g., functional near-infrared imaging, wireless EEG) offer great creative potential for moving the neuroscience of attachment into more nuanced and comprehensive cognitive and emotional territory.

- *Be sensitive to sex differences.* Little is known about how the sex of an individual under study affects activity in the attachment behavioral system, or indeed the neural constituents of attachment. Self-reported sex differences have been noted in behavioral studies, however. For example, women are more likely to endorse items indicating a preoccupied attachment strategy characterized by worry that their partners will leave them, whereas men are more likely to endorse a dismissive or avoidant strategy characterized by discomfort with interpersonal closeness (Bartholomew & Horowitz, 1991). And many have observed that women are most bothered by their male partners' avoidance, whereas men are most bothered by their female partners' anxiety (Mikulincer & Shaver, 2007). Others have reported sex differences in relationship stability as a function of attachment styles, suggesting that attachment styles may interact in important ways with gender roles (Kirkpatrick & Davis, 1994).

- *Pursue animal models of attachment style.* To date, there are virtually no studies of attachment styles in nonhuman animals, despite growing evidence that other personality dimensions are evident in nonhuman animals (Gosling, 2008). The "Big Five" personality structure and distribution are very similar in humans and chimpanzees (King & Figueredo, 1997), and the anxiety and avoidance dimensions of attachment style are somewhat related to the Big Five traits of Neuroticism and Agreeableness, respectively (Nofhle & Shaver, 2006). Other personality traits shared to one degree or another with humans have been observed in species as diverse as gorillas, hyenas, domesticated dogs, cats, donkeys, pigs, rats, octopi, and even guppies (Gosling & John, 1999). Attempts to study attachment styles in nonhuman animals would constitute a badly needed step toward bridging the gaps be-

tween the human and animal literatures addressing attachment behavior. Indeed, recent work suggests that dogs might be a good place to start looking at animal attachment styles. Dogs are increasingly understood to possess a degree of sensitivity to social cues in humans that may surpass even our nearest genetic relatives (Hare, Brown, Williamson, & Tomasello, 2002; Hare & Tomasello, 2005).

- *Allow for systemic effects in research designs.* Most attachment style research identifies effects of a given participant's attachment style on his or her own attachment behavior. One question of great interest is the degree to which the attachment style of one member of a dyad affects the behavior of the other member. (See J. A. Feeney, Chapter 21, this volume, for examples.) For instance, Coan, Schaefer, and Davidson (2005) presented evidence that in married couples, the husband's preoccupation score corresponded with increased neural threat reactivity throughout the wife's brain if she was holding the hand of a stranger (while her possibly jealous husband looked on). More generally, we know that relationship satisfaction is affected by the attachment style of an individual's relationship partner (Kane et al., 2007). A neuroscience of attachment will benefit from an understanding of how systemic or dyadic effects of attachment style affect current cognitive and emotional functioning.

- *Seek to understand contextual and situational influences.* Nearly a half-century of research makes clear that personality is most stable within classes of situations as opposed to across situations (Mischel, Shoda, & Mendoza-Denton, 2002). Indeed, individual differences in brain activity are more reliable and predictive when evoked by a laboratory challenge than when trying to capture a general trait that is situation-independent, as in the commonly explored "resting" condition (Coan, Allen, et al., 2006; Stewart, Coan, Towers, & Allen, 2014). Applied to attachment theory, we can reasonably ask: Is a particular woman secure in her relationship with her spouse to the same degree that she is in her relationship with her best friend, mother, or sister? Moreover, does her attachment style manifest itself in the same way to a threat to her relationship as to her personal sense of bodily harm? Would she have endorsed the same level of security during a previous relationship that she does in her current one? Some studies suggest that within-person variation in attachment style across different relationships may be substantial (La Guardia, Ryan, Couchman, &

Deci, 2000), even if a stable higher-order attachment style persists across time and situations (Fraleley, 2002; Fraley, Vicary, Brumbaugh, & Roisman, 2011). This is likely to be especially true at the neural level, where measures can be very sensitive to small changes in context.

- *Implement longitudinal designs.* One extremely important problem for the neuroscience of attachment is delineating the process by which two individuals progress from not being attached to being attached (for discussion, see Zeifman & Hazan, Chapter 20, this volume). What is the rate at which this typically occurs? How is this affected by attachment style? What is the role of distress and its alleviation (Beckes & Coan, 2015)? With special relevance to this chapter, which neural structures associated with emotional responding, motivation, and emotion regulation are particularly sensitive to this process? For example, at what point, or with what kinds of interpersonal experiences, does a stranger who regulates the brain's autonomic and musculoskeletal response to threat become a partner who regulates additional neural processes related to effortful affect regulation and threat vigilance? How does the ability to regulate one's own emotional responses covary with one's ability to yield to the regulatory efforts of a loved one? Longitudinal studies may also address questions of within-subject variation in attachment style over both time and relationships.

- *Pursue clinical implications.* As I reviewed briefly earlier, and as discussed by scores of other scholars in recent decades (Cacioppo et al., 2007; Holt-Lunstad, Smith, & Layton, 2010; House et al., 1988; *PLoS Medicine* Editors, 2010; Robles & Kiecolt-Glaser, 2003), social relationships hold major implications for health and well-being. As the neural mechanisms supporting these effects become better known, it may be possible to implement clinical interventions that not only emphasize the forging and maintenance of close relationships, but also focus on the use of social affect regulation for clinical purposes.

For example, we have used relationship therapy to transform couples that do not show a strong social regulation effect on neural threat responding into those that do (Johnson et al., 2013). But the inclusion of attachment figures may potentiate the therapeutic effects of individual interventions as well. For example, the presence of a relational partner may reduce the level of attentional disengagement that highly anxious people deploy in stressful situations (Maresh, Beckes, & Coan,

2013). This may at first blush not seem like much of an advantage, but consider that attentional disengagement—an extreme avoidance response to stress—may be implemented because individuals are unable to cope with stressors experienced as too overwhelming. This is why experiential avoidance can be a significant impediment to treatment in disorders such as PTSD, which can require sometimes intense emotional responding during exposure (Badour, Blonigen, Boden, Feldner, & Bonn-Miller, 2012). Indeed, there is a growing interest in providing individual therapy in conjunction with dyadic interventions (Baucom, Belus, Adelman, Fischer, & Paprocki, 2014; Johnson, 2002). It warrants emphasis here that most stress reduction techniques involve highly individualized activities (e.g., cognitive-behavioral therapy, mindfulness meditation) that may be less efficient or more effortful than they would be if done in the context of supportive social networks or attachment relationships. Few or no cognitive or meditation-based interventions are designed with this specifically in mind.

Finally, the careful delineation of neural systems underlying attachment can expand our basic understanding of a wide variety of disorders that implicate social processes. The potential exists for this work to inform research on disorders ranging from autism to fragile X syndrome, Williams syndrome, depression, social anxiety, schizophrenia, and virtually all of the personality disorders (most or all of which are more or less defined in terms of social behaviors).

- *Differentiate behavioral from neural systems.* A major challenge to future neuroscientists interested in the study of attachment will be the temptation to think of the attachment behavioral system as a unitary neural construct, which it almost certainly is not. Numerous neural processes, each with its own unique problems to solve, contribute to what we have come to call the “attachment behavioral system”; indeed, this system may be little more than a convenient rubric for describing the collective social activities of social bonding and social affect regulation. On the other hand, the attachment behavioral system may represent an emergent property of its constituent neural components that is, under some conditions and in some situations, relatively irreducible.

- *Collaborate.* The neuroscience of attachment represents uncommonly fertile ground for a wide variety of researchers, from neuroscientists to psychologists, biologists, physicians, epidemiolo-

gists, and others. Individuals from diverse scientific traditions can contribute many essential pieces to this fundamentally important puzzle. Because this area is so necessarily multidisciplinary, researchers interested in these and related questions will do well to explore contacts in related disciplines as their particular research questions call for it (Cacioppo et al., 2007). It is for precisely this reason that collaborations are increasingly the norm among the social, cognitive, and affective neurosciences, as well as among molecular geneticists interested in attachment-related neural functioning (cf. Bakermans-Kranenburg & Van IJzendoorn, 2008; Chapter 8, this volume; Puglia et al., 2015). Such collaborations enrich the science and often richly reward the scientists who take part. When focused on a question as fundamentally important as the neuroscience of attachment, I expect that collaborative efforts will be embraced with great enthusiasm.

Acknowledgments

I would like to thank Jude Cassidy and Philip R. Shaver for their helpful comments on this chapter.

Chapter 13

Normative Development

The Ontogeny of Attachment in Childhood

Robert S. Marvin
Preston A. Britner
Beth S. Russell

Whilst especially evident during early childhood, attachment behavior is held to characterize human beings from the cradle to the grave.

—JOHN BOWLBY (1979, p. 129)

During the 1940s and 1950s, a number of emerging studies suggested that very young children, when separated from their mothers for a considerable period of time, proceed through a series of reactions that have become known as protest, despair, and detachment (e.g., Burlingham & Freud, 1944; Robertson, 1953). These or similar reactions were so common, despite variations in the care received by the child, that John Bowlby departed from the contemporary scientific and clinical consensus and decided that the loss of the *specific mother figure* was the most important factor in these reactions. From here, Bowlby went on to develop his “ethological–control systems” theory of the infant’s tie, or attachment, to his or her mother or primary caregiver (Bowlby, 1958, 1969/1982, 1973, 1980). In a partnership that went on to span nearly 40 years, Bowlby and Mary Ainsworth (1967; Ainsworth, Blehar, Waters, & Wall, 1978), among others, sought to answer questions such as the following:

Why does the young child become so distressed by the loss of his or her mother?

What processes account for each of the three phases of loss?

What is the bond that ties the child to his or her mother?

What are its forms, and how do they emerge?

And ultimately, how do we understand form and functioning “when things go wrong?”

Bowlby and his colleagues decided that answering these questions required a shift to the study of the early development of this bond in normally developing children and their families. They were convinced that only by understanding the normal formation and functioning of an attachment relationship would we be able to understand its malfunctioning. These efforts resulted in some of the most empirically and theoretically significant contributions to the study of children’s development in the second half of the 20th century. The theory that emerged was consistent with then-current theories of biology, embryology, cognitive science, and general systems theory. It was at the same time specific enough to incorporate species and cultural

differences, and general enough to incorporate species and cultural similarity. It came closer than any other theory to being equally applicable to questions of normative development and of individual differences and maladaptive developmental pathways.

Through the mid-1970s, there was much excitement and controversy about Bowlby's theory of the ontogeny of attachment. However, by the 1980s, the field of attachment research had undergone a significant change: The study of individual differences had come to occupy so much of the focus that exploration of the *ontogeny* of attachment had nearly been abandoned. Ainsworth's identification of three "primary" strategies of attachment (e.g., Ainsworth et al., 1978), Main and Solomon's (1990) discovery of a "disorganized" pattern of attachment, and Main, Goldwyn, and Hesse's (2003) research on adults' attachment patterns have contributed enormously to our understanding of differential strategies within intimate relationships, as well as child and adult psychopathology. Ethological studies of behavioral development, however, point to the obvious but often ignored importance of survival of the individual at each developmental point. This will certainly be no less the case in the study of human attachment. Only by studying individual pathways *through the course of development* will we truly understand the origins, nature, and sequelae of the attachment bond.

Do we think that attachment behavior, and a secure attachment, are developmental tasks only of infancy, to be superseded by later tasks such as self-control and self-reliance (Garon, Longard, Bryson, & Moore, 2012), individuation (Kruse & Walper, 2008), autonomy (Beyers, Goossens, Vansant, & Moors, 2003), or independent and socialized behavior (Baumrind, 1980)? There are theoretical and empirical reasons for rejecting a strong developmental tasks position (Ainsworth, 1990).

Perhaps the most important reason for studying the developing forms of attachment behavior is related to common experience and to one of Bowlby's most fundamental theoretical claims: that the biological function of attachment behavior is protection of the youngster from a variety of dangers. Preschool and even older children, in our present environment and in our "environment of evolutionary adaptedness" (Bowlby, 1969/1982), are vulnerable to a wide range of dangers. How children and their caregivers organize protective proximity and contact, and how they continue to

use their caregivers as a secure base for exploration, remain as important during later periods of development as during the first year of life. Although the frequency of attachment behavior may wane across development, it remains as important when activated in a 4- or 8-year-old as it was during infancy. And how the attachment behavioral system is organized with other behavioral systems of the individual (and of the caregivers), such that the person is protected while exploring other developmental activities, becomes a crucial question for many developmental domains across the lifespan.

Bowlby (1969/1982) placed his theory of the development of attachment squarely within the biological, general systems, and cognitive sciences. The theory is actually an integration and elaboration of several conceptual schemes: general systems theory, including especially communication and control systems theory; cognitive science, much of which can be considered part of systems theory; evolutionary theory; ethology and the study of primate behavior; and descriptive studies of human infants and young children interacting with their caregivers. Our description of the development of attachment in childhood in this chapter presents Bowlby's theory, along with the elaborations provided by several scholars regarding developmental changes during the preschool and early school age years. More detailed descriptions of attachment theory as applied to adolescence and adulthood are presented in the chapters in Part IV of this volume.

General Systems Perspective

At an abstract information-theoretical level, if a system is to survive, certain invariant conditions must be maintained, both among its constituent elements and in its relationship with its environment (Ashby, 1952, 1956). In particular essential respects, variety must be kept within certain limits or the system will not survive. If a system cannot control input from the environment in a manner that keeps these essential variables within the limits, then it must be "coupled" with another system that can keep the variety in the first system within the limits. In other words, there must be a close coupling, bond, or attachment between the two systems that serves to protect the less "self-reliant" system. This is a formal statement of Bowlby's basic thesis regarding the biological function of child-parent attachment: It protects the child

from a wide range of dangers—from either internal changes or environmental inputs—that would push some essential variable(s) beyond the system's (i.e., the child's) limits of survival.

In a system that develops toward increasing self-reliance over time, this coupling can have another aspect. In many biological organisms, the protective bond has a component that facilitates the youngster's tendency to explore and learn (i.e., to develop the skills needed for its autonomous integration into the larger group). Within this protective relationship, the developing organism thus becomes progressively less dependent for protection on the bond with its parent. Eventually, the developing organism obtains the necessary skills, within its coupling with its larger social context, to control internal change and environmental input in ways that stay within the limits necessary for survival. This complex developmental pattern constitutes the crux of Ainsworth's (1967) concept of the child's use of its mother as a haven of safety and secure base for exploration. It emphasizes that at each point in development, the attachment–caregiving interactions between the youngster and his or her attachment figure(s) compensate for, and complement, the lack of motor, cognitive, communication, and social skills on the youngster's part, such that the youngster is always protected while being afforded as much independence as possible to learn those skills. Finally, it suggests that at any given point in development, skills or behavioral systems across developmental domains will fit together in a manner that makes adaptive sense in terms of survival at that point.

Bowlby's Control Systems Model of Development

Research on both primates and humans indicates that this developmental pattern takes place in the context of a complex network of “affectional bonds,” including the close attachment of infant to mother. Ainsworth (1967) defines an *affectional bond* as a relatively long-enduring tie in which the partner is important as a unique individual, and noninterchangeable. Harlow was one of the first to propose distinct affectional systems or bonds (Harlow & Harlow, 1965), with the explicit connotation that different bonds function to achieve different outcomes. Bowlby took this a step further in distinguishing among a number of behavioral systems, each with its own predictable outcome

and biological function (see Cassidy, Chapter 1, this volume). Following on Harlow's early work, a number of distinct affectional bonds have been identified, including the attachment bond; the parent's complementary, caregiving bond; the sexual pair bond; sibling/kinship bonds; and friendship bonds (Ainsworth, 1990; see B. C. Feeney & Woodhouse, Chapter 36, and Zeifman & Hazan, Chapter 20, this volume). In our opinion, the essential contribution of Bowlby's theory is his description of the behavioral systems underlying these bonds, and the developmental changes in those behavioral systems.

Behavioral Systems

Attachment theory proposes a number of behavioral systems that are species-universal, although there may be (subtle) differences across both individuals and breeding populations (e.g., Freedman & Gorman, 1993). Each behavioral system consists of a set of interchangeable, functionally equivalent behaviors (i.e., behaviors that have the same predictable effect or outcome; Bowlby, 1969/1982). At the same time, each behavior serves more than one behavioral system. For example, locomotion serves, among others, the attachment, exploration, and wariness behavioral systems. It is for this reason that Sroufe and Waters (1977) insisted that the infant's attachment behavior can be fully understood only from an organizational perspective.

A nonexhaustive list of behavioral systems would include those related to feeding, reproduction, caregiving, attachment, exploration, sociability, and fear/wariness. Following ethological theory, Bowlby proposed that the behavior patterns associated with each of these behavioral systems have been selected through evolution because they fulfill a biological function: They help to ensure the survival and reproductive success of the individual and his or her genes. The biological function of attachment behavior, and of wary behavior, is protection of the youngster from a wide range of dangers. The biological function of exploratory and sociable behavior is that of learning the skills necessary for more self-reliant survival, both in terms of individual skills and of smooth integration into the social group.

Behavioral systems include rules for the selection, activation, and termination of behaviors based on the individual's internal state and environmental context. As implied earlier, attachment researchers have focused on three specific behav-

ioral systems: attachment, fear/wariness, and exploration. Ainsworth (1990) and Marvin (1997) have suggested that it is useful to think of a fourth, the sociability behavioral system, which is related to children's friendly interactions.

Attachment theory proposes that in normal development, the operation of these four behavioral systems is affected by specific environmental and organismic events. They also exhibit a complex dynamic balance (Ainsworth, 1967), which has the predictable outcome of ensuring that the youngster develops more sophisticated coping skills, but does so within the protective bond to the attachment figure(s). Specifically, when the youngster's attachment and/or wariness behavioral systems are minimally activated, his or her exploration and/or sociability behavioral systems can easily be activated. Activation of the wariness system serves as a terminating condition for the exploration and/or sociability systems, and coincidentally as an activating condition for the attachment behavioral system. Proximity or contact with the attachment figure, then, often serves to minimize activation of the attachment and wariness behavioral systems, which in turn can reactivate the exploration and/or sociability systems. This is part of the underlying control system for what Ainsworth (1967) described as "using the mother as a secure base for exploration." Finally, as many mothers, fathers, babysitters, and child care providers know, a strongly activated exploration system can reduce activation of the attachment system.

There is some evidence that as the youngster develops through the preschool years, the organization among these four behavioral systems changes and becomes more elaborate (e.g., Greenberg & Marvin, 1982). There is also some evidence that in young children raised in environments extremely dissimilar from the "environment of evolutionary adaptedness" (e.g., in a maltreating or institutional setting without consistent caregivers), these four behavioral systems often do not exhibit this equilibrated organization, leading to what could appropriately be called a *developmental disorder* (e.g., O'Connor et al., 2003; Rutter et al., 2012; Zeanah, Smyke, Koga, & Carlson, 2005; see review by Dozier & Rutter, Chapter 30, this volume).

Complexity of Behavioral Systems

Drawing from ethology, Bowlby (1969/1982) proposed that behavioral systems differ not only in function but also in their structural complexity. The simplest is a *reflex*—a highly stereotyped be-

havior activated by a stimulus at a specific threshold and carried to completion. A more complex behavior, called a *fixed action pattern* by ethologists, is also a highly stereotyped behavior activated and terminated by specific stimuli, but its threshold for activation varies according to the state of the organism, and it often makes use of some feedback from the environment during its execution. Many of the basic attachment behaviors that Ainsworth (1967) identified, such as grasping, crying, and smiling, might also be considered fixed action patterns.

Although seemingly quite primitive, these simple behavior patterns can assume an elegant complexity when placed in the context in which they evolved. In the case of attachment behavior, the context is one of close proximity to a caregiver who responds with specific behaviors that complement the infant's behavior. The immediate effect of many behaviors is to bring about a change in the environment that serves as an activating condition for another behavior, often forming a lengthy sequence with an eventual outcome that is necessary for the individual's survival. For example, when a hungry neonate cries, that behavior *predictably* activates the maternal behavior of picking the infant up and placing it at the breast. The pick up, or at least the stimulus of the breast or nipple on the infant's face, terminates the cry and activates rooting. This predictably brings the infant's mouth in contact with the nipple, which serves as a terminating condition for rooting and an activating in the baby a condition for grasping the nipple with its lips. The stimulus of the nipple in the mouth, in turn, activates sucking, and finally liquid in the mouth stimulates swallowing. Whereas the complexity and predictability of this sequence might appear purposeful, goal-directed—or to use Bowlby's term *goal-corrected*—on the part of the infant, in fact it is not. Interruption of the sequence at any point would lead to failure of the overall sequence. Instead, Bowlby referred to these behaviors as having a specified "predictable outcome," as long as the behavior is executed in an environment similar to the one in which the behavior evolved. The predictable outcome of attachment behaviors more generally is proximity and/or contact with a caregiver/attachment figure. This construct of a predictable outcome is especially important for at least two reasons. First, it allows us to understand relatively simple forms of behavior as achieving an important outcome without our inferring that the youngster executed the behavior intentionally, despite the fact that the behavior sequence occurs in a predictable way.

Second, it forces us to view these simple behavior patterns as taking place in a dyadic or larger context: They have little meaning if they are not described and understood in the relationship context in which they evolved.

A yet more complicated pattern of behavior is a goal-corrected pattern. As with simpler forms of behavior, goal-corrected behaviors have activating and terminating conditions, as well as predictable outcomes, but they achieve the outcome through a more sophisticated process. In order to engage in goal-corrected behavior, an organism must have an especially complex, dynamic, internal representation of relevant aspects of self, his or her behavior, the environment, and the object or person toward whom the behavior is directed. Bowlby used the term *internal working model* (IWM) for these representations, but he also referred to them as “representational models,” which are loosely equivalent to Piagetian “schemes.” IWMs are not static images, but flexible models that are used to understand and predict one’s relations with the environment, and to construct complex sequences of behavior based on plans that can achieve specific, internally represented outcomes. Studies of the early parent–child relationship have identified crucial moments in the sequence of actions during a goal-directed exchange. Specifically, the moment of repair in a mismatched exchange carries the most crucial information to both parent and child (Kogan & Carter, 1996). For example, when the neonate cries in the night, signaling that she is cold, her distress may increase when she is exposed to check for a soiled diaper, as may her parent’s distress at failing to soothe her cry; both experience relief when settled in for a snuggle, warming the cold baby and reassuring the caregiver. When a goal-corrected behavior sequence is activated, the child continuously orients his or her behavior and selects alternative behaviors, based in part on the feedback received from the effects of the behavior. When the set-goal is achieved, the perceived discrepancy between the set-goal and the organism’s state is reduced to zero, and the behavioral plan terminates.

Drawing again from the work of the ethologists, Bowlby (1969/1982) proposed that there are variations in how behaviors, and behavioral systems, are coordinated into more complex wholes. Among them are the following:

1. Very simple behaviors can be coordinated in chain-linked sequences, with the terminating condition for one behavior serving as the activating condition for the next.
2. There can be chains with alternative links. In this case, when one link in the chain fails to achieve an outcome that activates the next link in the chain, some other link is activated in a non-goal-corrected manner. For example, studies employing the still-face paradigm describe infants who respond to an unavailable caregiver by switching behavior by similarly increasing their distress cues or by disengaging (Mesman, Van IJzendoorn, & Bakermans-Kranenburg, 2009; Toda & Fogel, 1993).
3. Complex, goal-corrected behavior patterns can themselves be organized together in chain-linked sequences, with the terminating condition for the first goal-corrected pattern serving as the activating condition for the second.
4. An action based on one behavioral system alternates with an action based on another system. Ethologists have found that these complex sequences often form the basis for important social interactions and communicative signals.
5. Partially executed behaviors from one behavioral system can occur simultaneously with partially executed behaviors from another, conflicting behavioral system.

Ontogeny of Behavioral Systems

The final step in laying the groundwork for Bowlby’s model of the ontogeny of attachment is to outline the three processes that he proposed as basic to development in general. First, the early forms of behaviors are sometimes directed toward different objects in the environment than those to which the mature form will be directed later in development. Usually, the range of stimuli that elicit a particular behavior becomes restricted over the course of development. Second, behavioral systems that are functional early in development are often of a very simple type. Over the course of development, these simpler systems tend to become superseded by more complex, sophisticated ones with correspondingly complex IWMs. Third, whereas some behavioral systems are functional in simple form early in development, others start out being executed only partially, in a nonfunctional way, or in an inappropriate place in a behavioral sequence. In this case, the important developmental process is the integration of these nonfunctional components into functional wholes.

One of the most important implications of this third process is that once a behavioral system has become organized, it assumes some inherent stability (Ashby, 1956; Thelen & Ulrich, 1991).

It may maintain the same organization even if it has developed along nonfunctional lines and may persist even in the absence of the conditions in which it developed. This part of the developmental model has clear implications for the study of developmental psychopathology. However, it also has important implications for more adaptive development, in suggesting both that there may be systemic, structurally based sensitive periods in development, and that beyond a certain point in development, it may be especially difficult—albeit not impossible—for a developmental process or outcome to take shape in a “normal” fashion.

The Ontogeny of Attachment

Development of Attachment during the First Year of Life

Bowlby proposed four phases in the development of the attachment behavioral system, with the first three occurring during the first year of life, and the fourth beginning sometime around the child's fourth birthday.

Phase I: Orientation and Signals without Discrimination of Figure

Consistent with much new research of the 1960s, Bowlby proposed that immediately or very soon after birth, the baby's signal and motor systems are especially adept at eliciting interest and caregiving from other humans, such that proximity, physical contact, nutrition, and warmth are the predictable outcomes. In this sense, the development of the infant's attachment behavior cannot be fully understood except as taking place in the context of the complementary behavior of his or her caregivers. An extensive body of research focuses on caregiving-as-context for many domains of development, and thorough consideration of these caregiving behaviors and their developmental changes is beyond the scope of this chapter (but see, e.g., Britner, Marvin, & Pianta, 2005; George & Solomon, 1996; B. C. Feeney & Woodhouse, Chapter 36, this volume).

During this first phase in the development of attachment, baby and caregiver engage in interactions of many types, and from the perspective of the caregiver's behavior, many of these interactions are goal-corrected. From the perspective of the baby's own behavioral organization and control, there are *predictable outcomes*, rather than set-

goals, of the behaviors. Thus, during Phase I, the infant's IWMs are present but primitive and are probably limited to internal “on again, off again” experiences associated with the activation and termination of individual behaviors. In this sense, the functioning of the young infant's IWMs are no more separate from actual behaviors than in Stage I of Piaget's (1952) theory of the sensorimotor period.

At birth or very soon thereafter, every sensory system in the infant is working and continues to improve in functioning. Among the sensory systems especially important in the development of attachment behavior are the auditory and visual systems. At or soon after birth, most infants are capable of visual orientation and tracking, and are especially responsive to contour and pattern, especially if the stimulus is moving slowly. By 4 weeks of age, most infants exhibit a preference for looking at the human face compared to other objects (Wolff, 1969). Very soon after birth, infants tend to quiet and attend to soft auditory stimuli and appear especially responsive to the human voice. Infants, and even full-term fetuses, recognize and prefer their own mother's voice to that of a stranger (Kisilevsky et al., 2003). During this first phase, each of these systems has its own activating and terminating conditions, and there is as yet no “internal” connection between the systems. Reaching, grasping, and clinging are also crucial attachment behaviors in all primates, and they develop relatively late in humans. It is not until after about 2 months of age that the human infant's grasp is highly developed and controlled by anything other than a reflex-like process of activation by stimulation of the palm of the hand. It is at about this same time that the visual system becomes chain-linked with the motor system in a manner allowing the infant to make ballistic-like movements toward an object in the visual field. Finally, smiling and crying are additional, important attachment behaviors displaying a similar developmental course. Smiling tends to be activated, and crying terminated, in a relatively automatic way by a range of specific conditions. These conditions become increasingly selective and integrated within more complex behavioral systems over the first 6 months.

Thus, at first it is largely the caregiver who maintains proximity and protects the infant, although the newborn is equipped to be especially responsive to other humans and to elicit caregiving and affection from them. Over the course of the first weeks of life, these patterns of infant–

caregiver interaction are repeated frequently. If the caregiver's initiations and responses are well attuned to the infant's behaviors (i.e., if the baby's attachment behaviors are predictably terminated by the caregiver's behavior), then stable patterns of interaction are established. These reciprocal patterns of caregiver–infant behaviors ultimately minimize the frequency and intensity of attachment behaviors such as crying, and more readily elicit other behaviors, such as visual orientation and smiling. In this context, the infant is seen as establishing its own behavioral and autoregulatory rhythms (e.g., Stern, 1985), so that stable “internal” and dyadic rhythms are established.

Bowlby (1969/1982) proposed that in the environment of evolutionary adaptedness, Phase I lasts from birth to sometime between 8 and 12 weeks of age, roughly coinciding with early developmental trajectories for crying in human and nonhuman primates and of dramatic neurobehavioral and sensory developments (Brazelton, 1962; Marshall, 2011). He suggested, however, that under unfavorable conditions, this phase can last much longer.

Phase II: Orientation and Signals Directed toward One or More Discriminated Figures

The shift from Phase I to Phase II is gradual, and it takes place earlier with some attachment behaviors and complex attachment behavior patterns than with others (Ainsworth, 1967; Bowlby, 1969/1982). Three related issues are important in defining this transition.

First, during Phase II, there is an elaboration of simple behavioral systems into more complex ones. The simple behavioral systems of the Phase I infant become integrated within the infant into complex, chain-linked behavioral systems. The primary focus here is on the *control* of the individual systems. Whereas in Phase I, the caregiver provided the conditions for terminating one behavioral link in a chain and activating the next, during Phase II, the infant assumes much of this control. Many of the sensorimotor advances of the 3- to 6-month-old infant illustrate this shift in behavioral control. For example, as early as 3 months of age, perception of the bottle or breast itself serves as an activating stimulus for opening the mouth, and often bringing the hand(s) toward the mouth (Hetzer & Ripin, 1930, as cited in Bowlby, 1969/1982). By 4 months, the infant's visual system begins to activate the motor behavior of reaching for an object. Through a reciprocal

feedback process, the infant alternates its gaze between hand and the object, then grasps the object. By 5 months, the infant is so adept at this that he or she is able to reach out and grasp parts of mother's body and clothing while being held by her, or as she is leaning over him or her. By the end of the first year of life, infants clearly understand the causal mechanism of reaching, grasping, and attaining an object (Sommerville & Woodward, 2005). Other researchers have studied related developmental elaborations using other theoretical models positing self-organization through social interactions with caregivers (e.g., Hsu & Fogel, 2003; Tronick, 2007).

The second defining issue for Phase II is the restriction of range of effective activating and terminating conditions. Bowlby proposed that as infant and caregiver repeat these sequences of interaction, and as the sequences come increasingly under the infant's control in this chain-linked fashion, there is a tendency for the activating and terminating conditions to become restricted to those most commonly part of the behavioral sequence (cf. Thelen & Ulrich's [1991] notion of “attractor states”). Specifically, Phase II is operationally defined in terms of the infant differentiating between the most familiar caregivers and others in directing his or her attachment behavior.

A third and equally important component of Phase II is the infant's increasing tendency to initiate attachment–caregiving and sociable interactions with the principal caregiver(s). Ainsworth (1967) observed that as early as 2 months of age, and increasingly thereafter, infants are active in seeking interaction rather than passively responding to it. Thus, in at least two ways, the infant of Phase II gains responsibility for maintaining contact and interaction with the attachment figure(s): initiating more of the interaction and being able to exert more control over the interaction through increasingly complex chain-linked behaviors.

The elaboration of chain-linked behavioral systems, and the infant's increasingly differential attachment and sociable behavior, may also have important implications for describing the distinct developmental pathways toward the individual differences in patterns of attachment that Ainsworth discovered (e.g., Ainsworth et al., 1978), and found to be applicable to preschoolers (Cassidy & Marvin, 1992; Etzion-Carasso & Oppenheim, 2000), young school-age children (Bohlin, Hagekull, & Andersson, 2005; Main & Cassidy, 1988), and adults (Bakermans-Kranenburg & Van IJzendoorn, 2009; Main, Kaplan, & Cassidy,

1985). There is substantial evidence that the pathways to differential strategies of attachment begin in the first 3 months of life. For example, parents of later-avoidant infants tend to terminate their infants' cries less often and hold them less during the first months of life (Ainsworth et al., 1978). In these cases, the infant is left in a distressed state for considerable periods of time. The context is then ripe for the infant to develop alternative links in its behavioral chains, where behavior on the part of the infant can terminate its distress (e.g., turning its focus in a rather forced manner to exploration). The patterns of infant–parent interaction along this developmental pathway can become stabilized through the same processes at work in the normative, eventually secure, infant, leading to an “avoidant” strategy and a tendency for the infant to contribute to the perpetuation of the pattern. The divergent developmental pathway of the “ambivalent” or “resistant” infant develops according to an analogous process (Ainsworth, 1967; Cassidy & Berlin, 1994).

Finally, these characteristics of Phase II have implications for describing the nature of the infant's IWMs. Most importantly, the infant can increasingly differentiate his or her primary caregiver(s) from others, and in that sense “know” who they are. However, the infant cannot yet conceive of the attachment figure as someone with a separate existence from his or her own experience. Consistent with Piaget's (1952) theory of Stages II and III of the sensorimotor period, Bowlby's theory also implies that this infant's IWMs parallel its chain-linked sequences of behavior: The infant's awareness has expanded to encompass the continuity represented by these sequences, but not yet to the point where he or she can use internal experimentation or manipulation of images, goals, and intentions to devise a plan for achieving a set-goal.

Phase III: Maintenance of Proximity to a Discriminated Figure by Locomotion and Signals

Phase III, beginning sometime between 6 and 9 months of age, is the phase during which the infant is thought to consolidate attachment to its caregiver(s). It is characterized by a number of important motor, cognitive, and communicative changes, as well as changes in organization among behavioral systems that lead most experts to consider the infant to be “really” attached during this phase.

NEW ATTACHMENT BEHAVIORS

Locomotion provides the infant with not only a vastly increased ability to control proximity to the attachment figure, to move off to explore, to expand his or her horizons in innumerable ways, but also to place him- or herself in significant danger. In fact, four of the six additional attachment behaviors that Ainsworth (1967) identified are based on this newly developed motor skill. Ainsworth observed these behaviors as differential approach to mother, especially on reunion or when distressed, at 28 weeks; differential following of the mother when she leaves the room at 24 weeks; use of the mother as a secure base for exploration (making exploratory excursions from her, returning to her from time to time, and terminating exploration and attempting to regain proximity if she moves off) at 28 weeks; and flight to the mother as a haven of safety when alarmed at 34 weeks. Two other attachment behaviors to emerge during this same period depend less directly on locomotion (Ainsworth, 1967): differential burying of face (while climbing on the mother; or after an excursion away from her, the infant buries its face in the mother's lap) at 28 weeks; and differential clinging to the mother when alarmed, ill, or distressed at 43 weeks. By 6–8 months, the baby is able to cling to the caregiver in a rather automatic way as its attention is directed elsewhere.

INFORMATION PROCESSING AND IWMS

A second, revolutionary change associated with the shift to Phase III is an elaboration of the infant's cognitive skills. Some of the systems mediating a child's attachment behavior and many of the earlier, chain-linked behaviors become organized under the infant's intentional control. Bowlby suggested that the Phase III infant has an internal image of a “set-goal” he or she would like to achieve (e.g., physical contact with the attachment figure). The infant can now: operate internally on available behaviors (i.e., a plan) and select behaviors that are likely to achieve that set-goal (e.g., crawl around the sofa to mother); execute the plan; alter it as a function of feedback; then terminate the plan when the discrepancy between the set-goal and the infant's perception of his or her position is reduced to zero.

This describes, in “control systems” terminology, what traditional cognitive theorists have referred to as the infant's newly emerging ability to differentiate means from ends. The ability to

organize attachment behavior on a goal-corrected basis also implies that the infant now has an internal image of the attachment figure that is independent of perception (object permanence). In a rather elegant longitudinal study, Bell (1970) demonstrated the parallel (in Piaget's terms, the "horizontal decalage") between the development of object permanence, person (mother) permanence, and the onset of goal-corrected proximity seeking. Consistent with the proposition that children will develop such a general purpose skill first in relationship-based and emotionally salient contexts, Bell found that most infants developed person permanence before object permanence. An active debate endures, however, on the human- or object-first hypotheses (e.g., Bonatti, Frot, Zangl, & Mehler, 2002).

The baby's set-goal in interactions with the attachment figure will vary because sometimes the set-goal will be to maintain some distance from the attachment figure while the infant explores the social and physical world. At other times, it will be mere proximity, or nothing short of close physical contact. What "setting" his or her goal takes at any given time is the result of many factors, including physiological state (e.g., hunger, fatigue); the presence or absence of an alarming event in the environment; assessment of the caregiver's attention to him or her; and whether the caregiver is present, departing/absent, or returning from an absence (Bowlby, 1969/1982). It will also depend on the dyad's history of relatively stable patterns (i.e., individual differences) of attachment-caregiving interactions.

COMMUNICATION SKILLS

Concurrent with these locomotor and cognitive changes are those in the infant's verbal and nonverbal communication skills. During Phase II, the infant displays increased visual and vocal engagement with others, much of which is of a turn-taking, prelanguage format to which caregivers tend to respond as if it were intentional (Bruner, 1981; Heilmann et al., 2006). During Phase III, the infant uses communicative signals in a goal-corrected manner as part of a repertoire of plans for achieving a set-goal that often involves regulating the behavior of others for purposes of requesting or rejecting actions or objects; attracting or maintaining another's attention; and/or establishing/maintaining joint attention for purposes of sharing an experience (Bruner, 1981). At first through the infant's display

and understanding of nonverbal utterances and signals, later through single-word utterances, and still later (18–36 months of age) through complex verbal communication, youngster and caregiver(s) are able to alter each other's behavior indirectly by directly altering each other's set-goals (Marvin, 1977).

All these changes have important implications for the Phase III baby's internal working models. At this point, the baby has separate models of caregiver(s) and of self. These consist of images and plans ordered in some form of a hierarchy—or event schemas or scripts (Stern, 1985)—of self and other. The content of the infant's IWMs are probably derived from some combination of the stable, chain-linked sequences of interaction already developed with the caregiver(s) and the newly stabilizing patterns that emerge with the motor, cognitive, and communication skills that develop during Phase III. The likely more elaborate content of infants' IWMs is also echoed in psychosocial theories of development, as Erikson (1950) proposed that the cumulative sense of trust or mistrust an infant builds across the first year relates to both a sense of confidence in the caregiver and a sense of confidence in the self as an effective agent in social exchanges—the later being a clear parallel to developing schemas or IWM. Indeed, Pittman, Keiley, Kerpelman, and Vaughn (2011) suggest that attachment history—with its foundation in infancy—provides the context for identity formation.

In Phase III, the infant's IWMs remain primitive in at least two ways. First, the infant is limited to thinking about caregiver and self only in terms of caregiver behaviors. The infant has yet to comprehend that the attachment figure has unique perceptions and goals, and that these can differ from his or her own. Second, the infant is unable to think about behaviors in terms of long sequences. The infant's ability to operate in this internal fashion is limited to individual goal-plan hierarchies, or event schemas, with each thought activated and terminated by specific stimuli.

THE EXPLORATION SYSTEM

The fourth important change that takes place during Phase III is especially related to the changes in the infant's locomotor and cognitive changes (i.e., the elaboration of his exploration behavioral system). The development of locomotion and of object permanence, the more sophisticated un-

derstanding of mean–ends relations, the ability increasingly to organize exploration on the basis of goal-corrected behavior, and emerging imitation and conversational skills (e.g., Piaget, 1952) all enhance the infant's ability to learn about the physical and social environment, to test and learn the "rules" that govern those interactions, and to categorize those interactions symbolically and linguistically.

THE SOCIABILITY SYSTEM

Closely related to the exploration system is the infant's sociability system. Although there appear to be individual differences related to both temperament and relationship history in Phase III infants, infants in this phase are likely to stop exploration when confronted by a strange person, remain wary (or even fearful) for some moments, and either remain stationary or move away from the stranger and toward the attachment figure. After some few moments, if the stranger displays positive affect, is not intrusive, and matches his or her responses to the infant's behavior, the infant is likely to interact sociably, with rapidly decreasing wariness (e.g., Bretherton & Ainsworth, 1974).

THE WARINESS SYSTEM

The fifth and final major Phase III change involves the infant's wariness behavioral system. Wariness toward novel, and especially sudden, nonhuman events has obvious survival value. What is less obvious is the nature, developmental course, and role played by wariness toward unfamiliar *humans*. Despite the earlier bias toward responding to human stimuli, during the last quarter of the first year, infants increasingly are more wary of unfamiliar adults (Bretherton & Ainsworth, 1974). Although there may be individual and reproductive gene pool differences in temperamental reactivity to strangers (e.g., Kagan, & Fox, 2006), this developmental shift appears to exist whether the infant is raised in a culture in which the norm is single or multiple caregivers (cf. Ainsworth, 1967).

Reciprocal linkages among the older infant's wariness, sociability, and attachment behavioral systems are more obvious and predictable than they were earlier. If the wariness system is highly activated, the infant tends to retreat to the parent as a haven of safety; if it is not, the infant may continue to stare at a nonintrusive stranger, or may initiate or respond sociably. In many cases, one can see a cycling of conflicting behavioral systems,

with the infant moving back and forth from parent to stranger, as the distance from each tends to activate one system and terminate the other.

SENSITIVE PERIODS

That infants become more, rather than less, wary toward unfamiliar humans over the period from 6 to 18–24 months of age, is important for at least two reasons. First, infants *are* vulnerable to danger from other humans, and until they are more able to predict which individuals are dangerous, it is adaptive that their initial reaction be wariness. Second, one of the developmental mechanisms involved in the consolidation of infants' attachment is the reduction in the range of individuals able to activate and terminate infants' attachment behavior (Bowlby, 1969/1982). The infant more and more comes to approach familiar caregiver(s) and to retreat from unfamiliar individuals of the same species. In its general form, this phenomenon is characteristic of many species and is common in the study of "sensitive periods" in development (Bateson, 1976; Knudsen, 2004; Marvin & Britner, 2008).

Bowlby (1969/1982) suggested that the readiness to become quickly attached remains intact at least through the end of the first year. This does not imply that the specific attachment, a more versus less adaptive *form* of attachment, or the lack of an attachment, is completely irreversible after this sensitive period. The results from studies of infants placed in foster care, or raised in East European orphanages and adopted into low-risk homes, suggest that children *can* form discriminating or selective attachments for the first time well after 1 year. However, infants placed in foster care after 12 months of age have been found to be more rejecting toward their new caregivers than younger infants (see Dozier & Rutter, Chapter 30, this volume). And contemporary studies of children adopted from orphanages (e.g., O'Connor et al., 2003; Rutter et al., 2012) increasingly indicate that these children form attachments, but that those attachments are at increased risk of being organized in a significantly less adaptive manner than would be expected given that they are being raised in a low-risk home.

ORGANIZATION AMONG BEHAVIORAL SYSTEMS

It is during Phase III that the dynamic balance described earlier among the four behavioral systems

fully emerges (Ainsworth et al., 1978). For most infants, this balance culminates in organizing the new developments of this phase into what Ainsworth (1990) referred to as the “hallmark” of an attachment—the infant’s use of the attachment figure as a secure base for exploration. Stable *variations* in this organization are evident in the different insecure strategies of attachment (Ainsworth et al., 1978; Main & Solomon, 1990). In the case of the “avoidant” strategy, the infant tends, when the attachment system is highly activated, to inhibit attachment behavior and (often) activate the exploration system. In the “resistant” strategy, the infant tends to overamplify the attachment and wariness systems. In the case of infants classified as having a “disorganized” attachment, the simultaneous and/or sequential activation and termination of behavioral systems are especially contradictory and take a form that puts the infant at risk of not being protected (e.g., with activation of the attachment system also serving to activate wary behavior toward the caregiver).

SUBORDINATE ATTACHMENT FIGURES AND TYPES OF RELATIONSHIPS

Throughout human evolution, children have been raised in families, which themselves are part of larger groups of varied size and composition. Most children have experienced multiple caregivers, giving them the opportunity to form specific attachments to a number of figures. Even in his early writings, Bowlby (e.g., 1958) proposed that infants tend to become attached to a number of caregivers, and that “for a child of 18 months to have only one attachment figure is quite exceptional” (Bowlby, 1969/1982, p. 304).

Several studies across many cultures have suggested that a minority of infants select more than one attachment figure almost as soon as they begin to show any differential attachment behavior, whereas a majority do so by 18 months (e.g., Ainsworth, 1967; Konner, 1976; Schaffer & Emerson, 1964). These and other studies (e.g., Myers, Jarvis, & Creasey, 1987; Umemura, Jacobvitz, Messina, & Hazen, 2013), however, suggest that not all attachment figures are treated by the infant as equivalent. Infants are attached to a range of caregivers; however, attachment behavior, especially when the infant is distressed, hungry, tired, or ill, tends to be focused on a particular person when both that person and other attachment figures are available. Thus, most infants seem to have a network of attachment figures, but the available

data suggest that they may tend to choose one figure as the “primary” attachment figure. Importantly, others may be chosen as the primary figure for play or other types of interactions (see Mesman, Van IJzendoorn, & Sagi-Schwartz, Chapter 37, this volume).

Development of Attachment during the Toddler and Preschool Years

Most research on social and emotional development during the postinfancy preschool period has focused on issues other than attachment—for example, autonomy, self-control, independence, and socialization. These issues imply a decline in attachment behavior, as the child deals with these later “developmental tasks.” Although the framework of developmental tasks can be helpful in guiding our research, it can also lead us astray by restricting the focus to single issues. A full understanding requires viewing development across multiple domains. In fact, while the child is becoming more autonomous and self-reliant during the preschool years, he or she remains vulnerable to a range of dangers. The child makes increasingly distant forays from the attachment figure while exploring the environment but is still at an early point in developing the skills needed for self-protection. The close attachment to the caregiver thus remains crucially important to the child’s survival and socialization. It is adaptive, rather than “regressive,” that attachment behavior remains easily activated.

As we move to the study of attachment in the postinfancy years, we must also be careful not to lose the focus on *behavior* as the child’s representational and communicative abilities become increasingly noticeable. Because infants’ mental models of attachment cannot possibly be symbolic (i.e., language-based), it must be assumed that those cognitive structures that relate to attachment *behavior* in infancy constitute the mental model (Bretherton, 1993). There is a natural shift in research on attachment past infancy to move to the level of cognitive–emotional representation. The trap is to move to the cognitive level to the relative exclusion of behavior. This would be a terrible error. Bowlby’s whole theory—or the cognitive-behavioral part of it—is based on the important linkage between IWMs and behavior. The point is that older children do not move from the level of behavior to the level of internal representation: They become able to process and manipulate plans and goals at that internal level, and

increasingly to control behavior with that internal processing. We must remember that the function of an IWM is to organize behavior in more flexible ways.

Changes in Attachment Behavior during the Toddler/Preschool Years

Although most of our knowledge about the ontogeny of attachment behavior is restricted to the first 12–15 months of life, a few naturalistic studies (e.g., Blurton-Jones, 1972; Konner, 1976; Lyons-Ruth, Connell, Zoll, & Stahl, 1987) and a number of laboratory-based studies (e.g., Main & Cassidy, 1988; Marvin, 1977; Marvin & Greenberg, 1982; Mittal, Russell, Britner, & Peake, 2013; Russell, Londhe, & Britner, 2013) provide a general outline of the normative course of attachment behavior over the preschool and early school years. In reviewing the literature, Bowlby (1969/1982) suggested that during the second and most of the third year of life, attachment behavior is shown neither at less intensity nor less frequency than at the first birthday. In fact, use of attachment figures as a secure base is a critical component of the child's rapidly expanding physical and social world, and attachment behavior therefore remains a major part of his or her behavioral organization.

Overall, 2-year-olds tend to maintain as much, or more, proximity to their mothers as do 1-year-olds. At the same time, they also make more extensive excursions away in order to explore with their more elaborate cognitive and motor abilities. Several studies (e.g., Schaffer & Emerson, 1964) have found that toddlers tend to monitor actively not only the mother's movements but also her attention. When she is not attending to him or her, the child often executes attachment behavior with the set-goal of regaining her attention. This adaptive behavior pattern is sometimes unappreciated in Western cultures, in which it is commonly seen as regressive or controlling "attention seeking" and as frustrating to parents.

Before the third birthday, children are not very adept at maintaining proximity when their attachment figure is moving. The perception of the caregiver moving off is typically a condition that terminates the toddler's exploratory behavior and activates attachment behavior. At this younger age, children can follow the caregiver around the familiar home but find following the caregiver difficult if he or she is moving steadily away from the child. In this situation, one or both members of the dyad initiate physical contact, and the tod-

dlar is carried. After the third birthday, with much improved locomotor skills, the child is much less likely to be carried under relaxed circumstances.

When undergoing a separation from the mother that is not of their own initiative, 2-year-olds tend to be as distressed as 1-year-olds, although they are more able to rely on calling and active search behaviors rather than crying. Many 3- and 4-year-olds also become mildly upset by such brief separations, but less so than 2-year-olds, and they are more willing than younger children to be left for brief periods in the company of friendly adults. By the third birthday, it appears that it is being left *alone* that is especially upsetting and likely to elicit strong attachment behavior. If briefly left alone, or if mildly distressed by being left with a friendly adult, most 3- and 4-year-olds are able to wait for the attachment figure's return before executing attachment behavior (Marvin, 1977). For a more detailed review of changes in preschoolers' responses to separations, proximity seeking and contacts with their caregiver, and the organization of the attachment system, see Marvin and Britner (2008).

Research by Marvin (1977; Marvin & Greenberg, 1982) and Cassidy (Cassidy et al., 1992; Main & Cassidy, 1988) suggest the importance of Bowlby's (1969/1982) proposed final phase in the development of attachment, the "goal-corrected partnership." They are also congruent with earlier research suggesting that sometime around age 4, children are much less dependent on physical proximity and contact with their attachment figure(s) to maintain a sense of security and are increasingly comfortable spending appreciable periods of time in the company of nonfamilial peers and adults (Blurton-Jones, 1972; Konner, 1976). In the following sections, we briefly review literature on other developmental domains relevant to the changes in attachment behavior outlined earlier, then review the theoretical and empirical work on the goal-corrected partnership.

Developmental Changes in Relations among Behavioral Systems

Ainsworth and colleagues (1978) showed how, in 1-year-olds, the attachment, exploration, wariness, and sociability systems function in the dynamic equilibrium described earlier. Observation of young children's behavior when they are introduced to a friendly adult stranger presents an excellent opportunity to study this dynamic balance, and it has yielded some evidence that this organi-

zation changes over the preschool years in a way that is consistent with the youngster's gradually increased responsibility for self-protection based on increasingly sophisticated behavioral organization.

Greenberg and Marvin (1982) studied young children's initial reactions to a friendly stranger. The most common response among 3- and 4-year-olds was to (apparently) ignore the stranger and continue exploring, without activation of either the wariness or attachment behavioral systems. The next most common response was the *simultaneous* activation of the wariness and sociability systems (usually in the form of coy expressions) and coincidental activation of the attachment system. No 2-year-olds displayed this more complex pattern. Most children of all three ages eventually played sociably with the stranger. Whereas a few of the younger children remained fearful of the stranger throughout the situation, none of the older children did so. Finally, all 2-year-olds (but none of the 3- or 4-year-olds) who displayed wariness toward the stranger while the mother was gone also displayed attachment behavior toward the mother when she returned. Greenberg and Marvin suggested that this decreased developmental coupling of the wariness and attachment behavioral systems, and the increased developmental coupling of the wariness and sociability systems, could have important implications for children's increasing ability to cope with strangers on their own: The careful approach implied by the coincidental activation of the wariness and sociability systems could provide the basis for strategies of social interaction that could fulfill the same protective function earlier fulfilled by the close physical bond between the child and his or her attachment figure(s).

Changes in Locomotor and Self-Care Skills

Humans exhibit a developmental organization during the preschool years that suggests the crucial importance of a continuing protective attachment, while at the same time providing the young child with the independence necessary to learn the skills that will be required during the following phase. Milk teeth are completed between ages 2 and 3 years, and by 3 years children are quite independent in feeding themselves. Although Western cultures are now clearly different, in less industrialized cultures, breast feeding tapers off between 3 and 4 years of age. By age 3, the child's locomotor skills have developed to the point that he or she

can assume much of the responsibility for gaining and maintaining proximity to the attachment figure under most conditions, as well as engage in vigorous play with other children and practice many of the social skills he or she will use in a over the next decade. By the beginning of the school-age period, the child is capable of most of the motor skills of older children, although strength, endurance, coordination, etc. continue to improve.

Changes in Communication Skills

It is during the preschool period that children develop most of the communication skills that will later be required for stable integration into their social group(s), independent of the close physical tie to their attachment figure(s). By 30 months, children increasingly communicate about past and future events and emotional states, and connected narrative discourse emerges as children begin to relate logical sequences of events across many utterances (e.g., Bretherton, 1993; Dunn, 1994). Dunn (1994) found that during the second and third years, children are increasingly able to recognize, understand, and converse about the feelings and behaviors of other family members; they comfort, tease, argue, joke, and blame. She concluded that by 3 years of age, children understand surprisingly complex rules for social interaction, interpret others' feelings and goals, and use such rules to manipulate others' internal states. It now seems clear that by age 4, most children are becoming competent at one of our species' most sophisticated communication skills: thinking and conversing about the feelings, goals, and plans of others with whom they are interacting (see Hughes & Leekham, 2004). This skill, indicative of children's developing theory of mind, should have important implications for the organization of attachment interactions.

Although there has been little recent research on the ontogeny of nonverbal expressions in preschool children, some of the early work in human ethology (Blurton-Jones, 1972; Hinde, 1976) suggested that many of the expressions used to regulate interactions during childhood and adolescence develop during the preschool years. Furthermore, studies of coy expressions (Marvin, 1997) and of posed expressions of happiness, surprise, anger, fear, sadness, and disgust (Lewis, Sullivan, & Vasen, 1987) again suggest that the period between the third and fourth birthdays is especially important in the developmental elabo-

ration and understanding of a range of complex expressions used to regulate interactions.

Changes in Information-Processing Skills and IWMs

Extensive research, including the work of Bretherton (1993), Callaghan and colleagues (2005), Cassidy and Marvin (1992), Dunn (1994), Stern (1985), and Ziv, Oppenheim, and Sagi-Schwartz (2004), suggests that during the second through sixth years of life, children are developing sophisticated and accurate (in the sense of nonegocentric) IWMs of their own, and of others' behavior and internal experiences. At the same time, they are developing surprisingly sophisticated IWMs of implicit and explicit rules for social behavior and interaction. The reader is referred to the studies listed earlier, and to other chapters in this volume (particularly Bretherton and Munholland, Chapter 4) for information about the *content* of, and individual differences in, these IWMs, and to Marvin and Britner (2008) for details on developmental changes in their underlying *form*.

Phase IV: Implications of the Partnership for the Organization of Attachment Behavior during the Preschool Years

Although this partnership is certainly a general purpose skill used in interactions with family members, other adults, and peers, it is likely that it will first be applied in emotionally powerful interactions such as attachment-caregiving interactions. Marvin (1977) and Marvin and Greenberg (1982) studied its application to this type of interaction and suggested two important organizational changes. The first is related to the young preschooler's ability to inhibit attachment behavior and insert the caregiver's plans into the child's own plan for proximity, resulting in what might be called the "emergent partnership." The second is related to the older preschooler's ability to operate internally on the goals and plans of self and other simultaneously, to understand objectively (i.e., nonegocentrically) the causal relations between the caregiver's goals/plans and behavior, and to engage in goal-corrected negotiations with the caregiver regarding a shared plan for proximity, forming a goal-corrected partnership.

With regard to the first organizational change, Bowlby (1969/1982) proposed that a toddler's attachment plans vary in the extent to which they are designed to influence the behavior of the

attachment figure. He suggested that the earliest goal-corrected plans for changing the caregiver's behavior are primitive (e.g., pushing her in certain directions, knocking a book off his lap, throwing a tantrum). These early attempts are based either on changing the caregiver's behavior directly through physical means or indirectly, through crying and anger. During this same period, parents rely largely on techniques such as distracting the toddler to influence his or her behavior.

As the dyad's conversational skills become elaborated, and as the child develops self-control, it should become increasingly the case that child and mother are able to change each other's behavior through linguistic communication. Although the child cannot yet negotiate a shared plan with the caregiver in a goal-corrected manner, the child *can* attempt to change the caregiver's goal or plan, inhibit ongoing behavior, insert one of the caregiver's goals into his or her own plan for action, and thus function in an interaction that has the "predictable outcome" of shared goals.

Marvin (1977) provided an initial test of this hypothesis by administering two analogous procedures to a sample of 2-, 3-, and 4-year-old children, one relevant to interaction in a nonattachment context (i.e., a waiting task), and the other in an attachment-caregiving context (i.e., the Strange Situation). The results of both procedures suggest that by 3 years of age, most children are able to inhibit ongoing, goal-corrected behavior across at least two types of interactions, insert one of mother's communicated goals into their own plan, and wait until the circumstances are appropriate for both mother and child before executing their plan.

The results also suggest a further change in the organization of attachment behavior sometime around the fourth birthday. The hierarchical reorganization of the older preschooler's IWMs and information-processing skills that enables the child to operate in a nonegocentric fashion *simultaneously* on the perspectives of self and others, and in a goal-corrected manner to construct shared plans with the caregiver, should have important implications for the organization of attachment behavior. Marvin (1977) suggested that at least five component skills are involved: (1) the ability to recognize that the attachment figure possesses internal events including thoughts, goals, plans, feelings, and so forth; (2) the ability to distinguish between the caregiver's point of view and one's own, especially when they differ; (3) the ability to infer, from logic and/or experience, what factors control the caregiver's goals and plans; (4) the ability to assess the degree of coordination, or

match, between their respective points of view; and (5) the ability to influence the caregiver's goals and plans in a goal-corrected manner. On the basis of much research over the past 20 years (e.g., Bretherton, 1993; Dunn, 1994; Mittal et al., 2013), it seems possible that by age 4, most children possess these component skills.

We do not mean to imply that children age 4 years or older do not want, need, or enjoy physical proximity and contact with their attachment figures. Under conditions of distress, illness, and fear, children—even much older children—continue to retreat to their attachment figure(s) as a haven of safety. As suggested by the attachment classification systems developed by Cassidy and Marvin (1992) and Main and Cassidy (1988), preschool and young school-age children also continue to maintain and enjoy this close tie through a range of intimate behaviors. What is implied by the model is that this older preschooler has come to organize attachment behavior in a new way: one that enables the child to realize that he or she and the attachment figure have a continuing relationship whether or not they are in close proximity. This new organization is one in which the child is increasingly responsible for maintaining whatever protective proximity is necessary. In conjunction with the other recently developed locomotor, communication, and information-processing skills, this organization allows the older child to maintain a close tie to the attachment figure(s) while increasingly moving off from them and spending more time with a peer group, teachers, and others.

Changes in Attachment Behavior beyond the Preschool Years

Bowlby (1969/1982) suggested that the goal-corrected partnership is probably the last phase in the ontogeny of attachment. By this he seems to have meant that there are no further “stage” changes in this behavioral system. The attachment behavioral system, however, remains important throughout the lifespan and does continue to undergo significant changes. These probably include further elaborations at the same “level,” as well as changes in the relations between the attachment and other behavioral systems, the higher-order control structures, activating and terminating conditions, and IWMs. Certainly, there are also many instances in which children form new attachments. One clear implication is

that attachment becomes increasingly difficult to measure as it becomes more sophisticated, more abstract, and less dependent on proximity and contact, as the behavioral systems becomes elaborated into more and more complex systems (Bowlby, 1969/1982). For a detailed account of the course of these developmental changes, see Marvin and Britner (2008), as well as the relevant developmental chapters in this volume.

Conclusion

Attachment theory began with Bowlby's (e.g., 1958) attempt to understand the psychopathological effects of maternal deprivation by studying the normative course of the ontogeny of this earliest relationship. Bowlby's hope was that if we better understood this normative course, we would be in an improved position to understand disruption. We are convinced that Bowlby's attempt to integrate the study of individual differences with that of normative development is as important today as it was six decades ago. The last 20 years have seen contributions to the attachment literature that emphasize descriptions of individual differences across special populations; in particular, there is a trend toward considerations of what might be considered comorbidity or the linkages between processes and outcomes for unique samples (i.e., populations of individuals identified as on the autism spectrum or struggling with attention disorders, or studies that consider connections between attachment quality in early childhood and later conduct disorders and other social or mental health pathologies). Perhaps the largest overarching need this field must address in future work is the current dearth of scholarship on the lifespan nature of normative attachment, across a diversity of populations and sociocultural contexts.

This volume is filled with chapters addressing a variety of populations, relationships, and developmental periods. A full understanding of each of these separate issues will not be possible without considering the organization of the individual's attachment behavioral system in the period under study. In fact, the most powerful design would be to *integrate* normative and differential approaches through the use of developmental pathway models first discussed by Bowlby (1969/1982; based on Waddington, 1957) and supplemented by our growing understanding of the different kinds of relationships that emerge across development.

Chapter 14

Precursors of Attachment Security

R. M. Pasco Fearon
Jay Belsky

Why do some infants develop secure attachments to their primary caregivers, whereas others establish insecure relationships? This is the central question addressed in this chapter. Even though John Bowlby was deeply concerned with the consequences of variation in the quality of early attachments, Mary Ainsworth brought the topic of the origins of individual differences in infant–parent attachment to center stage. Bowlby (e.g., 1944) originally focused his thinking on evolution, species-typical development, and the effects of major separations from parents early in life, whereas Ainsworth (1973) was the first to devote considerable empirical and theoretical energies to the determinants of secure and insecure attachments in normal, nonclinical populations.

Central to Ainsworth's extension of Bowlby's attachment theory was the contention that a sensitive, responsive caregiver is of fundamental importance to the development of a secure attachment bond during the opening years of life. Thus, a caregiver capable of providing security-inducing, sensitive, responsive care understands the child's individual attributes; accepts the child's behavioral proclivities; and is thereby capable of consistently orchestrating harmonious interactions between self and child, especially, though not exclusively, those in which the soothing of distress is involved. In extending Bowlby's theory,

Ainsworth never expressed the belief that the development of the relationship between infant and caregiver was determined entirely by the caregiver. Nevertheless, she was convinced that the developing relationship was not shaped equally by the two participants. Recognizing the greater maturity and power of the adult, Ainsworth attributed disproportionate influence to the adult caregiver.

Nonetheless, the notion of maternal sensitivity championed by Ainsworth in her efforts to account for individual differences in attachment security was defined at least in part in terms of what the child brought to the relationship and, more specifically, how the child behaved at a particular time (i.e., the child's cues, needs, focus of attention, ongoing activities). By definition, then, care that is sensitive and theorized to promote security in the child does not take exactly the same form for all children. Nor does it take the same form across all situations in the case of a particular child.

The first part of this chapter contains a summary of research on the effects of mothering and mother–infant interaction on attachment security—the issues raised most directly by Ainsworth. Related evidence pertaining to the effects of the quality of fathering and of nonparental caregivers' care on attachment to father and to caregivers, respectively, is also considered. In addition, the issue

of whether effects of sensitive care on attachment security are evident outside the Western world is considered, as this is important for understanding how universal or general these developmental processes are.

In the second part of the chapter, the broader social or ecological context of attachment and parental care is considered. An ecological perspective draws attention to the multiple levels of influence affecting care (see Belsky & Jaffee, 2006) and therefore, in principle, affecting attachment security. These influences include the psychological attributes of the mother, her relations with her partner, and the degree to which she has access to other social agents who provide instrumental and emotional support. Thus, whereas the core of attachment theory focuses on the microprocesses of development, emphasizing the daily interactional exchanges between parent and child and the developing internal working model of the child, the ecological/social-contextual perspective highlights the contextual factors and processes likely to influence these microdevelopmental processes.

The Quality of Maternal and Nonmaternal Care

Soon after Ainsworth (1973) first advanced her ideas and evidence of the role of maternal sensitivity in fostering the development of a secure attachment relationship, what might be regarded as a “cottage industry” developed within the field of developmental psychology, seeking to replicate—or refute—her findings. Child temperament was the major focus of those initially seeking to disconfirm Ainsworth’s theory and evidence (Chess & Thomas, 1982; Kagan, 1982), and in this chapter in previous editions (1999 and 2008) it was difficult to consider the role of maternal sensitivity and the quality of maternal care more generally without devoting some attention to the influence of this particular infant characteristic. But the field has moved on from this focus, no doubt because of the absence of evidence—reviewed in earlier editions of this volume—substantiating this claim. In fact, even the proposition that variation in the manifestation of insecurity—resistance versus avoidance—might reflect effects of temperament (Belsky & Rovine, 1987) has not been persuasively supported (Vaughn, Bost, & Van IJzendoorn, 2008). Rather than review the relevant research, we refer the interested reader to Bakermans-

Kranenburg and Van IJzendoorn (2012) and to previous chapters by Belsky and Fearon (2008) and Vaughn and associates (2008) in the preceding edition of this volume (see also Vaughn & Bost, Chapter 10, this volume).

Even if temperament, especially difficult temperament and proneness to distress, has not proven to be a major contributor to attachment security, it would be a mistake to presume that challenges to Ainsworth’s sensitivity hypothesis have been abandoned. As the next subsection makes clear, researchers have now turned to the role of genetics in shaping attachment. We consider this new body of research before considering evidence implicating sensitivity and the quality and nature of care that children receive more generally as an important determinant of attachment security.

The Role of Genes

Two distinct approaches to this issue are considered here, one quantitative-genetic in orientation, relying on twin designs, and the other molecular-genetic in character, focusing on measured genes. A more in-depth treatment of the behavioral genetics of attachment is provided by Bakermans-Kranenburg and Van IJzendoorn, Chapter 8, this volume.

Twin Studies

Four studies assessing infant–mother attachment in samples of monozygotic (MZ) and dizygotic (DZ) twins have proved strikingly similar in their results. In a sample of 157 MZ and DZ twins seen in the Strange Situation at 12 months, Bokhorst and colleagues (2003) found 60% correspondence in MZ twins and 57% in DZ twins. In genetic modeling, 52% of the variance in attachment security within the organized categories was attributable to shared environmental effects, whereas the remainder was estimated to be due to nonshared environment and measurement error. When disorganization was considered, no genetic or shared environmental effects were detected, and all of the variance was attributable to nonshared environment and measurement error. Broadly convergent results have been reported by O’Connor and Croft (2001) in an older sample of preschoolers using the MacArthur modified Strange Situation (see also Ricciuti, 1992, for an early small-scale study yielding comparable findings). More recently, Roisman and Fraley (2008) reported simi-

lar results from a relatively large ($N = 485$) twin study of 2-year-olds, using a shortened version of the observer-reported Attachment Q-Sort (AQS), and found that 53% of the variance in security was attributable to shared environment, 36% to non-shared environment and measurement error, and a nonsignificant 17% to genes. Bucking this trend of limited or no genetic influence is the investigation by Finkel and Matheny (2000), who documented significant genetic effects (25%) and no shared environmental effects on attachment security. This surprising result appeared to be due to the low DZ correspondence (compared to other DZ samples or fraternal siblings) of 48%, rather than a high correspondence among MZ twins (which was 66%). Conceivably, these researchers' reliance on a non-standard separation–reunion procedure originally designed to assess temperament could explain why their results are so different from the other four investigations.

Despite the relatively modest sample sizes of each of these studies, the cumulative picture is quite consistent, suggesting a significant role for shared and nonshared environmental effects and apparently little role for genetics, at least in the low-risk populations studied. This conclusion is buttressed by results from the only genetic study of infant–father attachment, which relied on AQS Security scores derived from mother sorts of infant behavior vis-à-vis the father (Bakermans-Kranenburg, Van IJzendoorn, Bokhorst, & Schuengel, 2004): Genetic modeling revealed that attachment was explained virtually exclusively by shared environmental (59%) and unique environmental (41%) factors. Moreover, these results are consistent with data indicating that the attachment security of infants placed in foster care is predictable from the adult attachment status of the genetically unrelated foster caregiver (Dozier, Stovall, Albus, & Bates, 2001), as well as the fact that infants can show different patterns of attachment to their mothers and fathers (e.g., Steele, Steele, & Fonagy, 1996). The apparent preeminence of the environment—and of the shared environment in particular—is a remarkable confirmation of a key hypothesis of attachment theory.

Molecular Genetics Research

Molecular genetic studies represent an alternative methodology for investigating the role of genes in the development of attachment. Much of this work was stimulated by Lakatos and colleagues' (2000,

2002) groundbreaking investigation linking disorganized attachment with a polymorphism of the *DRD4* dopamine receptor gene (*Exon III 48-bp VNTR*). Twelve of 17 disorganized infants had the 7-repeat allele of this gene (which has been found to confer lower dopamine neurotransmission than the more common 4-repeat allele), compared to 21 of 73 nondisorganized infants. Quite a number of efforts to replicate this genotype–phenotype association have failed to reproduce the finding. Indeed, Bakermans-Kranenburg and Van IJzendoorn's (2007) meta-analysis revealed a weighted effect size for the association of $d = 0.05$ ($N = 542$), which was not significant. And in the time since their report, five additional studies have proven consistent with this early multistudy analysis (Frigerio et al., 2009; Luijk et al., 2011 [involving two independent cohorts]; Raby et al., 2012; Spangler, Johann, Ronai, & Zimmerman, 2009).

Although the association between attachment and the *DRD4* gene has proved unreliable, several other gene variants have been examined in relation to attachment security and insecurity, mostly with respect to gene \times environment ($G \times E$) interactions (but see Spangler et al., 2009, for a genotype–phenotype study). Van IJzendoorn and Bakermans-Kranenburg (2006), for example, found that unresolved loss in mothers ($N = 85$) was more strongly associated with disorganized attachment among *DRD4/7+* infants relative to *DRD4/7-* infants, suggesting greater susceptibility to the effects of unresolved maternal loss in the former. Spangler and colleagues (2009; $N = 106$) examined the *DRD4* gene and parental responsiveness, detecting no $G \times E$ interaction (or main effect of *DRD4*), but they did find (in addition to a genetic main effect) an interaction with the *5-HTTLPR* (serotonin transporter) gene: Infants with less responsive maternal care and the short-form of the *5-HTTLPR* gene were more likely to be disorganized. Similar results were reported by Barry, Kochanska, and Philibert (2008; $N = 88$): Overall insecurity in the Strange Situation (rather than disorganization specifically) was predicted by the combination of low responsiveness and the short-form of the *5-HTTLPR* gene. When examining attachment security at both 12 and 18 months, Raby and colleagues (2012; $N = 154$) failed to find a genetic main effect of *5-HTTLPR* (as did Frigerio et al. [2009] and Barry et al. [2008]) or an interaction between the *5-HTTLPR* gene and responsiveness of maternal care, although it is notable that this study did not include codes for disorganized attachment. Perhaps most important are the results

of a report from Luijk and colleagues (2011) indicating that no genetic main effects or $G \times E$ interactions proved replicable across two large samples, the Dutch Generation R study ($N = 506\text{--}547$) and the U.S. National Institute of Child Health and Development (NICHD) Study of Early Child Care and Youth Development ($N = 478\text{--}522$), especially since all the candidate genes implicated in the attachment literature were considered (*DRD4*, *5-HTTLPR*, two oxytocin receptor genes, and *COMT*), along with their interaction with parental sensitivity in relation to security and disorganization. (Although one genetic main effect—of the *COMT* gene—was significant for disorganization in both samples at the uncorrected 5% level, it would not survive corrections for multiple hypothesis testing.)

A conservative interpretation of all the genetic data reviewed is that environmental effects are well substantiated, but genetic effects are not. It would nevertheless be hasty to exclude the role of genes given the current corpus of evidence. Data from psychiatric genetics clearly indicate that single-gene effects tend to have extremely small, but cumulatively significant, effects on psychopathology (see Kendler, 2013), and the same may prove true for other domains of development, including attachment (see Bakermans-Kranenburg & Van IJzendoorn, Chapter 8, this volume). Larger-scale studies capable of detecting small genetic effects and $G \times E$ interactions will be necessary to address these issues in the future. Furthermore, we lack large-scale twin studies of attachment that are properly powered to detect moderate or small genetic effects on disorganized attachment in particular, which is typically present at relatively low frequencies, especially in low-risk samples. Finally, current research has focused almost exclusively on the first 3 years of life. We cannot assume that attachment security measured in later development will show the same profile of environmental influence as that seen in infants and toddlers. Indeed, a recent relatively large twin study of adolescents ($N = 551$ twin pairs) using a representational measure of attachment, the Child Attachment Interview, found that nearly 40% of the variance in security–insecurity and narrative coherence was attributable to genes, and the influence of the shared environment was estimated to be zero (Fearon, Schmueli-Goetz, Viding, Fonagy, & Plomin, 2014). These striking findings suggest that the causal influences on attachment organization may change with development, perhaps particularly as attachment security shifts from a

predominantly behavioral and relational construct in very early childhood to one that is generalized (not relationship-specific) and representational in middle childhood and beyond. Whether similar patterns of heritability will be observed in adulthood remains to be seen.

The Role of Maternal Care

There can be little doubt, in accord with Ainsworth's (1973) original theorizing and her intensive research on just 26 mother–infant dyads, that variation in observed maternal sensitivity in the first year is linked to security in the Strange Situation. This is revealed in studies of middle-class U.S. (e.g., Braungart-Reiker, Garwood, Powers, & Wang, 2001; Fish & Stifter, 1995 [girls only]; Isabella, 1993; Kochanska, 1998; Teti, Gelfand, Messinger, & Isabella, 1995), Canadian (Pederson & Moran, 1996), and German (Grossmann, Grossmann, Spangler, Suess, & Unzner, 1985) families, as well as economically disadvantaged, often single-parent families (Egeland & Farber, 1984; Krupka, Moran, & Pederson, 1996; Susman-Stillman, Kalkoske, Egeland, & Waldman, 1996). Furthermore, security is associated with prompt responsiveness to distress (Crockenberg, 1981; Del Carmen, Pedersen, Huffman, & Bryan, 1993); moderate appropriate stimulation (e.g., Belsky, Rovine, & Taylor, 1984); and interactional synchrony (Isabella & Belsky, 1991; Isabella, Belsky, & von Eye, 1989), warmth, involvement, and responsiveness (e.g., Bates, Maslin, & Frankel, 1985; NICHD Early Child Care Network, 1997); as well as autonomy support (Bernier, Matte-Gagne, Belanger, & Whipple, 2014) and mutually responsive interactions (e.g., Kochanska, Aksan, & Carlson, 2005). In contrast, insecure-avoidant attachments are related to intrusive, excessively stimulating, controlling interactional styles, and insecure-resistant attachments to an unresponsive, underinvolved approach to caregiving (Belsky et al., 1984; Harel & Scher, 2003; Isabella et al., 1989; Lewis & Fiering, 1989; Malatesta, Grigoryev, Lamb, Albin, & Culver, 1986; Smith & Pederson, 1988; Vondra, Shaw, & Kevinides, 1995).

In addition to such associations from studies using the Strange Situation procedure, similar contemporaneous and time-lagged relations have emerged in North American research using the AQS to assess attachment security (Krupka et al., 1996; Moran, Pederson, Petit, & Krupka, 1992; Pederson et al., 1990; Scholmerich, Fracasso,

Lamb, & Broberg, 1995; note that this latter study used the mother-completed AQS, which appears less valid than those completed by objective raters, see Van IJzendoorn, Vereijken, Bakermans-Kranenburg, & Riksen-Walraven, 2004) and in related research conducted in Japan (Vereijken, Riksen-Walraven, & Kondo-Ikemura, 1997). All this is not to say that there have been no failures to replicate such theoretically anticipated results (e.g., Notaro & Volling, 1999; Schneider-Rosen & Rothbaum, 1993), but rather that the preponderance of evidence is more rather than less consistent with the sensitivity—or at least quality-of-care hypothesis.

It must be noted, however, that the strength of the discerned association between quality of rearing (e.g., sensitivity) and attachment security is not large. De Wolff and Van IJzendoorn (1997), drawing upon data from 66 investigations involving some 4,176 infant–mother dyads, discerned an overall effect size of 0.17 between attachment security and various measures of mothering and of mother–child interaction (e.g., sensitivity, contiguity of maternal response, physical contact, cooperation). These studies collectively produced highly heterogeneous effect sizes, suggesting substantial systematic differences between studies. When the meta-analysis was restricted to only the subset of 30 investigations that measured sensitivity ($n = 1,666$), the effect size was somewhat larger (0.22). And when the 16 studies ($n = 837$) that relied on Ainsworth’s original sensitivity rating scales were considered, the effect size was larger still (0.24)—and was no longer heterogeneous; that is, variation in effect sizes produced by these studies was no greater than would be expected by chance. Nevertheless, effect sizes across investigations that relied upon different operationalizations of mothering and mother–infant interaction were more similar than different. And, moreover, the magnitude of the discerned effects was not influenced (i.e., moderated) by the length of observations of mother–child interaction. Whether one regards the magnitude of the effect of maternal care as weak or moderate, it is indisputable that Ainsworth’s core theoretical proposition linking maternal sensitivity with attachment security has been empirically confirmed (Belsky, 1997).

Four possibilities might account for why attachment security is less well accounted for by maternal sensitivity than many expected. The first is a “technological” gap, in that the quality, intensity, or context of measurement of sensitivity (or indeed attachment) is suboptimal. The fact that

several recent studies using the Maternal Behavior Q-Set have repeatedly found substantially higher associations between sensitivity and attachment than the earlier meta-analytic average lends some credence to this first argument (Behrens, Parker, & Haltigan, 2011; Pederson, Gleason, Moran, & Bento, 1998; Raval et al., 2001; Tarabulsy et al., 2005; see also Atkinson et al., 2005). The evidence that associations between attachment and sensitivity are stronger when the AQS is used to measure security (average $r = .39$, see Van IJzendoorn et al., 2004) may also point to measurement issues, although the fact that the AQS is typically used with older children than the Strange Situation may also be relevant. Although not measuring child attachment security directly, recent findings by Lindhiem, Bernard, and Dozier (2011) make a critical point: When observational measurements of sensitivity were conducted repeatedly—and composited—the average correlation with maternal representations of attachment (measured with the Adult Attachment Interview [AAI]) rose quite dramatically: from $r = .37$ with just one observation, to $r = .46$ with two, $r = .51$ with four, and $r = .54$ with seven combined observations. Measurement error clearly plays a major—and generally underappreciated—role in the strength of association between observations of sensitivity and attachment-related constructs. Furthermore, it is almost certain that measurements of attachment security are noisier than the adult attachment classifications analyzed in this study (e.g., see Pinquart, Feusner, & Ahnert, 2013); hence, the real effects of error on the sensitivity–security association may be even greater than this research might lead us to infer.

The second possibility—a “moderator” gap—as to why quality of caregiving is not as predictive of attachment security as presumed by theory concerns the fact that unidentified variables may affect the sensitivity–attachment link. If this was the case and such moderation were not taken into account, it would diminish the overall meta-analytic average. This gap is addressed later in this chapter, when we discuss the proposition of differential susceptibility to rearing influences. However, it is worth noting that factors other than the child’s susceptibility to rearing influences may also moderate the sensitivity–security association. For example, middle-class samples tend to reveal larger effect sizes than lower socioeconomic status (SES) samples (De Wolff & Van IJzendoorn, 1997; see also Meins et al., 2012). Furthermore, Atkinson and colleagues (2005) have presented sugges-

tive evidence that sensitivity may interact with parental attachment representations—indicating either that sensitive interactions may attenuate, if not eliminate, anticipated effects of parental insecure attachment representations on child–parent attachment organization, or that sensitivity may have differential effects on child security depending on the parent’s representations of attachment. Such possibilities highlight the need to consider the role that parental characteristics may play in the extent to which quality of rearing affects child attachment.

The third and fourth possibilities for why effects of sensitivity emerge as small-to-modest in magnitude are that the most predictive elements of parenting behavior have perhaps not been identified and fall outside the definition of sensitivity (i.e., a “domain” gap), and that other factors unrelated to parental behavior contribute to attachment security and mediate the association (a “third-variable” gap) (Belsky, 2005a). We consider some examples of such possibilities later in this chapter, in the discussion of broader ecological influences on attachment security and when we examine personal/psychological resources of mothers—particularly the constructs of “mind-mindedness” and “reflective functioning.”

In any event, two recent trends are worthy of note. First, some recent evidence suggests that sensitivity may relate more strongly to attachment security when it is restricted to an assessment of the parent’s sensitivity to the child’s distress rather than a broader array of cues (Leerkes, 2011; McElwain & Booth-LaForce, 2006). This is a potentially critical insight because although it certainly was the case that Ainsworth defined sensitivity rather broadly, there are good theoretical reasons for expecting that sensitivity to attachment-related—and thus distress—cues and behaviors should be most causally influential. Having said that, the relatively strong associations between attachment and mutuality/synchrony (i.e., not clearly focused on responsiveness to distress cues) found in meta-analytic work (De Wolff & Van IJzendoorn, 1997) would seem to challenge an overly simplistic acceptance of the sensitivity to distress proposition. Either way, what is clear is that current explanatory frameworks for why some children develop secure and others develop insecure attachments are limited in terms of their power to predict such variation in attachment security.

A second notable trend, which in a sense directs attention in the opposite direction, is that investigators have begun to consider domains of

parenting that are quite different and even perhaps orthogonal to sensitivity. For example, Bernier and colleagues (2014) recently argued that maternal support for exploration and autonomy may influence attachment organization because it supports the “exploration side” of the secure-base concept. Consistent with that claim, these scholars observed that both traditionally defined sensitivity and maternal autonomy support independently predicted attachment security, as assessed using the observer-completed AQS. Furthermore, these researchers found that, collectively, these two dimensions of maternal behavior fully mediated the association between parental representations of attachment and infant security. The finding, though in need of replication, should lead future investigators to expand their measurement focus when trying to capture parenting behaviors that shape the development of attachment security. In any case, it is clear that the quest to elucidate the causal antecedents of attachment is far from over (De Wolff & Van IJzendoorn, 1997).

From Correlational to Experimental Evidence

The modesty of the meta-analytically derived correlation between maternal behavior and attachment security, coupled with the logical possibility that this reliably discerned association could be a product of the effect of infant characteristics—even if not apparently temperament or genotype—on maternal interactive style provides a basis for questioning the causal role of maternal care in fostering security or insecurity. Experimental intervention studies are the most compelling source of evidence about causation. In that regard, Van den Boom’s (1990) study of 100 highly irritable infants provides perhaps the clearest example. Three home visits designed to foster mothers’ “contingent, consistent, and appropriate responses to both positive and negative infant signals” were administered to 50 mothers randomly assigned to an experimental group. The home visitor/intervenor “aimed to enhance mothers’ observational skills . . . [and] assisted mothers to adjust their behaviors to their infant’s [sic] unique cries” (p. 258). Control group mothers were simply observed in interaction with their babies. Importantly, the two groups of mothers were equivalent in terms of maternal behavior prior to the implementation of the intervention.

Impressively, not only did postintervention observations reveal that maternal sensitivity was greater in the experimental group, but results of Strange Situation evaluations 4 months after the termination of the intervention were strongly consistent with predictions derived from attachment theory: Whereas a full 68% (34 of 50) of the infants in the control group were classified as insecure, this was true of only 28% (14 of 50) of the experimental subjects. No doubt these findings resulted from the fact that “experimental mothers respond[ed] to the whole range of infant signals (during post-intervention home observation), whereas control mothers mainly focus[ed] on very negative infant signals” (van den Boom, 1990, p. 256). More specifically, in the insecurity-producing control group,

mildly negative infant behaviors like fussing are ignored for most of the time or are responded to ineffectively. Positively toned attachment behaviors, on the contrary, are ignored for the most part. And infant exploration is either ignored or interfered with. The program mothers’ infants’ negative actions boost maternal positive actions. Maternal anger is not observed. . . . Positive social infant behaviors are also responded to in a positive fashion. And program mothers are attentive to the infant’s exploration, but they do not interfere in the process. (van den Boom, 1990, p. 256)

These findings that chronicle a causal—not just correlational—impact of the quality of maternal care on attachment security are mainly in accord with those of other experimental investigations. In a key meta-analysis on the subject, Bakermans-Kranenburg, Van IJzendoorn, and Juffer (2003) showed that interventions are effective in enhancing maternal sensitivity, and that in particular, short-term interventions (like van den Boom’s [1990]) are the most effective in promoting the development of a secure attachment. Indeed, the combined effect size for 10 studies that sought to promote security by focusing specifically on sensitivity was 0.39 (Bakermans-Kranenburg et al., 2003; for additional discussion of attachment-based interventions, see Berlin, Zeanah, & Lieberman, Chapter 32, this volume).

Parental Behavior and Disorganized Attachment

A related body of work has also sought to illuminate the role, if any, of relational experience in determining whether a child develops a disorganized attachment. Early studies documenting links

between child maltreatment and disorganized attachment—which a recent meta-analysis substantiates (Cyr, Euser, Bakermans-Kranenburg, & Van IJzendoorn, 2010)—gave birth to Main and Hesse’s (1990) hypothesis that fear in the attachment relationship serves as the driving force behind disorganization. Research testing of this proposition provides the clearest example of the need to move beyond sensitivity in seeking to understand the interactional determinants of attachment. This is because at least 10 independent studies have found that disorganized attachment is associated with disturbances in parenting behavior that may be considered frightening to the infant (rather than insensitive) or in other ways atypical (Abrams, Rifkin, & Hesse, 2006; Goldberg, Benoit, Blokland, & Madigan, 2003; Kelly, Grienerberger, & Slade, 2005; Lyons-Ruth, Bronfman, & Parsons, 1999; Madigan et al., 2011; Madigan, Moran, & Pederson, 2006; Schuengel, Bakermans-Kranenburg, & Van IJzendoorn, 1999; Tomlinson, Cooper, & Murray, 2005; True, Pisani, & Oumar, 2001). In fact, in a 2006 meta-analytic review of the evidence, Madigan and colleagues (2006) revealed the overall association between anomalous parental behavior and disorganized attachment to be equivalent to a correlation of $r = .34$. Intriguingly, meta-analytic evidence also indicates that maternal sensitivity is only very weakly associated with disorganized attachment (Van IJzendoorn, Schuengel, & Bakermans-Kranenburg, 1999), a result that also has emerged in more recent work focused on very preterm/very low birthweight infants (Wolke, Eryigit-Madzwamuse, & Gutbrod, 2014). In fact, three studies chronicle the effects of frightening/atypical maternal behavior on disorganization even when maternal sensitivity is statistically controlled (Moran, Forbes, Evans, Tarabulsky, & Madigan, 2008; Schuengel et al., 1999; True et al., 2001).

A number of researchers have sought to broaden the domain of inquiry from an emphasis on frightening/frightened/dissociative (FR) behavior to disconnected and extremely insensitive parenting (Out, Bakermans-Kranenburg, & Van IJzendoorn, 2009), and to disturbances in parental affective communication (Lyons-Ruth et al., 1999). The latter category subsumes FR behavior but also includes less obviously frightening atypical maternal behavior, such as affective communication errors (e.g., contradictory cues), role confusion (e.g., role reversal or sexualized behavior), and withdrawal (creating physical or verbal distance from the infant; see Lyons-Ruth et

al., 1999). Empirically, both of these broader sets of maternal behaviors have been found to be associated with disorganized attachment (Abrams et al., 2006; Goldberg et al., 2003; Lyons-Ruth et al., 1999 [see also Lyons-Ruth, Yellin, Melnick, & Atwood, 2005, on the same sample]; Madigan et al., 2006; Out et al., 2009; see Lyons-Ruth & Jacobvitz, Chapter 29, this volume, for a review of studies of affective communication errors and disorganization).

What currently cannot be discerned from this body of research is whether disrupted affective communication and disconnected or extremely insensitive parenting contribute additional predictive power over and above that accounted for by FR behavior because little research has evaluated this possibility; nor, indeed, has there been any examination of whether there is variable discriminative power within the domains of FR behavior itself. There are hints in the literature that dissociative behavior may be particularly important (Abrams et al., 2006; Madigan et al., 2006; Schuengel et al., 1999) but this is currently based on a limited and mixed evidence base. Quite apart from whether available measures of maternal behavior have greater or lesser predictive power, a critical question that no correlational study has addressed directly is whether any of the associations detected are truly causal, though one investigation has linked *change* in atypical maternal behavior with *change* in attachment disorganization from 12 to 24 months (Forbes, Evans, Moran, & Pederson, 2007). Interestingly, Juffer, Bakermans-Kranenburg, and Van IJzendoorn (2005) presented a reanalysis of data from their earlier sensitivity-based intervention study, reporting that the intervention reduced disorganized attachment. Intriguingly, despite the focus of the intervention, the intervention effect on disorganization was not mediated by changes in sensitivity. The investigators speculated that the intervention may have indirectly reduced FR behavior, perhaps by increasing parents' attention to and awareness of their child's behavior and the impact of their own behavior on the child. In any event, the positive impact of sensitivity-based interventions on disorganized attachment has been confirmed in a meta-analysis of 15 intervention studies, ones not originally designed to reduce FR behavior (Bakermans-Kranenburg, Van IJzendoorn, & Juffer, 2005). Notable, too, are the positive results of the Bernard and colleagues (2012) and the Moss and colleagues (2011) intervention efforts designed to lower rates of disorganized attachment and increase those of secure attachment

in maltreated children by fostering nurturing parental care. Collectively, these results indicate that disorganization is susceptible to environmental remediation, but how these changes take place is an important remaining question for clinicians and scientists alike.

Cultural Variation

Cross-cultural variation in parenting can shed further light on the nature of the interactional antecedents of attachment security (see also Mesman, Van IJzendoorn, & Sagi-Schwartz, Chapter 37, this volume). One might wonder, for example, whether the association between sensitivity and attachment emerges in non-U.S. or non-European samples, where cultural norms for raising infants may be quite different. To address this issue, Posada, Carbonell, Alzate, and Plata (2004) conducted an intensive investigation of patterns of parenting behavior in 30 Colombian families. Data were gathered via standardized assessments of maternal sensitivity (using the Maternal Behavior Q-Sort [MBQS]) and open-ended ethnographic transcripts of parenting behavior. There was considerable correspondence between the domains of parenting identified through ethnographical analysis and those originally developed by Ainsworth (1973) and refined by Pederson and colleagues (1990). Furthermore, both maternal sensitivity identified by the MBQS and the ethnographically derived parenting parallel to sensitivity correlated significantly with infant attachment security as measured with the AQS. Similar results were obtained by Zevalkink, Riksen-Walraven, and Van Lieshout (1999) with a Sudanese-Indonesian sample and by Peterson and colleagues (2001) in a study of Ugandan mothers and infants. Further evidence demonstrating the expected predictive associations between sensitivity and attachment is provided by Ding, Xiu, Wang, Li, and Wang (2012) in a sample of Chinese dyads and by Jin, Jacobvitz, Hazen, and Jung (2012) in a sample from South Korea. Tomlinson and colleagues (2005) also detected robust associations between attachment and various indices of parenting quality (sensitivity, intrusiveness, coerciveness, remoteness) in a sample of extremely impoverished black South African mother-infant dyads. These authors were also able to show that disorganized attachment was associated with a modified measure of maternal FR behavior administered when the infants were 2 months of age. True and colleagues (2001) further found infant disorganization to be correlated with observed maternal FR behavior in

a sample of Malian infants and mothers, whereas broader measures of sensitivity were only marginally correlated with security. Studies also tend to chronicle associations between sensitivity and attachment in samples of differing ethnicity within Western populations (e.g., Candelaria, Teti, & Black, 2011; Dexter, Wong, Stacks, Beeghly, & Barnett, 2013). Notably, using data from the NICHD Study of Early Child Care (Bakermans-Kranenburg, Van IJzendoorn, & Kroonenburg, 2004) examined whether patterns of association between attachment and sensitivity were similar between European American and African American families. The associations proved to be highly consistent across groups, and the significantly lower mean attachment security score (measured via the observer-reported AQS) in the African American group was fully accounted for by differences in SES.

Clearly, then, there is reasonably consistent evidence that the theoretically anticipated relation between quality of parenting and attachment security is observed across a wide range of cultural contexts, which is not to say that culture does not matter. Consider in this regard Carlson and Harwood's (2003) evidence that Puerto Rican mothers used more physically controlling tactics in caregiving than European American mothers, and that more of such behavior was associated with secure attachment in the Puerto Rican group but with greater avoidance in European American infants (see also Huang, Lewin, Mitchell, & Zhang, 2012). Although the small sample size and imperfect matching of the two groups limit interpretation of these findings, they do underscore the need for additional research on culture-specific associations between parenting and attachment. A recent book on the cultural anthropology of attachment provides a number of other intriguing examples of apparently marked differences in childrearing practices, which, while generally not strongly contesting the main thrust of current attachment theory, may help to refine our understanding of the culturally variable and universal aspects of parental behavior involved in the development of secure and insecure attachment (Otto & Keller, 2014).

Nonmaternal Care

Even though attachment theory is often cast as a theory of the infant–*mother* relationship, most attachment scholars consider attachment to be involved in emotionally close child–*adult* rela-

tionships more generally. Indeed, Bowlby made it clear that in writing about the mother, he was assuming that mothers are usually the primary caregivers. If, as is now widely recognized, infants and young children can establish relationships with more than a single individual (neither Bowlby nor Ainsworth argued otherwise), a theoretically important question is whether the interactional processes highlighted as important to the development of secure relationships with mothers also operate with other adults. The few available studies of fathers and of nonparental caregivers indicate that this is indeed the case.

Infant–Father Attachment

In fact, even though the majority of investigations that have examined the relation between quality of paternal care and infant–father attachment security have individually failed to document a significant effect of fathering on attachment security (e.g., Belsky, 1983; Braungart-Reiker et al., 2001; Schneider-Rosen & Rothbaum, 1993; Volling & Belsky, 1992), a different picture emerges when the results of studies are subjected to meta-analysis. The most recent meta-analysis of 16 studies ($N = 1,355$) found an average, highly significant, correlation of $r = .12$, which was homogeneous and showed little sign of publication bias (Lucassen et al., 2011). The association, though robust, is clearly smaller than that generally found for mothers, although whether methodological or substantive factors account for this difference is unclear; this is clearly a topic warranting more research in the future. One recent report calls attention to the potential utility of taking into account quantity of fathering (i.e., paternal involvement) when evaluating effects of quality of fathering (i.e., sensitivity). Brown, Mangelsdorf, and Neff (2012) found that the anticipated adverse effect of low sensitivity was attenuated when father involvement was high. Indeed, it was when sensitivity and involvement were both low that security vis-à-vis the father was lowest.

Infant–Caregiver Attachment

Ahnert, Pinquart, and Lamb's (2006) meta-analysis of 40 investigations involving almost 3,000 children (average age = 29.6 months) reveals a great deal about the security of children's relationships with nonparental caregivers. First, attachments to nonparental providers were less likely to be secure than attachments to parents

(in studies that measured both) when assessed by means of the Strange Situation, but equally secure attachments were more likely when Q-sort methods were used. Second, the security of children's relationships with their mothers and fathers was significantly related to the security of their attachment to their care providers. Third, secure attachment to caregivers was more likely in home-based than in center-based care, more likely for girls than for boys, and more likely when children had been with particular caregivers for longer periods. The fact that secure attachments to caregivers were more likely to be detected in older than in newer studies across the quarter century of research covered by the meta-analysis suggests that this trend may be the result of the ever-increasing emphasis on education (i.e., literacy, numeracy) in child care, at the expense of emotional development.

Most important from the standpoint of the current chapter was evidence addressing the influence of caregiver sensitivity on security of attachment to caregiver. Making a distinction between sensitivity to individual children (as always investigated in the case of parents) and sensitivity to a group of children, Ahnert and colleagues (2006) found that setting mattered: Whereas care providers' sensitivity to individual children predicted attachment security in the small groups that characterize home-based settings (and more so when the number of children being cared for was smaller), sensitivity to the group as a whole best predicted security of attachment to caregivers in larger groups (i.e., centers), though individual sensitivity was also related to security.

Evidence from an intervention study suggests, at least in the case of home-based care, that the relations detected in the meta-analysis are causal. When Galinsky, Howes, and Kontos (1995) improved the care of home-based caregivers via a training program, security of infant-provider attachments improved. Unfortunately, no such research has been carried out in groups to document either indisputably causal relations or differential effects of individual versus group sensitivity in the development of secure attachment to care provider. These comments notwithstanding, the evidence reviewed suggests that relationship processes somewhat similar to those delineated in studies of parenting appear relevant to the development of secure relationships with others with whom a child is expected to develop a close, affectional bond. (See Howes & Spieker, Chapter 15, this volume, for additional discussion.)

Summary of the Evidence

When considered in its entirety, the evidence summarized in this section pertaining to mothering, fathering, and the care provided by some other consistent caregiver offers support for Ainsworth's (1973) extension of Bowlby's theory of attachment. Individual differences in attachment security, whether measured with the laboratory-based Strange Situation or the home-based AQS procedure, are systematically related to the quality of the care that an infant or toddler experiences with a particular caregiver; this is true of both the role of sensitivity in fostering security and of FR or atypical parental behavior in fostering disorganization. What makes the former (and some of the latter) evidence particularly convincing is that it is both correlational and experimental in nature; longitudinal as well as cross-sectional; apparently cross-culturally generalizable; and derived from studies of fathers and child care providers, as well as mothers. Finally, the evidence currently indicates that genes and temperament play a rather limited role in the development of attachment security at least in early childhood.

Differential Susceptibility

However theoretically important the data linking adult-infant interaction to attachment security may be, the fact remains that associations between rearing and attachment are only modest in magnitude. Recent evolutionary theorizing highlights one possible reason—referred to above as a “moderator” gap—for this less than strong association. Moreover, intriguing evidence is offered that temperament may be important to attachment in ways that have not heretofore been appreciated.

Elsewhere, Belsky (1997; Belsky & Pluess, 2013) notes that because the future is uncertain, it makes biological sense for children to vary, particularly within a family, in their susceptibility to rearing influence (see also Ellis, Boyce, Belsky, Bakermans-Kranenburg, & Van IJzendoorn, 2011). If all children are equally influenced by parental care, then there may be—or would have been in the environment of evolutionary adaptedness—the risk that when the future does not prove consistent with parents' (not necessarily conscious) expectations, presumed to guide (often in unconscious ways) their rearing practices, then all children within a family may be led into a literal or at least a reproductive dead end.

Perhaps one way that natural selection has reduced the likelihood of this pitfall in the course of shaping human development is by increasing the probability that parents will conceive children who vary in their tendencies to be influenced by their rearing experiences, with some being more and others less susceptible. *Fixed strategists* may develop along lines established principally by their biological makeup, whereas *plastic strategists* may navigate the ship of development according to prevailing (rearing) winds (in line with general evolutionary terminology, the term *strategist* in no way implies conscious intent on the part of a child).

If differential susceptibility to rearing represents an evolved characteristic of our species, then research efforts failing to distinguish infants/children along these lines may both over- and underestimate effects of rearing, including studies of rearing influences on attachment security. Research may overestimate rearing influences for fixed strategists and underestimate them for plastic strategists. Evidence (both correlational and experimental) suggest that highly negatively emotional infants/toddlers may be especially susceptible to rearing influence, especially with regard to developmental outcomes related to self-control and socioemotional development (for a review, see Belsky, 2005b); this is also true in the case of studies of parenting and attachment. Consider first the fact that the intervention study documenting perhaps the largest indisputably causal effect of rearing on attachment was carried out on a sample preselected for being highly negatively emotional (van den Boom, 1994). Consider next the fact that when Klein-Velderman, Bakermans-Kranenburg, Juffer, and Van IJzendoorn (2006) formally tested Belsky's (1997) differential susceptibility hypothesis by means of their experimental intervention, they found support for it: Attachment security proved most susceptible to intervention-induced changes in maternal sensitivity among infants who were highly negative. Although a second sensitivity trial failed to replicate this effect (Van Zeijl et al., 2006), a third, more recent intervention trial in the United States did (Cassidy, Woodhouse, Sherman, Stupica, & Lejuez, 2011).

In light of these intriguing results, it is interesting to note that studies of $G \times E$ interaction have generally failed to find genetic variants that explain differential susceptibility effects related to attachment, and remarkably few studies have reported on sensitivity \times temperament interactions in nonexperimental studies in this domain. It may be that such observational studies have generally

failed to find such interactions because of constraints on the range of sensitivity (or temperament) often observed in normative samples, and because sensitivity provides only a partial picture of the key interactional determinants of attachment security. Both these limitations may severely limit statistical power. Intervention studies, by targeting at-risk groups and by experimentally changing sensitivity, may yield greater power to detect differential susceptibility effects and may also induce changes beyond that captured by sensitivity. There is a need for more attachment-focused interventions of sufficient scale and mechanistic focus to deepen our understanding of the causal influences on attachment and the populations of infants (or parents) most amenable to effective intervention.

For further consideration of the contribution of evolutionary theory to thinking about attachment and human development see Simpson and Belsky (Chapter 5, this volume).

Psychological and Social-Contextual Determinants

Having considered the interactional determinants of attachment security, we now consider the role of more "distal" factors implicated by an ecological perspective: in particular, parental personality and related psychological attributes, excluding parental state of mind regarding attachment, which is addressed in another chapter in this volume (see Hesse, Chapter 26), and the marital/partner relationship.

Parental Psychological Resources and Personality

Because the provision of security-inducing sensitive care requires the accurate reading of, and timely and empathic responding to a child's affective and behavioral cues, there are theoretical grounds for expecting the caregiver's psychological attributes to be related to the child's security of attachment. Moreover, much theory and evidence indicate that both mothers' and fathers' psychological health and well-being affect the quality of care that parents provide (see Belsky & Jaffee, 2006). Evidence from both normal and clinical samples underscores the importance of parental psychological makeup vis-à-vis infant attachment security.

Nonselected Samples

Cross-sectional studies and longitudinal ones (in which personality is measured prior to attachment security) indicate that in nonselected populations, secure attachment relationships are more likely to develop when mothers are psychologically healthy. Maslin and Bates (1983) found, for example, that mothers of secure infants scored higher than mothers of insecure infants on a series of personality subscales measuring nurturance, understanding, autonomy, inquisitiveness, and dependence, and lower on a subscale assessing aggressiveness. Subsequently, Del Carmen and colleagues (1993) reported that mothers who scored higher on prenatal anxiety were more likely than their lower-scoring counterparts to have insecure 1-year-olds, and O'Connor (1997) observed that mothers of secure infants were likely to describe themselves as self-confident, independent, cheerful, adaptable, and affectionate. In the largest study to date, involving more than 1,100 infants, maternal personality was assessed when infants were 1 month of age, and it was found that mothers of infants classified as secure at age 15 months scored higher on a composite index of psychological adjustment (Agreeableness + Extraversion – Neuroticism – Depression) than mothers of insecure infants (NICHD Early Child Care Network, 1997). Atkinson and colleagues' (2000) meta-analysis revealed, moreover, that across 13 studies, maternal stress was significantly associated with attachment insecurity (mean effect size = 0.19). It is notable that findings like these are not restricted to economically advantaged families, but also emerge in research on high-risk, low-SES households (Jacobson & Frye, 1991; Sims, Hans, & Cox, 1996), as well as in countries outside North America (Scher & Maysseless, 2000).

Not all relevant investigations, however, provide evidence of statistically significant associations between parental personality and attachment security (e.g., Belsky, Rosenberger, & Crnic, 1995; Levitt, Weber, & Clark, 1986; Zeanah et al., 1993). Perhaps more noteworthy, though, is the lack of any evidence indicating that parents of secure infants are *less* psychologically healthy than other parents.

In addition to focusing on maternal personality and psychological distress, research on attachment has considered other aspects of maternal psychological functioning in an effort to better understand what Van IJzendoorn (1995) has labeled the *transmission gap*—the fact that measured

sensitivity does not fully account for the link, as some anticipated it might, between a mother's own state of mind regarding attachment and infant attachment security. Meins, Fernyhough, Fradley, and Tuckey (2001, p. 638) have focused on *mind-mindedness*, which they define as a mother's readiness "to treat her infant as an individual with a mind, rather than merely as a creature with needs that must be satisfied." Support for their hypothesis that mind-mindedness contributes to attachment security comes from work showing that mothers of secure infants are more likely than mothers of insecure infants to make appropriate mind-minded comments when interacting with their infants, an association now multiply replicated (Laranjo, Bernier, & Meins, 2008; Lundy, 2003; Meins et al., 2001, 2012). Meins and colleagues (2001) also found that the effect of mind-mindedness was independent of the significant contribution of maternal sensitivity to the prediction of attachment security, though it has not yet been reported that this fills the "transmission gap." Slade, Grienberger, Bernbach, Levy, and Locker (2005) reported similar results upon measuring a construct seemingly related to mind-mindedness labeled *reflective functioning* (RF; Fonagy, Steele, Moran, Steele, & Higgitt, 1991), even showing in a pilot study that it mediates some of the effect of adult attachment on infant attachment. Stacks and colleagues (2014) also recently found RF to be predictive of attachment security, an effect partially mediated by maternal sensitivity and negativity. Oppenheim, Koren-Karie, and Sagi (2001), examining a different but closely related construct, found that mothers' insightfulness when discussing their children, particularly coherence, richness, and insight regarding the children's thoughts, feelings, and motives, is associated with secure attachment. Collectively, these studies provide compelling evidence that parental personal characteristics related to the capacity to think coherently and insightfully about the child's feelings and thoughts may be an important factor in determining the security of the child-parent attachment relationship, albeit via parenting behaviors that themselves remain in need of better identification and measurement.

Clinical Samples

Depression in its various manifestations—unipolar and bipolar—is the clinical disorder most often studied in relation to attachment security. On

the basis of evidence linking both unresponsive/detached and intrusive/rejecting mothering with maternal depression (see Belsky & Jaffee, 2006, for a review), there are strong grounds for expecting children of depressed mothers to be at heightened risk of insecure attachment. Perusal of the available evidence reveals seemingly inconsistent findings, however. Whereas some research fails to find the expected significant association between maternal depression and elevated rates of insecurity (Frankel, Maslin-Cole, & Harmon, 1991; Lyons-Ruth, Zoll, Connell, & Grunebaum, 1986; Sameroff, Seifer, & Zax, 1982; Stacks et al., 2014; Tharner et al., 2013), other investigations do document such a link (Campbell, Cohn, Meyers, Ross, & Flanagan, 1993; D'Angelo, 1986; Das Eiden & Leonard, 1996; DeMulder & Radke-Yarrow, 1991; Gaensbauer, Harmon, Cytryn, & McKnew, 1984; Gravener et al., 2012; Hayes, Goodman, & Carlson, 2013; Hopkins, Guze, & Lavigne, 2013; Lyons-Ruth, 1988; Murray, Fiori-Cowley, Hooper, & Cooper, 1996; Radke-Yarrow, 1991; Radke-Yarrow, Cummings, Kuczynski, & Chapman, 1985; Spieker & Booth, 1988; Teti et al., 1995; Tomlinson et al., 2005).

Martins and Gaffan (2000) conducted a meta-analysis of seven studies that compared rates of attachment insecurity in samples of mothers with a clinical diagnosis of unipolar depression and nondepressed controls. They statistically documented significant variability across studies in the rates of infant–mother attachment insecurity associated with depression. When one study outlier was removed, significantly higher levels of insecurity emerged in depressed samples than controls—although when another outlying sample was removed, this effect was diminished to non-significance. For a homogeneous set of studies that broadly found an association with attachment, rates of infant disorganization and avoidance were significantly elevated in depressed populations, but rates of resistance were not.

In a broader meta-analysis of depression and attachment that included 15 studies of clinical and nonclinical samples, Atkinson and colleagues (2000) discerned a significant overall association between depression and attachment (effect size $r = 0.18$), with clinical samples yielding a stronger effect size than nonclinical ones (0.27 vs. 0.09). Like Martins and Gaffan (2000), Atkinson and colleagues also noted significant variability within the group of clinical samples, but they could detect no reliable predictor of effect size. Importantly, further meta-analytic work by Van IJzendoorn and

colleagues (1999) indicated that in nonclinical samples, maternal depressive symptoms may have a rather limited association with disorganized attachment, with the overall meta-analytic correlation being $r = -.01$, compared to $r = .13$ in clinical samples.

In summary, the relation between depression and insecurity and, to a lesser extent, disorganization emerges repeatedly, though not in every study, suggesting that it is likely to be dependent upon a variety of factors. Some work raises the prospect that in addition to whether a sample comprises clinical or nonclinical cases, parental attachment security (McMahon, Barnett, Kowalenko, & Tennant, 2006) and degree of exposure to maternal depression may matter for the infant (i.e., chronicity of depression), though this latter prospect was not substantiated in the Atkinson and colleagues (2000) meta-analysis. In any event, evidence linking depression with insecurity and/or disorganization is likely to be driven by the effect of depression on the quality of care that mothers provide, as it is presumably when sensitive behavior is disrupted or FR behavior is manifested that links would be expected to emerge. This analysis is consistent with the mediational thinking informing this entire chapter, which stipulates that even though maternal psychological well-being, as well as a the mother's marital/couple relationship and social support, may directly affect attachment insecurity (through some unspecified process), most of the effect of such distal factors will likely flow through their impact on the quality of care the mother actually provides. Perhaps the best evidence of such a mediational process involving maternal psychological well-being comes from a recent report addressing parental depressive symptoms in relation to attachment security measured with the AQS in a large ($N = 796$) sample of 4-year-olds. It revealed multiple mediating pathways—and most notably ones involving observed insensitivity of interactions and self-reported hostile–coercive parenting (Hopkins et al., 2013; see also Benn, 1986).

The Marital/Couple Relationship

An abundance of evidence indicates that a supportive relationship with a spouse or partner during the infancy and toddler years is correlated with the very kinds of parenting theorized (and found) to predict attachment security (e.g., Tarabulsy et al., 2005; Tomlinson et al., 2005; for narrative reviews, see Belsky & Jaffee, 2006, and Grych, 2002;

for a meta-analytic review, see Krishnakumar & Buehler, 2000). Given data linking relationship quality with many of the aspects of parenting found to be predictive of attachment security (De Wolff & Van IJzendoorn, 1997), there are strong grounds to expect a relation between marital/couple functioning and infant–parent attachment security. The fact that a mediational perspective leads to such a prediction does not preclude the possibility that relationship quality may affect attachment security directly rather than exclusively via parenting-mediated processes. Not only does Davies and Cummings's (1994) emotional security hypothesis lead to such a prediction, but Owen and Cox's (1997) failure to find evidence of a parent-mediated linkage is also consistent with it. Especially in the case of overt conflict, it is not difficult to imagine how exposure to such aversive interactions between mother and father could foster insecurity directly.

Available evidence is consistent with both mediational and direct-effect theorizing. That is, children growing up with parents who have better functioning couple relationships are more likely to develop secure attachments than those growing up in households where parents are less happy in their relationships. Such results emerge from cross-sectional studies carried out in the United States (Crnic, Greenberg, & Slough, 1986; Goldberg & Easterbrooks, 1984; Howes & Markman, 1989; Jacobson & Frye, 1991; Lindsey, Caldera, & Tankersley, 2009) and in Japan (Durrett, Otaki, & Richards, 1984). Moreover, in work with poor African American mothers and infants, Sims and colleagues (1996) found that when fathers were physically violent with mothers, infants were more likely to be insecurely attached to their mothers.

More important than these results from cross-sectional research are those from several longitudinal studies. In one such investigation, Howes and Markman (1989) found that wives who prenatally reported higher levels of marital satisfaction and lower levels of spousal conflict had children who scored higher on the AQS 1–3 years later. Tracking similar middle-class families across a somewhat shorter time period, Lewis, Owen, and Cox (1988) reported that 1-year-old daughters (but not sons) were more likely to be securely attached to their mothers when marriages were more harmonious during pregnancy. Subsequently, Teti and colleagues (1995) showed that greater marital harmony before a second child was born predicted greater security (via the observer-rated AQS) on the part of the firstborn both in the

last trimester of the mother's pregnancy and up to 2 months following the birth of the younger sibling. In related work, Owen and Cox (1997) found that more marital conflict (observed prenatally and at 3 months postpartum) predicted less secure infant–father attachments and greater disorganization in infant–mother relationships (assessed at 12 months), even after researchers controlled for each parent's psychological maturity. Such findings seem consistent with those reported by Belsky and Isabella (1988), indicating that relationship quality declines more precipitously across the transition to parenthood in the case of infants subsequently classified as insecurely attached to their mothers. Also noteworthy is Spieker's (1988; Spieker & Booth, 1988) research on high-risk mother–infant dyads, showing that the lowest levels of spousal support measured prenatally and at 3 months postpartum characterize the marriages in families in which infants develop disorganized attachments. Especially important given mediational thinking that links distal factors with attachment security is evidence that insecure attachment and reciprocity of parent–child interactions may mediate the association between early marital distress and the child's later peer relationships (Lindsey et al., 2009).

Despite the seeming persuasiveness of the cross-sectional and longitudinal data, it would be a mistake to cite only the aforementioned research and leave the impression that all studies of marital/couple relationships and attachment present such positive and statistically significant results. Not only have a number of investigations failed to find a significant association between some index of relationship quality and infant–parent attachment security (Belsky, 1996; Belsky et al., 1995; Das Eiden & Leonard, 1996; Harrison & Ungerer, 2002; Levitt et al., 1986; Teti, Nakasawa, Das, & Wirth, 1991; Wong, Mangelsdorf, Brown, Neff, & Schoppe-Sullivan, 2009; Zeanah et al., 1993) but one study of an unusual sample—Japanese mothers living in the United States due to their husbands' employment—also produced results showing higher levels of marital quality to be associated with less AQS-rated security (Nakasawa, Teti, & Lamb, 1992).

A number of studies draw attention to the potential importance of indirect effects mediating between parental relationship quality and child attachment, which may help account for the fact that not all studies consistently show the predicted association. In one illuminating piece of work, Isabella (1994) found that even though no direct

relation between marital quality (measured prenatally) and attachment security (at 1 year) could be discerned, an indirect pathway of influence did appear to exist, mediated by maternal role satisfaction. Whereas the work of Isabella underscores an indirect (and not typically studied) process by which relationship quality might affect the infant–mother attachment bond, work by Das Eiden, Teti, and Corns (1993) draws attention to the need to study relationship quality in context, and to consider moderators as well as mediators. Although Das Eiden and colleagues found that higher levels of marital quality were related to higher levels of security, as measured via the AQS, further analyses revealed that this relation was restricted to families in which mothers were classified as insecure on the AAI. Also illustrating interactive mechanisms, Finger, Hans, Bernstein, and Cox (2009) studied a group of poor, urban African American mothers, fathers, and their infants. The mothers of disorganized infants reported less father support, and more mother–father conflict, and showed less sensitive and more problematic (i.e., harsh, or passively withdrawn) parenting. Notably, disorganized attachment was particularly prevalent among non-coresiding families that experienced high levels of conflict. These effects were not robustly mediated by parenting, although insensitive and problematic parenting was correlated with mother–father conflict. In a large-scale study of 4-year-olds, using the observer-completed AQS, Hopkins and colleagues (2013) revealed multiple pathways mediating marital conflict and attachment security, particularly via maternal depression and self-reported hostile/coercive parenting behavior. Similarly, Dickstein, Seifer, and Albus (2009) found that couple relationship quality indirectly influenced attachment via the pattern of family interactions and overall family functioning (see also Holland & McElwain, 2013, for similar findings regarding coparenting as a mediator of the marital quality–attachment association). What all these data indicate, in conclusion, is that for a full understanding of the relationship’s impact on the development of secure or insecure attachment bonds, additional information about family context and family processes is useful.

One final empirical observation about interparental relations and attachment security merits attention—the potential effects of custody and visitation on attachment in separated families (Lamb & Kelly, 2001). Simply put, how does overnight visitation—typically with noncustodial fathers—affect early attachment, especially with

the mother? One longitudinal study of high-risk families that has addressed this issue empirically found that “frequent overnights were significantly associated with attachment insecurity among infants” (Tornello et al., 2013, p. 871). Further work is clearly needed to verify these findings.

Integration and Conclusions

Evidence considered in the first part of this chapter documented the role played by the quality of maternal and nonmaternal care in fostering secure and insecure attachments to mothers and fathers/other caregivers, respectively, as well as the apparent influence of FR and atypical maternal behavior on attachment disorganization in both Western and non-Western cultural contexts. Importantly, the evidence pertaining to infant–mother attachment security is experimental—and thereby causal—as well as correlational in nature. Also considered was the possibility that effect sizes may be modest because children may vary in their susceptibility to rearing influence, with high levels of negative emotionality perhaps demarcating infants maximally susceptible to such influence. Since the version of this chapter in the previous edition, two key trends have emerged in the literature: First, questions regarding the possibility that specific genes may be implicated in the development of attachment—alone or in interaction with the caregiving environment—have not been borne out by the weight of more, and larger, studies. Recent work continues to attest to the importance of the environment in the development of attachment, as Ainsworth would have predicted. Second, researchers have highlighted the potential importance of shifting the focus of inquiry regarding the interactional determinants of attachment beyond sensitivity, broadening out in some cases (e.g., Bernier et al., 2014), and narrowing down in others (e.g., Leerkes, 2011). Our view of the state of play of the field is that measurement issues (domains of parental behavior, contexts of observation, age-to-age changes in influential parental behaviors, and measurement unreliability) will be critically important if we are to move toward a more comprehensive understanding of the interactional determinants of attachment. Crucially, sophisticated models explaining precisely how parental behavior influences the organization of attachment are largely lacking, and have not moved much in recent years, beyond the rather

general internal working models concept. These are critical challenges for the coming decades of attachment research.

In the second half of this chapter, we focused on determinants of attachment suggested by an ecological perspective. Central to the discussion of psychological and contextual factors is the assumption that so-called “distal” influences—be they less distant (e.g., personality) or more distant (e.g., the marital relationship)—exert most of their effects by influencing more proximal processes of parent–child interaction. Although ample evidence provides grounds for concluding that all of the factors we have considered play a role in shaping the development of a secure or insecure attachment bond, inconsistency in the evidence has been repeatedly and purposefully highlighted. Up to this point, however, these factors have themselves not been placed “in context.” By organizing the second part of the chapter around various factors, even while emphasizing mediational processes of influence, we have run the risk of leaving the impression that these sources of influence on the parent–child relationship, and thus on the child’s attachment to his or her parent, operate in isolation. Nothing could be further from the truth.

Theory and research draw attention to the need simultaneously to consider stresses and supports (Belsky, 1984; Belsky & Isabella, 1988; Belsky & Jaffee, 2006)—or, in the terms of developmental psychopathology, risk and protective factors (Cicchetti, 1983; Sroufe & Rutter, 1984). Central to both of these theoretical orientations are the postulates (1) that risks can be balanced by strengths; and (2) that risks of problematical developmental outcomes, including attachment insecurity, are more likely to be realized as risk factors accumulate and are not balanced by supports or compensatory factors. Consider in this regard, Belsky and Isabella’s (1988) finding that the more indications that a family and a specific infant–parent relationship were “at risk”—due to lower levels of parental psychological adjustment, poorer marital/couple relationship quality, more negative and less positive infant temperament, less social support, more work–family stress, and lower SES—the more likely infant–mother and infant–father relationships were to be insecure (Belsky, 1996; Belsky et al., 1995; see also Scher & Mayseless, 2000). Thus, not only do processes of mediation need to be central to our understanding of the origins of individual differences in attachment (distal factors → parent–child interaction → attachment security), but so too do moderational

ones because the impact of one source of influence is highly likely to be contingent on another. As Bronfenbrenner (1979, p. 38) so astutely noted in regard to the ecology of human development, and thus with respect to the etiology of secure and insecure infant–parent attachment bonds, “the principal main effects are likely to be interactions.”

Chapter 15

Attachment Relationships in the Context of Multiple Caregivers

Carollee Howes
Susan Spieker

In his early writings, Bowlby (1969/1982) proposed that a child develops a hierarchy of attachment relationships—usually first with the mother as the primary caregiver. In 1967, Ainsworth wrote that “nearly all the babies in this sample who became attached to their mothers during the period spanned by our observations became attached also to some other familiar figure—father, grandmother, or other adult in the household, or to an older sibling” (p. 315). The Ainsworth sample comprised Ghanda infants in East Africa. Ainsworth’s next major work was the Baltimore study of child–mother attachment (Ainsworth, Blehar, Waters, & Wall, 1978). Although this work was concerned with patterns of infant–mother attachment relationships, Ainsworth and colleagues (1978) still acknowledged the possibility of other attachment figures: “The mother figure is, however, the principal caregiver, whether the natural mother or someone else plays that role” (p. 5).

Although, as these quotations show, recognition of alternative attachment figures has been part of attachment theory from the beginning, attachment research involving children has been conducted largely on the child–mother attachment relationship. There are practical reasons to consider children as having a network of attachment figures. In the United States, families outside the dominant culture (particularly people of

color, immigrant families, and families living in or close to poverty) have historically used a variety of childrearing configurations involving networks of caregiving adults rather than a single caregiver (Jackson, 1993). As the roles of women and men in family life have changed, and as the two-income family has become an economic necessity, most children are now regularly cared for by more than one adult. Some children who are adopted, and children in foster care, experience multiple attachment relationships not only simultaneously but also sequentially. As research on multiple attachment relationships has become more common, there is little dispute that children form attachment relationships with child care providers, and that child–mother and child–other attachments are independent in antecedents and quality (Ahnert, Pinquart, & Lamb, 2006).

Considering multiple attachment figures raises theoretical issues for attachment theory. Central to the theory is a set of propositions about how attachments are formed and the influence of attachment relationships on subsequent development. Because alternative attachment relationships are formed in different contexts, and often in different developmental periods (i.e., subsequent to maternal attachments), examining antecedents of alternative attachment relationships can inform and expand the theory. Similarly, examining the

predictive power of attachment quality with alternative attachment figures for aspects of children's development can expand our understanding of the roles of relationships in development. Moreover, including multiple caregivers as part of a network of attachment figures may expand our understanding of the organization of internal working models of attachment.

While research published in the interval between the second and third editions of the *Handbook of Attachment* has not challenged the assumption that children may establish attachment relationships with their nonparental child care providers, there is some evidence that asking these caregivers for their perceptions of their relationships with particular children may result in relationship descriptions less aligned with attachment theory than observations of child-caregiver attachment behaviors in child care settings (Howes, Fuligni, Hong, Huang & Lara-Cinisomo, 2013; Hughes, 2012; Sabol & Pianta, 2012; Spilt & Koomen, 2009; Thijs & Koomen, 2009). Recent research has placed greater emphasis on child care providers as teachers who are responsible for children's school readiness, and has extended the measurement of teacher-child relationships to older children (prekindergarten, elementary school). In these newer research efforts, caregivers' perceptions of caregiver-child relationships may include perceptions of self-efficacy, particularly in areas of behavior management and academic instruction, as well as perceptions of warmth and closeness. These teacher perception measures, most commonly the Student-Teacher Relationship Scale (Pianta, 2001), appear to refer not only to attachment behaviors but also to sociability and compliance behaviors (Howes et al., 2013; Hughes, 2012; Verschueren & Koomen, 2012). Notably, Howes and colleagues (2013) found less convergence between Attachment Q-Set (Waters, 1987) and Student-Teacher Relationship Scale (Pianta, 2001) scores than had previously been reported (Howes & Ritchie, 1998). Therefore, in this chapter we review only research utilizing observational measures of attachment behaviors.

While research using caregiver perceptions of child-caregiver relationships has raised fundamental questions about measuring multiple attachments to other-than-mother caregivers, a second body of research provides new evidence for the potentially supportive nature of these child-caregiver relationships. Two studies link children's diurnal cortisol profiles to the quality of their child-caregiver relationships (Ahnert, Harwardt-

Heinecke, Kappler, Eckstein-Madry, & Milatz, 2012; Badanes, Dmitrieva, & Watamura, 2012). In both studies children with more secure attachments to caregivers were more likely to show falling cortisol levels across the child care day (Badnes et al., 2012) or week (Ahnert et al., 2012).

Finally, in this chapter of this new edition we review a number of intervention studies designed to improve the quality of child-caregiver attachment security in other-than-mother child dyads. Changing caregiver practices to be more sensitive and responsive, and increasing caregivers' ability to reflect on their practice, are associated with increases in child-caregiver attachment security.

In this chapter, we first consider children's attachments to other-than-mother caregivers (alternative caregivers), then describe, in some detail, child-mother attachment relationship quality when children attend child care and may also develop attachment relationships with nonparental caregivers.

Attachment to Nonparental Caregivers

Developmental Issues

Attachment theory assumes that a caregiver and infant will begin to construct their relationship from the moment of birth. Children's repertoires of social signals and their capacities for memory, internal representation, and affective knowledge develop at the same time as first attachments. Children encounter other attachment figures at varying points in their development. For some alternative caregivers—fathers; grandparents and other relatives; adoptive and foster parents with whom a child is placed at birth; and infant child care providers—we can assume that the course of attachment relationship construction is similar from a developmental point of view to that of child-mother attachment relationship construction. However, other relationships between the child and caregivers begin later in the child's life, and regarding these relationships, both developmental considerations and previous relationship history may have shaping influences.

Simultaneously Formed Attachment Relationships

In two-parent families, children, from birth onward, are assumed to construct attachment rela-

tionships simultaneously with both of their parents (Easterbrooks & Goldberg, 1987). However, even when multiple parental attachment relationships are constructed within the same developmental period and within the same household, attachment security with the two parents often differs, suggesting that each attachment relationship is shaped by specific interactions (Fox, Kimmerly, & Shafer, 1991; Grossmann et al., 2002; Van IJzendoorn & De Wolff, 1997).

There is almost no literature on grandparent–child attachment relationships constructed concurrently with child–parent relationships. There is also little research on attachment relationships between children and child care providers when a child is enrolled in child care prior to the formation of an attachment relationship with one or both parents or parental figures. For example, the youngest children in the large ($N = 2,867$) sample used in Ahnert and colleagues' (2006) meta-analysis were toddlers enrolled in child care after establishing parental attachments. In one more recent study, Howes and Wishard Guerra (2009) followed a sample of children born to low-income Mexican immigrant parents and placed in child care by age 2 months. Over the 3 years of the study, children tended to have secure relationships with both mothers and caregivers, but the two kinds of security scores were statistically independent at each assessment period. In this sample, the family circumstances of the mother tended to influence child security scores with mothers but not with caregivers, further suggesting independence of the two relationships.

Sequentially Formed Attachment Relationships

Most toddlers or older children who encounter alternative attachment figures already have at least one internal working model (IWM) of an attachment relationship because these representations are developed during the first year. In sequentially formed attachments, both the developmental context and the relationship history differ from those affecting infant–mother attachments. In this section, we review literature on the construction of attachment relationships with sequential nonparental caregivers. When we describe the construction of sequential attachment relationships with child care providers, we are concerned with whether these relationships are constructed according to developmental processes similar to

those seen in child–mother attachment relationships. When we describe the construction of sequential attachment relationships to foster and adoptive parents, we are concerned with not only developmental processes but also the issue of prior difficult relationships.

Forming New Relationships with Child Care Providers

The formation of infant–mother attachment relationships can be observed as children track or follow their mothers, cry to alert the mothers to their distress, or maintain social contact through smiles and vocalizations. Do children use these same behaviors when they are left in the care of a child care provider or a teacher, or is there another developmental process? Three studies have explicitly examined this question in relation to toddlers. Raikes (1993) had center-based providers complete Attachment Q-Sorts (Waters, 1987) for the children in their care. Security scores increased as the toddlers spent more time with the providers, indicating relationship formation. Barnas and Cummings (1997) compared toddlers' attachment behaviors with long-term staff members (3 months or more in the center) and short-term staff members. Children directed more attachment behaviors to the long-term staffers, and long-term staffers were more successful than short-term staffers in soothing distressed children. Howes and Oldham (2001) observed toddlers daily, then weekly, during their first 6 months in child care. The frequency of attachment behavior decreased over the children's first 2 months in child care. However, the initial frequency of attachment behaviors and their rate of decrease over time were unrelated to the children's attachment security by the end of 6 months in child care. Thus, the formation of toddler–child care provider attachment relationships appears to be similar to the formation of an infant–mother attachment. When toddlers begin child care, they direct attachment behaviors to the caregivers, and with increased time in the setting, children's interactions with the caregivers become more organized, similar to attachment organizations found in mother–child dyads.

Forming New Relationships with Adoptive or Foster Parents

Classic studies of adoptive children indicated that children adopted after the beginning of attach-

ment relationship formation (6–8 months) had difficulty forming positive, trusting relationships with their adoptive parents (Tizard & Rees, 1975; Yarrow, Goodwin, Manheimer, & Milowe, 1973). More recent studies of children adopted before, during, and after the developmental period of initial attachment formation suggest that attachment formation in infants adopted during their first year is similar to child–mother attachment formation and does not have a critical period (Dontas, Maratos, Fafoutis, & Karangelis, 1985; Marcovitch et al., 1997; Singer, Brodzinsky, Ramsay, Steir, & Waters, 1985). (See Dozier & Rutter, Chapter 30, this volume, for further discussion of issues concerning adoption.)

Describing attachment formation in foster care children and children adopted from institutions with severe caregiving deprivation policies is a stringent test of the dual influences of developmental period and prior relationship history on the process of constructing an attachment relationship. Most foster care children have experienced difficult relationships but not necessarily severe deprivation. Researchers question whether these children can form secure attachments with alternative caregivers, and whether the process of attachment formation is similar to attachment formation in typical children. In an early study (Howes & Segal, 1993), almost half of the children (47%) removed from their homes because of maternal abuse or neglect and placed in high-quality shelter care were able to develop secure attachment relationships with shelter caregivers within 2 months of placement. Foster children placed in therapeutic preschool programs are also able to form secure attachments to their caregivers (Howes & Ritchie, 1999). Extensive and long-term follow-up of children in institutional care suggest that while these children may, when adopted, form attachment relationships, indiscriminate behavior persists (Bakermans-Kranenburg et al., 2011). See Dozier and Rutter, Chapter 30, this volume, for more detailed discussion of these issues.

Pathways to Secure Attachment Relationships with Alternative Caregivers

An important premise of attachment theory and research is that caregiver behavior, specifically, sensitive and responsive behavior, and caregiver attachment representations are important in the

construction of secure attachment relationships (Ainsworth et al., 1978; Cassidy et al., 2005; Van IJzendoorn, 1995). Not surprisingly, sensitive and responsive behaviors—and, to a lesser extent, caregiver “states of mind with respect to attachment” assessed in the Adult Attachment Interview (AAI)—have been the topics of research on the antecedents of secure attachments with nonparental caregivers.

Sensitive and Responsive Caregiver Behaviors

Early studies on child–father and child–caregiver attachments (with the term *caregiver* referring to a nonparental child care provider) revealed that more sensitive previous or current caregiving was linked to more secure attachment relationships (Anderson, Nagel, Roberts, & Smith, 1981; Cox, Owen, Henderson, & Margand, 1992; Easterbrooks & Goldberg, 1987; Goossens & Van IJzendoorn, 1990; Howes & Hamilton, 1992a; Howes & Ritchie, 1998; Howes, Rodning, Galluzzo, & Myers, 1988; Howes & Smith, 1995).

Meta-analytic work suggests that for child–caregiver attachment relationships, the form of child care may influence caregiver sensitivity (Ahnert et al., 2006). Security in child–caregiver relationships in child care centers was best predicted by warm and sensitive care that monitored both individual children’s needs and the needs of the entire group of children. Caregivers were, not surprisingly, more successful at this dual focus when the groups of children were smaller. In family-based child care, with smaller groups of children, dyadic responsiveness by itself predicted attachment security.

Caregiver States of Mind

When children in the meta-analysis (Ahnert et al., 2006) had experienced discontinuous care, and perhaps were less trusting of child care providers in general (see Howes & Hamilton, 1993), they were less likely to be secure. This suggests that the average professional caregiver’s level of sensitivity may not be sufficient to produce secure attachment relationships with children whose relationship histories have predisposed them to consider adult caregivers unavailable or untrustworthy (Howes & Ritchie, 2002). Caregivers’ perceptions of children can influence attachment security, particularly if the children differ from them in ethnic

background. If children are ethnically mismatched with caregivers, and if the children evoke negative emotions from these caregivers, the caregivers are more likely to report conflictual child–teacher relationships (Rudasill, Rimm-Kaufman, Justice, & Pence, 2006; Saft & Pianta, 2001; Stuhlman & Pianta, 2002).

Two recent intervention studies involved directing intervention efforts toward each caregiver's state of mind regarding attachment. Biringen and colleagues (2012) combined course work on attachment with coaching onsite in caregiving practices associated with caregiver and child mutual emotional availability. Caregivers from the intervention group and the children for whom they cared increased in both emotional availability and attachment security compared to caregivers and children in the control group. Spilt, Koomen, Thijs, and Van deLeij (2012) more directly addressed caregivers' state of mind regarding attachment. Using relationship-focused reflection, they targeted caregivers' mental representations of relationships with specific children. Caregivers in the experimental group were more likely than caregivers in the control group to report increases in closeness with the children and were observed to be more sensitive in their interactions with them.

Organization of Child IWMs in Multiple-Caregiver Contexts

Examining attachment in the context of multiple caregivers requires that we consider how representations of multiple attachment relationships are organized in a child's IWMs. According to attachment theory, the child forms internal representations of self and relationships with others based on repeated interactions with attachment figures (Bowlby, 1969/1982). Several different possibilities for the organization of IWMs of multiple attachment relationships have been suggested: "hierarchical," in which the child's representation of the most salient caregiver, most often the mother, is the most influential (Bretherton, 1985); "integrative," in which the child integrates all of his or her attachment relationships into a single representation (Van IJzendoorn, Sagi, & Lambermon, 1992); and "independent," in which the different representations are independent both in quality and in their influence on development (Howes, 1999). To evaluate the empirical support for a model of organization of IWMs, two bodies of literature must be considered. In one body of

literature, researchers have examined the concordance in the quality of children's attachments to more than one caregiver. In the second, researchers have compared the predictability of children's developmental outcomes from their attachment security with different caregivers.

Concordance of Attachment Quality

There have been two major meta-analyses examining concordance of attachment relationship quality across caregivers. Fox and colleagues (1991) conducted a meta-analysis examining the concordance of infant–mother and infant–father attachment security. They concluded that mother and father relationships were modestly concordant; that is, they were not independent. This is consistent with the literature suggesting that the mother may shape father–child interaction and subsequent relationship quality (Steele, Steele, & Fonagy, 1995), and it supports a hierarchical model of organization.

Ahnert and colleagues (2006) examined the concordance of child–mother and child–caregiver attachment security and like Fox and colleagues (1991) concluded that the two relationships were independent. Although children were less likely to be secure with their professional care providers than with their mothers, there is little evidence in the literature suggesting that the child's mother shapes child–caregiver interaction patterns. Therefore, this analysis supports an independent rather than a hierarchical model of organization.

Prediction of Developmental Outcomes

Relatively few studies have examined the differential prediction of developmental outcomes from attachment quality of relationships with more than one caregiver. As might be expected from the greater amount of time mothers, compared with fathers, spend with their children, child–mother attachment quality is generally (but not always) more predictive of child outcomes than is child–father attachment quality (Main, Hesse, & Kaplan, 2005; Main, Kaplan, & Cassidy, 1985; Suess, Grossmann, & Sroufe, 1992; Volling & Belsky, 1992; but see also Easterbrooks & Goldberg, 1987; Grossmann et al., 2002; Lamb, Hwang, Frodi, & Frodi, 1982; Main & Weston, 1981; Steele et al., 1996). Two longitudinal studies have examined children's developmental outcomes using child–mother and child–caregiver

relationships as predictors of children's outcomes. The Haifa longitudinal study examined prediction from quality of child–mother, child–father, and child–*metapelet* relationships in infancy to social and emotional outcomes in early childhood, early and late adolescence, and early adulthood (Sagi-Schwartz & Aviezer, 2005). In early childhood, previous child–*metapelet* attachment security predicted preschool children's social competence with peers better than did child–parent attachment security (Oppenheim, Sagi, & Lamb, 1988). Furthermore, scores based on a network of caregivers (mother, father, and *metapelet*) better predicted general social competence in early childhood than did child–mother attachment security (Van IJzendoorn et al., 1992). Network security in early childhood was also most predictive of child competence with peers in a Dutch sample of children, mothers, and childcare providers (Van IJzendoorn et al., 1992). These findings support an independent or integrative model of IWM organization. By adolescence and adulthood, results from the Haifa study were less conclusive with regard to the organization of IWMs. Beyond early childhood, networks of attachment relationships were not as predictive of outcomes as was early attachment security with mother and father (Sagi-Schwartz & Aviezer, 2005).

The Howes longitudinal study examined the ability of child–mother, child–caregiver, and child–teacher relationships from infancy through middle childhood to predict concurrent and early and late adolescent social and emotional outcomes. In the toddler period, attachment relationships with mother and child care providers predicted behavior with peers, supporting an integrative organization of IWMs (Howes et al., 1988). At preschool, the findings suggested an independent organization, with early security of attachment to a child care provider predicting preschool children's social competence with peers (Howes, Matheson, & Hamilton, 1994). At age 9 (Howes, Hamilton, & Phillipsen, 1998) and at age 14 (Howes & Tonyan, 2000), early attachment security with mother was the best predictor of child–mother relationship quality, and early attachment security with child care providers was the best predictor of child–teacher attachment security. These results argue for an independent organization. However, peer friendships in these last two developmental periods were best predicted by preschool friendship quality, suggesting that whereas early attachment security with child care providers predicted early friendship with peers, peer relation-

ship quality in later developmental periods was independent of early attachments to adults. By late adolescence (Howes & Aikens, 2002) the pattern of relations between early attachments to mothers and caregivers on the one hand, and social and emotional competence on the other, did not fit any of the proposed models of IWM organization. Complex relations were found among adolescent functioning, gender, and early emotion regulation in child care and early relationships with adults.

Far more research than two longitudinal studies is needed to support any of the proposed conceptions of IWM organization resulting from multiple attachment relationships (for further discussion of these issues, see Kobak, Rosenthal, & Serwik, 2005; Thompson & Raikes, 2003). As more and more children develop social and emotional competence through attachment relationships with mothers and other salient caregivers, researchers should consider planning studies that describe relationships with multiple attachment figures across time.

Relations between Child Care and Maternal Attachment

A dramatic demographic shift in the rearing experiences of infants in the United States occurred in the closing decades of the 20th century. By the mid-1980s, the number of mothers in the paid labor force with infants under 1 year of age reached 50%. Social scientists began to ask whether the experience of repeated separations from mother, and time away from mother during the development of a child's primary attachments, had adverse consequences for the quality of infant–mother attachment.

Concern That Child Care Was a Risk for Insecure Infant–Mother Attachment

During the 1980s, two multistudy analyses converged on the conclusion that more than 20 hours/week of child care in the first year of life was associated with elevated rates of insecure infant–mother attachment, as measured by the Strange Situation (Ainsworth & Wittig, 1969; see Solomon & George, Chapter 18, this volume). Belsky and Rovine (1988) and Clarke-Stewart (1989) reported insecurity rates for infants with extensive child care to be 43 and 36%, respectively, compared

with rates of 26 and 29% for groups with no or limited early child care experience. These differences were particularly marked for insecure-avoidant classifications. Lamb, Sternberg, and Prodromidis (1992) reanalyzed data from 13 studies and also found that children in exclusive maternal care had higher rates of security than other infants. In contrast to the earlier studies, however, Lamb and colleagues found elevated insecurity and avoidance for infants in any child care exceeding a mere 5 hours/week, and insecurity and avoidance rates for infants receiving this low level of child care were not different from those receiving extensive care of more than 20 hours/week.

The explanation of these effects was a matter of controversy. Barglow, Vaughn, and Molitor (1987) hypothesized that the elevation in the rate of insecure-avoidant attachment indicated that these infants experienced repeated separations from their mothers as rejection. Others wondered whether time away from each other might disrupt the proximal processes of mother-child interaction, affecting a mother's ability to respond to her infant with sensitivity (Brazelton, 1985; Jaeger & Weinraub, 1990; Owen & Cox, 1988) or the infant's expectation of an available and responsive parent (Sroufe, 1988).

Eventually, two interpretations of the data became common in the developmental and popular literature. One was that the experience of extensive child care in the first year of life was indeed a risk factor for the development of insecure infant-mother attachment (Belsky, 1990), although the majority of infants with this early experience did develop secure attachments. The second interpretation focused on the measurement of attachment insecurity itself. Clarke-Stewart (1989) suggested that the two brief separations in the Strange Situation procedure were not stressful enough for infants with extensive child care experience, and that the autonomy and independence displayed by these less distressed infants upon reunion with their mothers was in fact misinterpreted as avoidance. Clarke-Stewart asserted that the Strange Situation may not be a valid measure of attachment for infants with extensive child care experience.

The evidence relevant to these two interpretations was mixed. The results of the 1980s studies were consistent, but Roggman, Langlois, Hubbs-Tait, and Rieser-Danner (1994), studying a small but later-born cohort, found no association between child care experience and infant-mother attachment security. Other researchers

found no differences in distress or exploration in the Strange Situation for infants with insecure-avoidant classifications and varying amounts of child care experience (Belsky & Braungart, 1991; McCartney & Galanopoulos, 1988), and Berger, Levy, and Compaan (1995) supplied evidence that the Strange Situation was equally valid for infants with and without extensive child care in the first year. Thus, the "infant day care controversy" (Westman, 1988) was in full swing when the National Institute of Child Health and Human Development (NICHD) initiated the Study of Early Child Care to address these and other questions about the effects of early child care on children's social, emotional, cognitive, and language development.

The NICHD Study of Early Child Care

The 1,364 participants in the NICHD Study of Early Child Care and Youth Development (NICHD SECCYD; "Youth Development" was added to the title of the study when it was extended in its third phase to follow participants through sixth grade) were recruited throughout 1991 from 31 hospitals in 10 sites across the United States, in accordance with a conditionally random sampling plan designed to ensure that participant families reflected the educational, economic, and ethnic diversity of their respective sites. The corporate author, the NICHD Early Child Care Research Network (NICHD ECCRN), published two articles (1997, 2001) on the effects of early child care on attachment as assessed by the Strange Situation at 15 and 36 months. Subsequent named-author papers (e.g., Huston & Rosenkrantz Aronson, 2005; Tran & Weinraub, 2006), using the same data set, also addressed this question, although the question has not been the focus of inquiry since the previous edition of this volume. Others have used the data to examine predictors of attachment security (e.g., Campbell et al., 2004) or the influence of attachment security on child development (e.g., Fearon & Belsky, 2011; O'Connor, Collins, & Supplee, 2012), regardless of child care experience. And, as the title of the study suggests, the ECCRN has published extensively about the influences of early child care experiences on a wide range of developmental outcomes up to age 15 (e.g., Vandell et al., 2010). Other analyses focus on topics that are not related to early child care, such as afterschool experience, physical activity,

family processes, and school environments. Currently, the sample has been followed into early adulthood (e.g., Fraley, Roisman, Booth-LaForce, Owen, & Holland, 2013).

The NICHD SECCYD has considerable methodological strength. The sample size has been nearly as large as the largest of the multistudy analyses in the 1980s (Clarke-Stewart, 1989). The study has been prospective and longitudinal, following children identified at birth, thus reducing selection biases. Parents determined the timing, type, and amount of child care, and presumably considered quality in their choices; the researchers recorded this information regularly and observed the quality of the major arrangements during the first phase of the study at child ages 6, 15, 24, and 36 months. The design of the study used a broad multivariate framework, permitting the effects of child care on infant–mother attachment security to be studied “in context.” The examination of effects in context was important because none of the previous studies had indicated that insecurity was inevitable for children with extensive early child care experience—only that rates of insecurity were elevated. Characteristics of the child (e.g., sex, temperament), child care experience (type, amount, age of entry, stability, and quality), and characteristics of the family (including socioemotional processes and economic resources) could all interact with each other to influence child outcomes, including attachment security. Children were not randomly assigned to child care, and complex family selection factors influenced family decisions about the type of child care children would experience. The basic analytic approach of the NICHD ECCRN was to assess the amount of variance of any outcome explained by child care-related variables that was over and above that explained by selection, family, and child factors. The major child care associations with attachment reported in the ECCRN papers are reviewed below.

The NICHD Study of Early Child Care and Infant–Mother Attachment

The NICHD ECCRN (1997) analyses had two purposes. The first was to explore the validity of the Strange Situation for assessing attachment security of infants with extensive experience in child care by comparing a subsample of infants who experienced more than 30 hours/week of child care from ages 4 to 15 months ($n = 263$) with infants who had fewer than 10 hours/week of child care

during this period ($n = 251$). The validation measures included 5-point ratings of the infants’ distress during the separation episodes of the Strange Situation, and the coders’ self-rated confidence (5-point scale) with which they assigned the various secure or insecure major classifications. In these validity analyses, the five-category attachment classification (A, B, C, D, U) was used. Results of 2 (high vs. low child care intensity) \times 5 (attachment classification) analyses of variance for the distress and confidence ratings provided no support for the hypothesis that the Strange Situation was a less valid measure of attachment for children with extensive child care experience. There was no main effect of child care intensity on either of these ratings.

The second purpose of the 1997 analyses was to examine the main effects of age of entry and child care quantity, stability, and quality on infant attachment security, as well as the interaction of these features of child care with aspects of the family and/or child. Two kinds of interactions were tested. The first set addressed the “dual-risk” hypothesis, namely, that large amounts of child care, poor-quality child care, or frequent changes in care over time would promote insecure infant–mother attachment in the context of other risks, such as difficult temperament, being a male, or residing with a mother who had poor psychological adjustment or was less sensitive and responsive to the infant. A “compensatory” hypothesis was also tested, namely, that when family or child risks were high, child care that began early in life and was stable, extensive, or of high quality would foster the formation of a more secure infant–mother attachment. In a series of logistic regression analyses, the dichotomous dependent attachment variable (secure–insecure or secure–avoidant) was predicted from one of five characteristics of the mother or the child, one of five characteristics of child care, and the interaction between the two selected (mother–child and child care) variables, entered one at a time.

The “main effects” hypotheses for child care received no support. None of the five child care variables (two measures of observed quality of care, the amount of care, the age of entry, and the frequency of care starts), entered after the selection and family–child variables, significantly predicted attachment security. Six of the 25 interaction terms included in the logistic regression analyses were significant predictors of attachment security. A consistent pattern observed across five of the six significant interactions was that the

highest rates of insecurity occurred under dual-risk conditions. Infants were less likely to be secure when low maternal sensitivity/responsiveness was combined with poor-quality child care, more than minimal amounts of child care, or more than one care arrangement. In addition, boys experiencing many hours in care were somewhat less likely to be securely attached (and girls experiencing more hours in care were somewhat more likely to be secure). The interaction analyses also provided evidence for compensatory effects. The proportion of attachment security among children with the least sensitive and responsive mothers was higher in high-quality child care than in low-quality care.

Additional detailed analyses of the NICHD SECCYD data set likewise found no evidence of main effects. Booth and colleagues (2002) and Huston and Rosenkrantz Aronson (2005), analyzing detailed data, examined amount of mothers' time with their infants in the first year of life and found no associations with attachment security at 15 or 36 months. Thus, one of the hypothesized mechanisms for earlier findings on attachment security—that extensive child care did not give mothers and children sufficient time to get to know one another—was not supported. Nevertheless, another paper by the NICHD ECCRN (1999), based on longitudinal analyses that controlled for selection, child, and family predictors, reported that more hours of child care predicted less maternal sensitivity and less positive child engagement with the mother. Apparently the effect of hours in child care does not overlap completely with the effect of time with mother. Another failure to replicate prior results completely, using different analyses from the data set, was reported by Tran and Weinraub (2006), who did not find an interaction between maternal sensitivity and stability of child care predicting infant attachment. Tran and Weinraub used a slightly different measure of stability and a somewhat different subset of participants. These instances of lack of replication highlight the relatively small effect sizes of the significant interactions in the 1997 article.

In comparing the results of the NICHD SECCYD with those of earlier studies, considerable weight should be given to the NICHD study because of its size and the quality of the data. But the possibility of cohort effects is real and may be responsible for some of the differences in findings between this and earlier studies. Families in the 1990s that used child care may have differed in important ways from their earlier counterparts. Maternal employment during a child's infancy be-

came an increasingly "mainstream" practice; also, families and child care providers may have been more aware of the child care controversy than were families in the 1970s and 1980s, and so may have worked harder to support the infant-parent relationship.

The limitations of the NICHD SECCYD should not be ignored. The highest-risk families, including those with adolescent mothers or families with vulnerable, ill, or premature newborns were not included in the sample. Although nearly one-fourth of the sample was low-income, low income was almost completely confounded with racial minority status (specifically, African American), making it impossible to examine these factors independently. Finally, the researchers were less likely to be permitted to observe child care arrangements presumed to be of low quality. All of these limitations affect the generalizability of conclusions from the seminal 1997 study about the main and interactive effects of family-child characteristics and child care quality on infant attachment and other outcomes.

The Haifa Study of Early Child Care and Infant-Mother Attachment

A later Israeli study modeled on the NICHD SECCYD was designed to address some of these issues. The Haifa Study of Early Child Care (Sagi, Koren-Karie, Gini, Ziv, & Joels, 2002), also funded by the NICHD, "was designed to shed further light on issues pertaining to the effects of early child care on the development of the infant-mother attachment relationship in general, and on the published data from the NICHD Early Child Care Research Network in particular" (p. 1167). Because in Israel child care centers are part of a nationwide network, the quality is relatively homogeneous and not confounded with socioeconomic status (SES) because infants from families of all income and education levels are placed in the same centers. The researchers used a randomized, stratified sampling strategy for all healthy, singleton births in the greater Haifa metropolitan area in a 1-year period. The final sample included 758 families at all SES levels. The analytic approach closely followed that reported by the NICHD ECCRN (1997). Like the NICHD SECCYD researchers, the Haifa researchers controlled for selection, family, and child characteristics before testing for main and interaction effects involving features of child care. Sagi and colleagues (2002) found that infants who experienced center care in the first year of life (46% insecure), as

compared to those who experienced no child care or care by relatives, paid individuals, or family day care (26% insecure overall), were more likely to be insecurely attached to their mothers. Further analyses implicated the high infant–caregiver ratio ($M = 8.01$, standard deviation = 1.69) in Israeli centers. Among infants cared for by professional caregivers, those experiencing infant–caregiver ratios of 3:1 or less had a security rate of 72%, compared to 57% for infants experiencing higher infant–caregiver ratios. The researchers also demonstrated that infant–caregiver ratios, not amount of care, were what predicted infant attachment security. When only infants cared for in centers were considered, there was no difference in amount of care experienced by infants who were secure or insecure with their mothers. Finally, eight of 24 interaction terms were significant, most supporting a dual-risk interpretation. Low maternal sensitivity combined with an indicator of low-quality child care always yielded the lowest proportion of securely attached infants. Three interactions with child gender indicated that boys were particularly vulnerable to center care, unstable care, and high infant–caregiver ratios.

Most of the insecure Israeli infants were ambivalent; very few were avoidant, consistent with previous studies of infant attachment in Israel (Scher & Mayseless, 2000; Van IJzendoorn & Sagi, 1999). In contrast, many of the U.S. child care studies found that most of the infants in child care classified as insecure with their mothers were avoidant, and this difference underscores the cultural context in which these studies were conducted. Both the NICHD ECCRN (1997) study and the Haifa study found small effect sizes for child care variables. The results of the two studies are similar and complementary. The Haifa study compensates for one of the limitations of the NICHD SECCYD, which was that observations of quality in the lowest-quality settings were frequently denied. In Israel, the centers were of uniformly very poor quality, and access was readily available. The Haifa study's inclusion of very low-quality center care for infants from a range of SES groups expands the continuum of quality under which the effects of child care have been studied, and has important policy implications for the well-being of infants placed in center care.

In summary, the NICHD SECCYD and the Haifa infant study examined effects of child care experience during the development of primary attachments in infancy on the security of the infant–mother attachment relationship. The 2001

report of the NICHD ECCRN extended the approach of the 1997 article to examine the continued effects of this early experience, and also examined the effects of child care that began after the formation of the infant–mother attachment relationship on children's preschool Strange Situation classifications with mothers at 36 months. Because the 1999 NICHD ECCRN report found that more hours per week in child care was associated with lower maternal sensitivity and less positive engagement of child with mother over the first 3 years of life, main effects of child care on attachment security that were not noted at 15 months might have emerged by 36 months. The 2001 analyses addressed whether child care experience (amount, number of arrangements, age of entry, and quality), alone or in combination with family, maternal, or child factors, was associated with attachment security at 36 months. In addition, analyses examined child, family, and child care correlates of stability–instability of Strange Situation attachment classifications from 15 to 36 months.

Child Care and Infant–Mother Attachment Stability

Several authors have reported links between early child care experience and attachment stability from infancy to preschool. In a low-risk sample, Howes and Hamilton (1992b) found significant stability in attachment from infancy to the preschool period. In addition, they found instability to be associated with hours per week in child care. Children who entered part-time child care as infants or 3-year-olds had more stable maternal attachment classifications, regardless of quality of attachment, than children who entered full-time care as infants or 3-year-olds. The stability described by Howes and Hamilton is interesting in light of a report by Egeland and Heister (1995). In their high-risk sample from the 1970s, early and extensive child care beginning in the first year seemed to have a negative effect on children who were secure as infants, but a positive effect on those who were insecure. Furthermore, infant attachment security predicted later outcomes only for children who were not in early and extensive child care before 18 months of age. Egeland and Heister speculated that these relations may be mediated by a change in attachment security from infancy to preschool for children in child care, with greater stability of attachment to mother for children who did not experience child care. Egeland

and Heister did not, however, actually assess preschool security in their study. In contrast, Rauh, Ziegenhain, Muller, and Wijnroks (2000), following a German sample, found that attachment stability in the first 2 years of life was related to maternal sensitivity, but not to variations in child care experience across that time period.

Unlike the 1997 NICHD ECCRN study, the NICHD ECCRN (2001) analyses considered all four attachment classifications (A, B, C, D) using multinomial logistic regression. Results revealed that mothers who exhibited more sensitivity and responsiveness across play assessments between 6 and 36 months were more likely to have children with secure- rather than insecure-controlling classifications, and marginally more likely to have children with insecure-avoidant versus insecure-controlling, insecure-ambivalent versus insecure-controlling, and secure versus insecure-ambivalent classifications. None of the three child care predictors available for the whole sample significantly predicted any attachment classification. That is, variations in the amount of care, the frequency of care arrangements, or age of entry did not increase or decrease a child's chances of being assigned a particular attachment classification, after controls for all selection and mother-family-child variables were imposed. As a direct follow-up of the 15-month interaction findings, four interactions (sensitivity \times quality, sensitivity \times hours, sensitivity \times number of arrangements, and hours \times child gender) at 36 months were tested, one at a time, in the multinomial logistic regression models. One interaction term was significant, suggesting that as hours in care increased, children with more sensitive parents were more likely to be classified as secure, and children with less sensitive parents were more likely to be classified as insecure-ambivalent. Thus, overall, findings on the follow-up effects of child care experience were congruent with the findings on earlier effects, and they support the conclusion that the effects of child care experience that begins during the development of primary attachments persist into the preschool years.

The ECCRN (2001) also reported logistic regression analyses predicting security versus insecurity at 36 months within both the initially secure and initially insecure groups. These analyses determined whether child care experience could explain why some children who were initially secure remained that way over time, whereas others did not, and why some children who were initially insecure remained that way, whereas others did

not. There was one effect of child care experience for children who were classified as secure at 15 months: Those whose classification changed from secure to insecure were more likely to have initiated at least 10 hours/week of child care during the interval between 15 and 35 months, compared with children whose classification remained secure. This was a small effect ($r^2 = .09$). These new results for sequential effects of child care after the formation of primary attachments are in contrast to the results for simultaneous child care experiences, described earlier.

In summary, analyses from the NICHD SECCYD have consistently found that family influences are stronger than child care effects in determining the quality of child-mother attachment as measured by the Strange Situation at 15 and 36 months. However, some evidence for dual-risk effects has been found at both ages. It seems that for children whose interactions with their mothers are already distressed, long daily separations from mothers increase the likelihood of insecure attachment. Entry into child care after developing a primary attachment also appears to elevate risk for insecurity somewhat. A similar finding was reported by Lamb and colleagues (1992), who found that insecure infant-mother attachments were significantly more common among infants assessed after 15 months of age, and among those who entered care between 7 and 12 months of age rather than earlier.

In both the NICHD SECCYD and the Haifa study, any adverse effects of child care on child-mother attachment were observed more in groups at risk because the quality of maternal care was less sensitive and responsive—that is, because the relationship was already troubled. As an extreme example of this phenomenon, Crittenden (1983) reported on the effects of mandatory protective day care (respite care) for young children of maltreating and neglecting mothers. After 4 years, the outcomes for the two groups were similar except that those placed in day care had earlier removals for foster care than comparable children who could not be placed in day care. Crittenden concluded that mandatory protective day care had hastened, but not caused, the removal of the children. She explained this surprising outcome in terms of attachment theory, citing evidence that both maltreating mothers and their infants could be considered anxiously attached, and that, as such, they would be more vulnerable to experiences of separation. Both mothers and infants reacted to the day care placement with a combination

of direct and repressed anger, which exacerbated their already strained relationship and accelerated infants' removal from the home.

The Haifa study complements the NICHD SECCYD by including a range of child care quality that was not confounded by family SES. Together, these studies add to the literature on child–mother attachment in the context of multiple caregiving. Much of child care (especially in infancy, and for some cultural groups more than others) is provided by fathers, grandparents, relatives, friends, and neighbors. The literature suggests little or no impact of these caregiving arrangements on the primary infant–mother attachment relationship. However, there appears to be a threshold effect that is illustrated by results from the Haifa study: More formal group care, with large numbers of children and large child–caregiver ratios, may make the formation of *any* secure attachment—whether to the mother or an alternative caregiver—less likely. This conclusion is supported by the meta-analysis of Ahnert and colleagues (2006) meta-analysis, who found that children's attachments to caregivers in child care were observed to be less secure when group size and child–caregiver ratios were large. It may be that children under these adverse circumstances develop strategies with all of their caregivers that are adapted to increase the probability of protection and survival under threatening conditions, which after all is the evolutionary purpose of attachment.

Summary and Conclusions

Most children grow and develop within a changing network of attachment relationships, which includes some enduring attachment figures and some that change with time and circumstances. The child is a co-constructor of all of these relationships. Children construct relationships with mothers and residential fathers within the same family. Children come and go between home and child care facilities; the adult caregivers communicate with each other or do not; they collaborate in caring for the child or they do not. However, child–parent and child–caregiver attachment relationships are largely independent in quality and may have different antecedents. The process of forming attachment relationships is similar for parents and alternative caregivers for typical children, particularly children who are very young and/or experiencing positive parental relation-

ships. The construction of secure attachments appears more dependent on particularly skilled and sensitive adult behaviors when children have experienced prior difficult relationships. As with parents, the quality of caregiving may influence attachment formation, but other attributions of the children by the caregivers may also be important.

We know less about the role of alternative caregivers in terms of children's long-term development. Parents, particularly mothers, are undoubtedly the emotionally salient and sustaining attachment figures in most cases. Child care providers are not long-term participants in the social networks of most children. In general, we can draw few conclusions about the importance of early versus later or sustained experiences with alternative attachment figures. We could find no longitudinal studies of long-term alternative attachment relationships—for example, those with grandparents. Far more research than currently exists is needed to support any of the proposed conceptions of the organization of IWMs based on multiple attachment relationships.

Chapter 16

Early Attachment and Later Development

Reframing the Questions

Ross A. Thompson

How does the child foreshadow the adult-to-be? Philosophers, spiritualists, playwrights, and, most recently, behavioral scientists have sought to understand how early dispositions and influences provide a foundation for adult personality. Among the answers they have offered is the influence of early, close relationships. This view was eventually crystallized in Freud's (1940/1963, p. 45) famous dictum that the infant–mother relationship is “unique, without parallel, established unalterably for a whole lifetime as the first and strongest love-object and as the prototype of all later love-relations.” Drawing on this psychoanalytic heritage, Bowlby (1969/1982, 1973, 1980) enlisted formulations from evolutionary biology, developmental psychology, and control systems theory to argue that a warm and continuous relationship with a caregiver promotes psychological health and well-being throughout life in a manner that accords with the adaptive requirements of the human species. In collaboration with Ainsworth (1967, 1973), he proposed that differences in the security of infant–mother attachment have significant long-term implications for later intimate relationships, self-understanding, and even risk for psychopathology. Bowlby's conceptual integration was provocative, and with the validation of reliable methods for assessing the security of attachment in infants and young children, it could be examined empirically.

There have been three stages to the research that followed on early attachment and later development. The first consisted of studies in the late 1970s, confirming that early attachment relationships *could* be stable over time and predict later aspects of psychosocial functioning, such as peer sociability, positive affect, and cooperativeness (e.g., Matas, Arend, & Sroufe, 1978). These studies were important because they provided initial support for the claims of attachment theory and distinguished this approach from earlier approaches, guided by social learning theory, in which researchers had found little consistency in attachment measures and little prediction of later behavior (see Masters & Wellman, 1974).

The second stage consisted of several decades of subsequent research exploring the breadth of later behavior that was associated with attachment security. Consistent with Bowlby's formulations, developmental researchers explored the association between early security and later relations with parents, peers, friends, and other social partners, as well as with self-concept, competence in preschool and kindergarten, personality development, social cognition, behavior problems, and indicators of emergent psychopathology. Moreover, guided by a general expectation that a secure attachment would predict better later functioning, researchers broadened their inquiry to explore how security predicted later cognitive and lan-

guage development, exploration and play, curiosity, ego resiliency, math achievement, and even political ideology, extending the range of predictive correlates far beyond what Bowlby originally envisioned. This breadth of documented sequelae was possible, in part, because of the availability of large longitudinal data sets, such as the National Institute of Child Health and Human Development Study of Early Child Care and Youth Development (NICHD SECCYD), even though they had not really been designed to test the later outcomes of attachment security (Thompson, 2008a). Attachment theory was thus stretched to explain a variety of empirical associations between attachment and later behavior, some of which were theoretically unpredicted and may have resulted from unmeasured mediators as well as direct causal influences. To illustrate, a number of studies have documented an association between security of attachment and later measures of cognitive performance and IQ, but more carefully designed mediational studies show that this is because of differences in parental quality of assistance, peer relationships, and children's cooperativeness at school—mediators that are fully consistent with attachment theory (Drake, Belsky, & Fearon, 2014; West, Mathews, & Kerns, 2013).

This has led to a third stage of research characterized by broader analyses of what is reliably known about the consequences of attachment (through meta-analysis and other approaches) and the use of more incisive methodologies to examine direct and indirect outcomes of early security. These methodologies have included growth curve modeling, mediational analyses, and the use of biologically informed designs. In a sense, this third stage involves a thoughtful reconsideration of how and why early attachment security should be associated with later development, and exploration of alternative models for why security might predict later behavior in direct and indirect ways. These studies also draw on samples in which the security of attachment was not stable over time. The discussion of empirical studies that follows includes examples of these approaches to reframing the question of attachment and later behavior in more sophisticated ways.

This chapter begins, therefore, with consideration of alternative explanations for why a secure attachment should be associated with later behavior, with a focus on attachment security in the early years. Following this is a review of the research examining these associations in the developmental domains that have been best studied:

parent–child relationships, close relationships with peers and other partners, personality, emotion regulation, emotion understanding, social cognition, conscience, and self-concept. In a final section, these results are discussed in light of what we can conclude about how attachment security influences later development, which research approaches are most likely to elucidate this association in future studies, and future directions.

Conceptual Perspectives

To an observer, it might appear surprising that it is necessary to begin this discussion by sorting through the various conceptual explanations for why early attachment security should be associated with later development. After all, wasn't Bowlby clear on this issue?

The challenge facing contemporary attachment researchers is not only Bowlby's theory, but also its generativity. Attachment theory was formulated decades ago, at a time when scientific understanding of infancy and early childhood underestimated the cognitive and behavioral sophistication of the young child and the dynamics of early parent–child relationships. There have also been significant advances in behavioral genetics, evolutionary biology, and developmental neuroscience since Bowlby's time, as well as advances in research methodology. It is natural that Bowlby's heirs would update, elucidate, and expand his formulations in ways that he could not anticipate in their efforts to keep the theory current with advancing knowledge. Furthermore, as would be expected of a conceptually innovative approach, Bowlby's theory provides a conceptual umbrella for broad and narrow constructions of the developmental impact of attachment relationships. Grossmann (1999), for example, has identified at least two different conceptualizations of "internal working models" in Bowlby's theory (and two others are profiled below). The breadth of Bowlby's theory offers room for diverse explanations for the impact of early attachment based on the biologically adaptive qualities of attachment relationships, the quality of parent–child interaction, the dynamics of personality growth, emergent social representations, developing stress neurobiology, and other influences. Beyond theoretical breadth, of course, is the fact that subsequent attachment researchers have had their own ideas about the influence of early attachment security, which they have sought to harmonize with Bowlby's formulations.

These are all signs of a vibrant, generative theory. Indeed, it can be argued that today the proper role of Bowlby's theory is not as a source of orthodoxy for attachment theorists (much as Freud's theory was treated in the early decades of psychoanalysis), but rather as a foundation for new thinking about early parent-child relationships. The problem this presents for contemporary researchers, however, is the proliferation of conceptual explanations for why early attachment might be associated with later development. Beyond the casual post hoc explanations offered by researchers for unexpected empirical findings, in other words, there have grown from the foundation of Bowlby's theory various attachment minitheories, with somewhat different views of the nature of the developmental influences arising from secure or insecure early relationships.

In this section, therefore, the goal is to summarize and evaluate several alternative views of the developmental influence of attachment that have become significant in contemporary attachment research. Each approach is discussed with respect to certain key conceptual questions. For which developmental domains is early security likely to be most important, and at what ages? How much should the effects of early attachment be expected to endure, and what mediators might affect its continuing influence? What are the conditions in which attachment should most influence later development? Although most approaches do not provide clear answers to all of these conceptual questions, the purpose in posing them is to clarify our thinking about why early attachment should be developmentally provocative.

Internal Working Models

One of Bowlby's most heuristically powerful formulations is the view that attachment security influences psychological growth through children's developing mental representations, or *internal working models* (IWMs), of the social world. IWMs are based on infants' expectations for the accessibility and responsiveness of their caregivers. These expectations develop into broader representations of their attachment figures, interpretations of their relational experiences, guidelines about how to interact with others, and even beliefs about themselves as relational partners. These mental representations initially enable immediate forecasts of the caregiver's responsiveness, and they expand into broader interpretive filters through which children and adults reconstruct their experience

of new relationships in ways that are consistent with past experiences and the expectations arising from secure or insecure attachments. As a consequence, children choose new partners and behave with them in ways that are consistent with, and thus help to confirm, the expectations created from earlier attachments. IWMs therefore constitute the bridge between an infant's experience of sensitive or insensitive care and the development of beliefs and expectations that affect subsequent experience in close relationships. This concept has been theoretically generative: Bretherton and Munholland (Chapter 4, this volume), Crittenden (1990), Main (1991), Sroufe and Fleeson (1988), Thompson (2006), and Dykas and Cassidy (2011) have each offered contemporary extensions of Bowlby's concept of IWMs.

In Bowlby's formulation, therefore, IWMs would be expected to be most directly associated with the child's capacities to create and maintain successful close relationships (with parents, peers, teachers, and others), establish a positive self-image, and develop constructive social representations of people and of relationships. However, because Bowlby used the IWM concept as a kind of conceptual metaphor rather than creating a rigorously defined theoretical construct, its abstraction has enabled this concept to assume wide-ranging explanatory breadth in attachment research. IWMs have been enlisted to "explain" the association between attachment security and a wide range of correlates, causing some to question whether IWMs constitute a "catch-all, post-hoc explanation" for almost anything to which a secure attachment is found to be associated (Belsky & Cassidy, 1994, p. 384). At the least, this use of the IWM concept has led to considerable uncertainty about its defining features, functioning, and measurement.

One solution to this problem of underspecificity is to clarify what IWMs are and how they develop. Unfortunately, theoretical views diverge among attachment researchers. While some researchers view IWMs as primarily unconscious, prelinguistic perceptual-affective processes akin to the Freudian dynamic unconscious, others regard IWMs as consciously accessible cognitive representations (Grossmann, 1999). Attachment researchers also differ in how IWMs function (Thompson, 2008b). To Dykas and Cassidy (2011), for example, IWMs govern information processing, and individuals with secure attachment histories are more likely to process, in an open manner, a broad range of positive and nega-

tive information related to attachment concerns in a positively biased manner. By contrast, insecure individuals are more likely to defensively exclude information that is likely to lead to psychological pain, such as the child who “forgets” being abandoned in childhood, but if information does not risk psychological pain, they will process this information in a negatively biased fashion. Thompson (2006, 2010) focuses instead on the content of IWMs, arguing that secure individuals are likely to have more constructive representations of other people, more positive expectations for social interaction, greater social and emotional understanding, more positive self-concept, and more advanced conscience development compared to insecurely attached individuals. In this view, IWMs develop in concert with other allied advances in event representation, social expectations, autobiographical memory, self-awareness, and a variety of other social-cognitive skills. In this view, moreover, IWMs are shaped by not only the child’s direct relational experience but also secondary representations through conversational discourse with adult caregivers, reflecting the significance of language for providing young children with insight into others’ motivations, thoughts, and feelings, relationships, and the self. Rich, supportive conversational discourse, especially about difficult issues, thus becomes another manner by which parental sensitivity is manifested and contributes to the intergenerational transmission of attachment working models (Thompson, 2010).

These alternative formulations are not necessarily mutually exclusive, although they have different implications for how IWMs influence social behavior, their accessibility, and the factors influencing consistency and change in IWMs over time. However, these alternative views share in common the expectation that IWMs change developmentally with the child’s conceptual advances and that social experience is formative to the development and potential revision of early IWMs. The field needs greater theoretical development of the IWM construct, building on Bowlby’s theory and subsequent advances in developmental science, to guide thinking about their development, behavioral influences, and measurement.

Emergent Personality Organization

Another conceptualization of the influence of early attachment on later development is that attachment security shapes emergent personality processes in infancy and early childhood which,

as they mature and become consolidated, exert a continuing influence on subsequent personality growth. Early attachment is important because it inaugurates adaptive or maladaptive organizational processes in personality that render young children more or less competent in facing subsequent challenges in personality growth.

This view is best articulated in the “organizational perspective” that has been advanced by Sroufe (2005; Sroufe, Egeland, Carlson, & Collins, 2005) and others (e.g., Cicchetti, 2006). This neo-Eriksonian perspective portrays personality growth as a succession of developmental challenges around which critical aspects of personality development are organized. During the first year, of course, the development of a secure attachment is central. In successive years, relevant developmental issues include the growth of an autonomous self in toddlerhood, the acquisition of effective peer relationships in preschool, successful adaptation to school, coordination of friendship and group membership in middle childhood, and identity and self-reflection in adolescence. The successful mastery of earlier developmental challenges is believed to provide a stronger psychological foundation for subsequent challenges because of the internal resources in personality organization that have developed and the supportive relationships on which the child can rely. In this view, therefore, the sequelae of early attachment security vary depending on the salient developmental challenges facing the child at subsequent ages, but in each case a secure attachment provides a better foundation for successful adaptation.

The organizational view is an influential and powerful model for attachment researchers, especially its description of the developmental challenges characterizing each stage of life. Moreover, the fact that these challenges tend to be broadly conceived permits attachment researchers to examine a wide variety of potential outcomes during each subsequent period of development. However, research from this perspective sometimes overlooks the continuing influence of supportive parental care, which may also contribute to the child’s developmental adaptation at each stage and its association with early attachment security, as described next.

Consistency and Change in Parent–Child Relationships

In infancy and early childhood, parent–child relationships are described as secure or insecure. By

adulthood, security is often viewed as an attribute of the person. Attachment theory seeks to explain how characteristics of relationships become incorporated into personality. In the developmental transition from attachment-as-relationship to attachment-as-personal-attribute, however, the continuing importance of the quality of parent-child relationships should not be overlooked. Stated simply, an early secure attachment provides a stronger foundation for subsequent psychosocial achievements if the sensitive, supportive parental care initially contributing to attachment security is maintained over time (Lamb, Thompson, Gardner, & Charnov, 1985). In that ongoing relationship of parental support, young children continue to enjoy the benefits of parental sensitivity in the rich sharing of parent-child conversation, their cooperative activity in learning and exploration, the emotional understanding and coaching that parents can provide, and in other ways. Children respond to parental support in these ways by becoming increasingly receptive to their parents' influences and socialization incentives as they identify with the adults' goals and behavior (Kochanska, 2002; Waters, Kondo-Ikemura, Posada, & Richters, 1991). However, if the earlier sensitive care that initially inspired a secure attachment is not maintained, there is less reason to anticipate that early attachment security would be associated with later positive behavior. In this view, therefore, the significance of early attachment for later development is contingent, to some extent, on the continuing sensitivity of parental care, especially in a child's early years.

In an empirical assessment of this formulation, Belsky and Fearon (2002) used data from the NICHD SECCYD. Analyzing attachment classifications in the Strange Situation at 15 months and subsequent measures of maternal sensitivity at 24 months, they reported that the children who obtained the highest scores on a broad range of social and cognitive measures at 36 months were those who were securely attached and who subsequently experienced sensitive care. Those performing most poorly at 36 months were insecurely attached in infancy and experienced later insensitive care. Of the two intermediate groups, children who were initially insecurely attached but who subsequently experienced sensitive care scored higher on all outcome measures than did children who were initially secure but later experienced insensitive care. These researchers also found that maternal reports of life stress, depression, social support, and family resources at infant age 24 months helped

to explain why some securely attached infants subsequently experienced insensitive maternal care, and why some initially insecure infants later experienced sensitive care. In each case, declines in maternal sensitivity were associated with the number of negative life events and lack of support that mothers experienced when children were age 2, which were likely to affect children as well as their mothers.

These findings are consistent with those reported by other researchers (e.g., Beijersbergen, Juffer, Bakermans-Kranenburg, & Van IJzendoorn, 2012; Sroufe, Egeland, & Kreutzer, 1990), and with the literature concerning the correlates of stability and change in the security of attachment (see Thompson, 2006, for a review). Taken together, they indicate that early security of attachment interacts with the quality of subsequent experience (particularly sensitive parental care and broader life stresses) in predicting developmental outcomes. Indeed, these findings suggest that later quality of care may be at least as important as early security in predicting later development. The continuing sensitivity of parental care may be especially important in the early years, when IWMs are still rudimentary and personality is taking shape. In this respect, the continuing harmony of the parent-child relationship may constitute a bridge between a secure attachment in infancy and the development of later personality and working models of relationships.

Biological Processes

Biological processes can mediate the association of early attachment with later developmental outcomes. There are three ways this may occur: through species-typical reproductive strategies, the effects of early experience on stress neurobiology, and genetic and epigenetic processes.

First, attachment was viewed by Bowlby (1969/1982) and his followers as an evolved behavioral system to promote the inclusive fitness of the human species. When infants seek the protective proximity of adults, especially when offspring are distressed, alarmed, or in danger, this behavior promotes survival to maturity and eventual reproductive success. This is most likely to occur when adults are sensitively responsive to the infant's cues and secure attachment develops. But patterns of insecure attachment can also be regarded as evolved adaptations to alternative forms of parental care to enable offspring survival, such as avoidance (and potential search for alternative

attachment figures) when the adult is consistently unresponsive, and resistance (and demand for support) when the adult is unreliably responsive (Chisholm, 1999). Viewed in this light, early attachment patterns can be regarded as *ontogenetic adaptations* that function to help individuals to reach maturity but have no necessarily enduring significance.

However, early attachments may instead be *deferred adaptations* that facilitate growth to maturity and also provide a foundation for lifelong behavioral patterns related to reproductive success (Bjorklund, 1997). This view is consistent with life history theory (Chisholm, 1999; Stearns, 1992). In an influential application of life history theory to attachment, Belsky, Steinberg, and Draper (1991) argued that the quality of parental care sensitizes young organisms to the supportiveness or aversiveness of the environment into which the children have been born, and this early experience thus affects not only the security of attachment but other behavioral adaptations related to reproductive success, such as the timing of pubertal maturation, the onset of sexual activity, preferences in pair bonding, and eventual parental investment in their own offspring (see also Simpson & Belsky, Chapter 5, this volume). In essence, children whose early family experiences are characterized by high stress (and consequent insecurity) are likely to develop reproductive strategies that are low-investment and opportunistic, whereas children in low-stress, secure families develop in the opposite manner. This formulation is important, therefore, for defining a somewhat wider range of later outcomes that are affected by early attachment and the quality of parental care. The range of outcomes depends, however, on whether attachment is viewed as an ontogenetic or a deferred adaptation.

Second, whether or not early attachment is viewed in the context of species-typical reproductive strategies, the stress or support of early experiences can have significant biological and behavioral consequences for young children. Several research literatures underscore how early experiences of chronic stress can alter the neurocircuitry of developing stress reactivity and other neurobiological systems, causing children to develop dysregulated patterns of stress responding that can undermine self-regulation, heighten threat vigilance, and blunt attentional focus and cognitive functioning (see review by Thompson, 2015). These early experiences of chronic stress can include enduring maternal depression and an adult's emo-

tional inaccessibility, as well as abusive events, underscoring the reliance of young children on adult solicitude. Consistent with this view, this research literature also shows that social support buffers the effects of stress, and an important manifestation of social support in early childhood is sensitive parental care. Thus one reason that early security or insecurity may be associated with later behavior is that the stress-buffering consequences of a secure attachment, especially for young children in difficult circumstances, enable better emotion regulation, socioemotional, and cognitive functioning. Although there is some evidence that securely attached infants show diminished biological markers of stress responding in the company of their mothers compared to insecurely attached infants (Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996; Spangler & Grossmann, 1993), more research is needed to determine the biological stress-buffering effects of secure attachment.

Third, genetic characteristics that contribute to a secure or insecure attachment may help to account for the later consequences of that attachment. Thus, for example, a child with a genetic polymorphism associated with impulsive behavior (i.e., the dopamine D4 receptor [DRD4] 7-repeat polymorphism) may be more likely to develop an insecure attachment in early childhood and also have later conduct problems. This has, however, proven to be a challenging formulation to study, even in the context of rapid advances in molecular genetics because large samples (typically much larger than those common to attachment research) are required to yield reliable conclusions concerning the association of specific polymorphisms with behavior (Roisman, Booth-LaForce, Belsky, Burt, & Groh, 2013). In light of the failure to confirm significant associations of hypothesized polymorphisms with attachment in at least one large data set (Roisman et al., 2013), and the finding of behavioral genetics research that the genetic component of variability in early attachment is negligible (Roisman & Fraley, 2008), further study is needed to determine whether early attachment is directly associated with specific polymorphisms and, if so, their association with later outcomes.

It is likely, however, that more complex gene \times gene and gene \times environment interactions characterize the development of attachment security. Moreover, emerging work in behavioral epigenetics suggests that experiential influences may be important to gene expression as they alter the biochemical regulatory system that activates, silences, or changes the transcriptional activity of

genes without altering structural DNA (see Bakermans-Kranenburg & Van IJzendoorn, Chapter 8, this volume). As the elegant rat pups studies of Meaney (2010) and his colleagues illustrate, the quality of maternal care is a major influence of early experience associated with gene expression (see Thompson, 2015, for a review). It is therefore possible to hypothesize that one of the consequences of a secure or insecure attachment is its epigenetic effects on gene expression, particularly genes associated with stress reactivity. It remains to be seen whether this is a promising means of understanding the behavioral correlates of early attachment security.

Interim Conclusion

It is apparent, therefore, that attachment researchers have a variety of conceptual approaches to guide their inquiry into the developmental outcomes of early security. Moreover, these formulations differ in important and meaningful ways. They emphasize different outcomes, for example: Some approaches highlight the relational consequences of early secure or insecure relationships; others, the representational consequences of attachment security; some highlight the influence of attachment on stages of personality growth, whereas others focus on reproductively adaptive strategies. Although some formulations view the continuing influence of parenting practices in childhood as a mediator of the enduring effects of early security, others make no such claim. In several approaches, the consequences of attachment security are developmentally graded—that is, the effects of attachment depend on when security is assessed and when outcomes are evaluated—but others offer more general predictions. Most of these approaches also expect stronger associations between attachment security and its contemporaneous correlates than those in long-term predictive relations, but they differ in the reasons why.

These conceptual differences are important because they have implications for research design (Thompson, 2000; Thompson & Raikes, 2003). If, for example, researchers expect that later behavior arises from an interaction between early security and the continuing quality of parental care, it is important to measure each of these factors in follow-up studies. Likewise, other potential moderators of this association should also be assessed, such as family stress or the child's biological individuality. Furthermore, the association of

attachment with the *rate of change* in psychosocial outcomes is a potentially important but underexplored implication of several of the formulations discussed earlier. In the research review that follows, promising examples of research designs such as these are highlighted. Unfortunately, most of the research uses a straightforward pre–post design in which early attachment is associated with outcomes measured later (and sometimes attachment and outcomes are measured contemporaneously) in which potential mediators are unmeasured and causal associations are sometimes obscured. With the current effort to better understand the processes underlying direct and indirect consequences of attachment security, informed by ideas from developmental neurobiology, life history theory, personality theory, and new ideas about the development of representation and relationships from developmental science, we can hope that there will be further advances in the use of research designs that are equal to the conceptual richness of this field.

Empirical Perspectives

Consistent with these conceptual perspectives, this review of research is organized according to the various outcome domains to which attachment security has been theoretically and empirically associated most strongly. The review begins with the relational outcomes anticipated from a secure attachment (warmer subsequent parent–child relationships, closer relationships with peers and other partners); then moves on to personality outcomes and emotion regulation. It then examines work on the representational correlates and outcomes of a secure attachment—emotion understanding, social cognition, conscience, and finally self-concept. The biological processes associated with attachment security have been studied most recently and this chapter touches on the more limited findings that this work has yielded. The prediction of early attachment relative to risk for psychopathology is also an important outcome domain, but it is not considered in this chapter because it is discussed extensively elsewhere in this handbook (see DeKlyen & Greenberg, Chapter 28, and Lyons-Ruth & Jacobvitz, Chapter 29). In light of the enormous empirical literature in this area, this review should be viewed as a selective, not an exhaustive, overview of the major findings and important new directions for research.

Parent–Child Relationship

The strongest and most direct outcome of a secure attachment should be more positive parent–child interaction in follow-up assessments. This expectation has been partially confirmed in a series of short-term longitudinal studies in which securely attached children showed greater enthusiasm, compliance, and positive affect—and less frustration and aggression—during shared tasks with their mothers during the second year (e.g., Frankel & Bates, 1990; Matas et al., 1978), although longer-term associations between infant security and parent–child interaction at ages 3 (Youngblade & Belsky, 1992) and 5 (Van IJzendoorn, van der Verr, & van Vliet-Visser, 1987) were inconsistent. These and other studies suggest that securely attached infants tend to maintain more harmonious relations with their mothers, but (as discussed earlier) this likely depends on consistency over time in the quality of mother–child interaction. Consistency in the quality of parent–child interaction over time is often mediated by intervening events, such as family stress, significant changes in family circumstances (such as parental separation or divorce), or other conditions affecting relational harmony (Thompson, 2006). Viewed more broadly, early security seems to inaugurate what Kochanska (2002) describes as a “mutually responsive orientation” between parent and child that, if maintained, contributes to shared cooperation, the socialization of behavior and values, and the child’s enthusiastic responsiveness to the parent’s incentives.

If this is so, it suggests that the security of attachment is not only a direct predictor of developmental outcomes but also a moderator of other aspects of parent–child relationships that contribute to those outcomes. Parenting stress may, for example, more strongly predict later problem behavior for children who are in insecure relationships with their parents than for secure children (Tharner et al., 2012). Another example comes from a longitudinal study in which parents’ observed power assertion with their 2- to 3-year-olds predicted a composite of measures of children’s “resentful opposition to parents” at age 4½, which in turn predicted children’s antisocial conduct at age 5½. These associations were observed only for children who had been insecurely attached in infancy, however, and they were absent for securely attached children (Kochanska, Barry, Stellern, & O’Bleness, 2009). Similar findings were reported by Kochanska and Kim (2012). In each study,

the direct associations between attachment and later outcomes were weak or nonexistent. Taken together, these findings suggest that early attachment can either contribute to or buffer the development of broader characteristics of the parent–child relationship—cooperativeness, negative reactivity, responsiveness—to which other child and parent characteristics also contribute.

Consistent with attachment theory, moreover, children’s secure or insecure representations of their family relationships also mediate the effects of family processes on developmental outcomes. The research program of Cummings, Davies, and their colleagues illustrate these processes. In one longitudinal study, for example, first graders’ insecure representations of their parents’ marital relationship explained the association between interparental conflict observed 1 year earlier and children’s emotional and classroom difficulties in second grade (Sturge-Apple, Davies, Winter, Cummings, & Schermerhorn, 2008). Heightened interparental conflict was associated with greater insecurity a year later, and with school difficulties a year after that. In a similar manner, the effects of parental depressive symptomatology on second graders’ externalizing problems were mediated by children’s insecure representations of family relationships assessed 1 year earlier (Cummings, Schermerhorn, Keller, & Davies, 2008). It is not easy to assess young children’s representations of relationships, but further attention to these representations as mediating and moderating influences on developmental outcomes is clearly warranted, especially with evidence that these representations may emerge very early (at least when studied using visual expectancy paradigms in infancy; see Johnson, Dweck, & Chen, 2007). In therapeutic contexts, for example, it may not be enough to change the behavior of a parent who has been an inadequate or abusive caregiver without also altering the child’s mental expectations for the behavior of that adult (see, e.g., Toth, Maughan, Manley, Spagnola, & Cicchetti, 2002).

Other Close Relationships

Another relational context in which the benefits of early security might be observed is peer relationships. In a meta-analysis, Groh and colleagues (2014) found a robust association between child–mother attachment and peer social competence: Avoidant, resistant, and disorganized children each showed comparably lower levels of peer competence relative to secure children. The

association of attachment and social competence with peers did not vary by children's age or the amount of time between attachment and peer assessments. Interestingly, and contrary to earlier meta-analytic findings, the association was *weaker* when social competence with friends was compared to competence with nonfriends (see Pallini, Baiocco, Schneider, Madigan, & Atkinson, 2014, for similar meta-analytic results). It appears, however, that attachment security is important both to the development of peer social competence and of friendships, although different developmental processes may be involved with each.

Building on these findings, attachment researchers have delved into why these associations exist. Raikes, Virmani, Thompson, and Hatton (2013), enlisting the NICHD SECCYD longitudinal sample, used growth curve modeling to show that children decreased in peer conflict from preschool to first grade, but securely attached children (assessed at 24 months) showed a steeper decline over this period and were lower in peer conflict in first grade. Also, children with greater social problem-solving skills and lower hostile attributions showed lower levels and greater declines in peer conflict. Raikes and Thompson (2008a), using the same NICHD SECCYD sample, showed further that children with early secure attachment showed enhanced social problem-solving skills and diminished hostile attribution bias at 54 months and in first grade. Securely attached children were also less lonely than insecure children, reflecting the self-referential elements of peer social competence (see also Berlin, Cassidy, & Belsky, 1995). These social representations may be shaped by aspects of mother-child interaction associated with a secure attachment. McElwain, Booth-LaForce, and Wu (2011) reported that talk about mental states during play with their 24-month-olds was more characteristic of the mothers of secure than insecure children, and that attachment indirectly influenced the quality of children's friendships at 54 months and first grade through maternal mental-state discourse. In another study with the NICHD SECCYD sample, mother-child affective mutuality at 54 months was one avenue by which early attachment security predicted friendship quality in third grade (McElwain, Booth-LaForce, Lansford, Wu, & Dyer, 2008). The emotional catalysts of mother-child interaction and discourse, children's constructive social representations, their social self-confidence, and greater social skills are among several developmental processes by which

early attachment security can influence later peer relationships. Others meriting further exploration include parents' coaching social skills and the opportunities provided by parents to socialize with other children (see Berlin, Cassidy, & Appleyard, 2008).

As young children's social worlds expand, they develop relationships with a broader range of adults and children, with some adults (e.g., care providers and early childhood teachers) assuming a caregiving role. Relationships with these adults are affected, as we would expect, both by the child's relational history (e.g., mother-child attachment security) and by the specific characteristics of that adult, such as his or her sensitivity and responsiveness (see reviews of this research by Ahnert, Pinquart, & Lamb, 2006; Berlin et al., 2008; Howes & Spieker, Chapter 15, and Williford, Carter, & Pianta, Chapter 41, this volume). Throughout these experiences, children with secure attachments are more competent at creating and maintaining more extensive and supportive social networks, and experiencing greater social support as a result (see, e.g., Anan & Barnett, 1999; Booth, Rubin, & Rose-Krasnor, 1998; Bost, Vaughn, Washington, Cielinski, & Bradbard, 1998). These social and emotional resources are likely to offer secure children many benefits in their interactions with others, further underscoring the indirect, as well as direct, avenues by which secure attachment contributes to psychological well-being.

Personality

The largest and most comprehensive study of early attachment and its developmental consequences is the Minnesota Study of Risk and Adaptation from Birth to Adulthood (Sroufe, 2005; Sroufe et al., 2005). This prospective longitudinal study of children and families in poverty focused on the association between attachment and personality, thus enlisting the "organizational perspective" described earlier. In this study, children were recruited in infancy with their families and followed through age 34 years. Strange Situation observations were conducted at 12 and 18 months; in the years that followed, personality characteristics were assessed regularly through behavioral observations, interviews, observer ratings, self-reports, and semiprojective instruments.

The reports based on this study revealed significant associations between early attachment se-

curity and personality characteristics throughout childhood and adolescence, including relations with measures of emotional health, self-esteem, agency and self-confidence, positive affect, ego resiliency, and social competence in interactions with peers, teachers, camp counselors, romantic partners, and others (see Sroufe et al. [2005] for a detailed discussion, including a list of citations to specific research reports). The researchers concluded that the association between attachment security in infancy and emergent personality owed primarily to the continuing quality of care—or, in the authors' words, "continuity at this age is still primarily at the level of the relationship" (Sroufe et al., 2005, p. 110).

As children matured, moreover, the continuing importance of early attachment was in the context of subsequent developmental influences. Sroufe and his colleagues found that the prediction of later personality was enhanced when early attachment measures were supplemented by other indicators of the quality of subsequent care, which could transform as well as sustain the effects of early security (see Carlson, Sroufe, & Egeland, 2004). Moreover, as time progressed between Strange Situation assessments and later personality outcomes, the effects of early security were more likely to be indirect—mediated and/or moderated by subsequent relational influences (Sroufe, Cofino, & Carlson, 2010). In recognizing that personality outcomes are multidetermined and that attachment security is only one of many constituent influences, in other words, these researchers emphasized that both developmental history and current experience are important in shaping personality growth.

The Minnesota study has been an important and provocative contribution to the research on the consequences of early attachment, and it is one of the most important studies to document long-term associations between attachment security and later personality outcomes. Few other studies have sought to replicate the findings reported from this study, however, but in view of some nonreplications (e.g., Bates, Maslin, & Frankel, 1985; Easterbrooks & Goldberg, 1990), continued efforts to confirm and extend these important findings are warranted. Equally important are future studies that are designed, as was the Minnesota study, to view the significance of early attachment security in the context of subsequent developmental influences on multidetermined personality outcomes (see Sroufe, Chapter 43, this volume).

Emotion Regulation

One of the functions of attachment relationships is to assist in regulating children's emotions, especially emotions that are potentially disturbing or overwhelming (Cassidy, 1994; Thompson, 1994). This is most evident when parents respond sensitively to the distress of their infants, but it is also an ongoing feature of secure relationships, even as children mature and become more capable of emotion self-regulation. Moreover, through the parents' acceptance of children's emotions and willingness to communicate openly about them, parents in secure relationships foster children's developing emotional awareness and scaffold the growth of competent, flexible skills in emotion self-regulation. Thus children in secure relationships are stronger in emotion regulation than are children in insecure relationships, in which parents may be more dismissive, punitive, or critical of the children's emotional expressions (Thompson, 2015).

The relevance of a secure attachment to emotion regulation is apparent from infancy through adolescence, and is observed behaviorally and neurobiologically. In a study of the responses of 18-month-olds to moderate stressors, for example, Nachmias and colleagues (1996) reported that postsession cortisol elevations were found only for temperamentally inhibited toddlers who were in insecure relationships with their mothers. For inhibited toddlers in secure relationships, their mothers' presence helped to buffer the physiological effects of challenging events. Gilliom, Shaw, Beck, Schonberg, and Lukon (2002) reported that boys who were securely attached at age 1½ were observed to use more constructive anger management strategies at age 3½. Securely attached boys were more likely to use distraction, ask questions about the frustration task, and wait quietly than were insecurely attached boys. Contreras, Kerns, Weimer, Gentzler, and Tomich (2000) found that security in middle childhood was significantly associated with children's constructive coping with stress, and that the measure of coping mediated the association between attachment and children's peer competence.

A variety of influences can help to account for the association between secure attachment and more competent emotion regulation skills (Thompson, Virmani, Waters, Meyer, & Raikes, 2013). Securely attached infants can better enact behavioral strategies (e.g., proximity seeking) that

are likely to result in greater emotion management by the mother (Leerkes & Wong, 2012). Mothers in secure relationships are likely to perceive and interpret more sensitively their children's emotions as they arise (Waters et al., 2010), and they are more likely to talk with children about their emotion-related experiences in a richly elaborative manner (Laible & Thompson, 2000; Ontai & Thompson, 2002). Perhaps as a consequence, securely attached children have greater depth in their emotion understanding, including their appreciation of effective emotion regulation strategies (Waters & Thompson, 2014). These intervening influences contribute to an awareness of the multiple avenues by which secure and supportive caregiving relationships foster the growth of emotion regulation skills.

Emotion Understanding

Several attachment researchers have proposed and tested the hypothesis that owing to the greater psychological intimacy they share with the attachment figure, securely attached children should have deeper emotion understanding than insecure children. Several studies have confirmed this to be true in contemporaneous associations with preschoolers using the Attachment Q-Sort (AQS; Laible & Thompson, 1998; Ontai & Thompson, 2002), and in predictive associations with infant Strange Situation classifications (Steele, Steele, Croft, & Fonagy, 1999) or early childhood AQS ratings (Raikes & Thompson, 2006). Secure children are indeed more proficient at identifying emotions in others and, in some cases, empathizing with them (Murphy & Laible, 2013). These studies also indicate that securely attached children are especially skilled at understanding negative emotions and mixed feelings, which are conceptually more complex than positive emotions.

Several studies have sought to understand the relational catalysts of this enhanced emotion understanding. They have drawn on Bowlby's (1973) portrayal of the emotionally more open communication between securely attached children and their caregivers that enables more candid sharing and discussion—particularly of negative emotions, which may be more troubling, disturbing, or confusing to young children (see Bretherton & Munholland, Chapter 4, this volume). Ontai and Thompson (2002) and Laible (2004) found that more secure preschoolers had mothers who, in discussions with them of recent past events and in storybook reading, used a more descriptively rich,

elaborative style of conversation about emotion. These findings are consistent with others indicating that the mothers of secure children use a more elaborative conversation style with offspring, which has also been found to enhance young children's memory representations and autobiographical recall, as well as emotion understanding (Reese, 2002). Mothers in secure relationships have been found to provide greater validation and support of their child's viewpoint and to engage in greater coaching of emotion regulation (Raikes & Thompson, 2008b; Thompson et al., 2013). Indeed, Raikes and Thompson (2006) found that the quality of mother-child conversations about emotion mediated the association between attachment security and emotion understanding in 3-year-olds. In reciprocal fashion, preschool children in secure relationships spontaneously talk about emotions more often in their everyday conversations with their mothers (Raikes & Thompson, 2008b).

When talking about shared events in a rich, interactive, elaborative manner, the mothers of securely attached children are likely to provide them with enhanced understanding of the psychological dimensions of human interaction and of the influence of emotions and other mental phenomena in everyday events (Thompson, Laible, & Ontai, 2003). This is important for at least two reasons. First, as described below, it provides an avenue by which emotion understanding becomes enlisted into other developmental achievements, including social-cognitive understanding and conscience development, in which securely attached children are also more proficient. Second, it promotes in young children the capacity for mentalization that may be at the heart of secure relationships and their intergenerational transmission (see Fonagy Luyten, Allison, & Campbell, Chapter 34, this volume).

Social Cognition

Enhanced understanding of emotions may contribute to the greater social competence of secure children. In a study by Denham, Blair, Schmidt, and DeMulder (2002), multiple measures of attachment security were obtained when children were age 3, along with several measures of emotional competence (including assessments of emotion understanding, emotion regulation, and anger expression). Children were subsequently studied in their kindergarten classrooms to assess peer social competence. The researchers confirmed a direct pathway from early attachment security

to kindergarten social competence and also an indirect pathway through children's emotional competence. The greater emotion understanding of securely attached children benefits their social interactions with peers.

Secure attachment is also associated with other social-cognitive contributors to peer competence. In three studies, Cassidy, Kirsh, Scolton, and Parke (1996) examined the association between attachment and children's attributions concerning peer motivation. Infant attachment classifications were not strongly predictive of preschoolers' responses to story questions concerning the motivations of peer story characters when their negative behavior had ambiguous intent. But when attachment and attributional probes were assessed contemporaneously, securely attached kindergartners and first graders responded as predicted: Secure children were more likely to attribute benign motives to, and insecure children to infer hostile intent in, the story characters. Moreover, these attributions concerning peer motivation were found to mediate the association between attachment security and peer friendship nominations in a sociometric procedure. Ziv, Oppenheim, and Sagi-Schwartz (2004) examined differences in social information processing in Israeli middle schoolers on the basis of infant attachment classifications. Based on children's responses to interview questions after watching a filmed series of peer interaction vignettes, the researchers found that there were no differences on questions concerning the encoding or interpretation of social behavior or generation of alternative responses, but securely attached youth were more likely to believe that peers would respond positively and constructively to competent social initiatives.

Analyzing data from the NICHD SECCYD, Raikes and Thompson (2008a) examined the association between early attachment security (at 15 months in the Strange Situation, 24 months based on the AQS, and 36 months in the modified Strange Situation for preschoolers) and several measures of social cognition when children were 54 months and in first grade. They found that children deemed resistantly attached at 36 months were more likely to make negative motivational attributions to peers as first graders than were secure children (replicating Cassidy et al., 1996). Securely attached children at 24 and 36 months were more likely to identify socially competent and relevant solutions to social problem-solving tasks than were insecure children. This study is noteworthy for several reasons. First, in each of

these predictive outcomes from attachment security, researchers controlled for the influence of parenting (including maternal sensitivity and depressive symptomatology) at multiple assessments to ensure that these were outcomes of early security rather than of continuity in parenting practices. Second, the prediction of these social-cognitive variables was especially strong when children were securely attached at more than one assessment. Finally, infant Strange Situation classifications never predicted later social cognition, perhaps because of the more rudimentary IWMs underlying infant attachments compared to attachments at 24 and 36 months of age (Thompson, 2000).

Taken together, these findings suggest that the enhanced peer social competence of securely attached children derives from a variety of social-cognitive skills related to emotion understanding, attributional tendencies, social problem-solving skills, and social expectations, consistent with Bowlby's IWM construct. But what about social cognition in relation to partners other than peers? There has been much less research on this topic, and existing studies are less clear. With respect to theory of mind, for example, studies of false-belief understanding have yielded a mixed pattern of results, and even when methods were adapted to characteristics of the mother-child relationship, securely attached children have shown no consistent advantage (e.g., Meins, Fernyhough, Russell, & Clark-Carter, 1998; Meins et al., 2002; Ontai & Thompson, 2008). But other social-cognitive capacities may be more relevant to attachment security. In an intriguing study, Corriveau and colleagues (2009) asked whether the security of attachment in infancy would predict children's judgments of the credibility of information provided by the mother compared to an adult stranger more than 3 years later. Three tasks involving ambiguous stimuli were used in which the mother and the stranger offered different interpretations of the stimuli. In two tasks, either adult could plausibly be correct, but in the third task, the stranger was more clearly correct than mother. Securely attached children accepted the mother's judgment when she was plausibly correct but used the stranger's information when it was apparent that the stranger was correct. By contrast, insecure-resistant children relied on the mother's information in all tasks, and insecure-avoidant children did not use the mother's judgments even when she might be accurate. Studies like this underscore the value of further studying both person-specific and generalized social understanding derived from

mother–child relationships and the influence of attachment security on this understanding.

Conscience

Conscience concerns the young child's development and application of generalizable standards of conduct, and is thus viewed as an early foundation of moral development. Kochanska (2002) has argued that one of the motivators of conscience development is the young child's commitment to maintaining a relationship of warm, mutual responsiveness with the caregiver. In this respect, a secure attachment might be expected to be associated with greater compliance and cooperation, and this association has been confirmed (Kochanska, Aksan, & Carlson, 2005; Laible & Thompson, 2000). Kochanska (1995) has also shown that a secure attachment is especially influential for children who are temperamentally relatively fearless; for these children, the emotional incentives of the mother–child relationship (rather than the anxiety provoked by discipline practices) motivate conscience development.

As in research on emotion understanding, researchers have also sought to understand in more depth the role of attachment, in relation to other developmental influences, in the growth of conscience. Kochanska, Aksan, Knaack, and Rhines (2004) reported that for securely attached children (assessed in the Strange Situation at 14 months), the parents' responsiveness and use of gentle discipline (from 14 to 45 months) predicted later conscience (assessed at 56 months in assessments of morally relevant behavior and thinking), but that for insecure children, there was no such association. These findings complement other studies, reviewed earlier, documenting a negative developmental trajectory from parental power assertion to child noncompliance that was observed only for insecurely attached children, and suggest that parental practices have differential emotional impact depending on the security of child–parent attachment. Indeed, there is further longitudinal evidence that a secure attachment helps to amplify the benefits of early, positive parent–child influences for later conscience development (Kochanska et al., 2010). Other research shows that mothers of secure preschoolers are more likely to use justifications and compromise and less likely to aggravate conflict during disputes with their children (Laible, Panfile, & Makariev, 2008).

These findings offer a new perspective on early moral development. Contrary to the tradi-

tional view that young children comply with their parents to avoid negative sanctions, these studies suggest that the positive incentives of mutually cooperative, secure parent–child relationships are motivationally very important in conscience development. Moreover, several studies suggest that when mothers focus attention on people's feelings and needs, rather than rules and the consequences of breaking them, conscience development is enhanced because it enlists young children's capacities for emotion understanding (Laible & Thompson, 2000, 2002; also see Thompson & Winer, 2014). Taken together, these findings suggest that a new approach to early moral development is needed to better recognize the humanistic, relational foundations of early conscience (Thompson, 2012).

Self-Concept

Bowlby's (1969/1982, 1973, 1980) argument that attachment security influences young children's self-concept, particularly their conceptions of themselves as loved and lovable, has guided several research inquiries into attachment and self-concept. Cassidy (1988) found that securely attached 6-year-olds described themselves in generally positive terms in a puppet interview but were capable of admitting that they were imperfect (i.e., they were flexible or "open"). Insecurely attached children either revealed a more negative self-image or resisted admitting flaws, and similar results were reported by Verschueren, Marcoen, and Schoefs (1996). Clark and Symons (2000) also found that attachment at age 5 (on the AQS) was significantly associated with the positivity and openness of children's responses to a contemporaneous puppet interview, but not with self-esteem, although a previous assessment of attachment at age 2 (also using the AQS) was not associated with either measure. Goodvin, Meyer, Thompson, and Hayes (2008) found that AQS attachment at age 4 predicted the positivity of young children's self-concept at age 5, even when they controlled for contemporaneous attachment security. Secure children also viewed themselves as more agreeable and as expressing less negative affect. Doyle, Markiewicz, Brendgen, Lieberman, and Voss (2000) found that secure attachment was associated with a more positive self-concept in young adolescents.

Each of these studies measured explicit self-concept in young children. Only two studies have measured implicit self-concept. One was by Colman and Thompson (2002), who presented

5-year-olds with both manageable and difficult puzzle tasks. Children with lower AQS security scores spontaneously expressed more self-doubt about their abilities or negative self-appraisals during *both* tasks, such as saying, "This is too hard for me." The second study was by Cassidy, Ziv, Mehta, and Feeney (2003) who examined the association between security and children's preferences for receiving positive or negative feedback about the self. They found that a more secure attachment was associated with seeking more positive feedback about the self, and that this association was mediated by global self-worth.

Thus, research on implicit self-concept is consistent with the findings of young children's explicit self-descriptions in highlighting the more positive self-representations of securely attached children. More research is needed into *why* attachment has these associations with self-concept. One clue comes from the previously described study by Goodvin and colleagues (2008). In this sample, a composite measure of the mother's emotional stress was negatively associated with her child's positive self-concept. In another longitudinal clinical study, maternal depression when children were 20 months old was associated with young children's concurrent attachment insecurity and their insecurity at 36 months, which in turn predicted negative representations of the self at 48 months (Toth, Rogosch, Sturge-Apple, & Cicchetti, 2009). Each study supports a view of more supportive parent-child relationships (and better parental functioning) contributing to more positive self-representations by young children.

Conclusion

This review does not exhaust the range of correlates and outcomes of early attachment security that have been studied. But by focusing on these, it is possible to evaluate the outcomes most germane to Bowlby's theory and to derive lessons for the future of attachment research.

What Have We Learned?

In the broadest sense, the picture that this vast empirical literature yields is both encouraging and daunting. On the one hand, there is a broader, more coherent network of correlates and outcomes of early attachment security than has ever before been revealed. This literature indicates,

usually in replicated findings, that children with a secure attachment history are capable of developing and maintaining more supportive relationships, especially with their parents and with peers, than are insecure children; they develop a variety of desirable personality qualities in childhood and adolescence; they are more likely to exhibit constructive forms of emotionality and emotion self-regulation; and they exhibit more positive self-regard in both explicit and implicit assessments of self-concept. Some of the more interesting recent findings come from studies of the representational correlates and outcomes of attachment security. Securely attached children exhibit greater emotion understanding, demonstrate more competent social problem-solving skills, assume more benign attributions for peers' motivations in ambiguous situations, are more advanced in conscience development, and are less lonely than are insecurely attached children.

Early security clearly makes a significant difference for psychological development, but more progress is needed in the design of research to elucidate *why* this difference occurs. There are clues. Early security is more strongly associated with psychological sequelae when children continue to experience sensitive parental care, and security is maintained over time. The content and quality of mother-child conversation may be part of that sensitive parental care, with the mothers of secure children conversing with their offspring in more elaborative and psychologically supportive and informative ways. Attachment security may also mediate the effects of other parenting practices on early psychological development and contribute to trajectories of positive or negative parent-child interaction and child well-being over time. Early secure or insecure attachment may thus be especially predictive of later psychological outcomes when it is considered in the context of broader aspects of parental care and family life. The social-cognitive advantages of children with a secure attachment history are important mediators of their social competence, especially with peers and other relational partners. In addition, how secure and insecure children perceive themselves and their own characteristics may be another significant contributor to their better psychological functioning. Attachment security may be important not only for how young children think but also how they attend to, process, and remember events related to their relational experiences. Finally, research in this field is increasingly examining three potentially important mediators of the influence of attachment on

psychological development: the effects of attachment security as a biological buffer of stress, the influence of supportive parental care on the development of self-regulatory capacities, and the value of a secure attachment for the growth of psychological understanding and mentalizing ability.

Future Directions

These important clues to how early attachment influences later psychological functioning constitute an agenda for future study. Future advances in understanding the association between early attachment and psychological growth will occur as studies are designed to examine more incisively the intervening processes that connect them, consistent with this third stage of research on early attachment and its sequelae. Carefully designed longitudinal research and analytical designs that enable the detection of direct and mediated associations between attachment and later outcomes are likely to be important contributions to that productive future research literature. In addition, consistent with some of the more exciting research insights of this field, exploration of continuing parental influences (e.g., conversational fluency, discipline practices), contextual demands (e.g., family stress and disruption), biological processes (e.g., stress reactivity, genetic and epigenetic influences), representational processes (e.g., self-referential beliefs, motivational influences), and self-regulatory processes mediating attachment and its outcomes will be especially informative. Moreover, the one study that has used growth curve modeling to examine the association of attachment security with the *rate of change* in psychosocial functioning (Raikes et al., 2013) offers a model for how other researchers can exploit the benefits of longitudinal research to elucidate the impact of attachment on psychological development.

Further understanding of these developmental processes will benefit from continued use of meta-analysis to elucidate the strength of the associations between attachment and developmental outcomes, and the various influences that can mediate these associations. Moreover, research in this field will continue to benefit significantly from the secondary analysis of large-sample longitudinal data sets in which attachment measures have been included. Along with this benefit, however, there are two cautions. The first is that the availability of these data sets further encourages attachment researchers to examine atheoretically the predictive association of attachment with any and all possible outcomes (after all, the data are available

for doing so), then to devise post hoc explanations for the significant associations that emerge, often without consideration of whether direct or mediated explanations are best warranted. This data-driven approach is problematic for the construction and clarity of attachment theory. The second caution is that researchers' strong reliance on the NICHD SECCYD data set compels greater attention to replication and confirmation of findings yielded by a single, albeit uniquely informative, data set.

This chapter has devoted comparable attention to theoretical and empirical perspectives because their integration has been generative for attachment research. Theory development remains, therefore, another important future goal. "All good things go together" is not a sophisticated developmental theory, but the ever-widening network of outcomes to which attachment security has become associated and the failure to attend to discriminant validity of the attachment construct combine to undermine the clarity of what a secure attachment means and contributes to early development. If attachment theory does not have a coherent explanation for this variety of outcomes, and cannot provide a clear account of what outcomes should *and should not* be related to early security, the integrity of the attachment construct is in doubt because theory development cannot be bootstrapped by findings of empirical research alone without potentially holding attachment theory accountable for formulations it should not and perhaps cannot embrace. Future research must be designed to examine, therefore, in a theory-driven manner, both the convergent and the discriminant validity of the attachment construct, and the extent to which the associations between attachment and other behaviors derive from theoretically predicted mediators (see also Sroufe, Chapter 43, this volume).

Attachment research continues to be vigorous and exciting decades after Bowlby's theory (Cassidy, Jones, & Shaver, 2013). These new avenues to explore are one reason why.

Chapter 17

Attachment in Middle Childhood

Kathryn A. Kerns
Laura E. Brumariu

Research on children's attachments in middle childhood is a relatively new area of inquiry. The first chapter on the topic appeared in the second edition of the *Handbook of Attachment* (Kerns, 2008). Our goals in this chapter are to provide an update on what we know about attachment in middle childhood (7–12 years of age) and to highlight areas in need of further study. Several themes are highlighted. First, we now have a greater understanding of the key features of attachment in middle childhood. Second, there continue to be clear differences in opinion regarding how to conceptualize and measure attachment in this age period, and still surprisingly thin data on the validity of attachment assessments for this period. Finally, as in other developmental periods, attachment is related to parenting and to children's social, emotional, and cognitive development. Following the elaboration of these themes, we conclude with several recommendations for future research.

The Nature of Attachment in Middle Childhood

The developmental period of middle childhood can be distinguished from both early childhood and adolescence. In early childhood, children's social worlds are largely oriented around and

shaped by family members. Even if young children spend substantial time outside the home (e.g., in day care), parents are clearly the primary social figures in children's lives, and they often function not only as attachment figures but also as teachers and playmates. In middle childhood, children's social worlds expand: They may spend significant time away from parents, and parents may have less control and influence over the environments and social contacts children experience. Entrance to formal schooling places new demands on children and provides an important context for mastery or failure experiences. Peers take on greater salience, and by middle childhood, children have a clear preference for peers rather than parents as playmates (Kerns, Tomich, & Kim, 2006; Seibert & Kerns, 2009). Children become more self-reliant and assume greater responsibility for their behavior both at home and at school. There are also important advances in metacognition, memory, and cognitive flexibility; greater self-awareness, more consideration of psychological traits, and enhanced understanding of others; and a greater capacity to regulate emotions (Raikes & Thompson, 2005). Children also begin to undergo the physical changes associated with puberty (Richardson, 2005). Middle childhood can also be distinguished from adolescence; during the latter period, children gain increasing

independence (autonomy from parents, greater decision-making authority). For example, there may be a normative shift toward greater avoidance or a more dismissing attitude toward parental attachments between late middle childhood and early adolescence (Ammaniti, Van IJzendoorn, Speranza, & Tambelli, 2000), and there is an emergence of attachments, including romantic ones, to peers in late adolescence (see Allen & Tan, Chapter 19, this volume).

We believe there are four defining features of attachment in middle childhood. First, Bowlby (1987; cited in Ainsworth, 1990) suggested that the goal of the attachment system changes from *proximity* to the attachment figure in early childhood to the *availability* of the attachment figure in middle childhood. Thus, in contrast to preschoolers, a boy or girl in middle childhood is content with longer separations and increased distance from the attachment figure, as long as he or she knows that it is possible to make contact with the figure (e.g., by telephone) and to reunite with the figure if needed (e.g., following an injury to the child). These changes probably occur partly because of a child's increased self-regulation, and partly because of parents' and children's expectations regarding greater child autonomy. These expectations may in turn be influenced by requirements for children to spend more time away from parents (e.g., because of school attendance and other formal activities, such as clubs and sports). Although children report relying less frequently on attachment figures as they get older (Kerns et al., 2006; Lieberman, Doyle, & Markiewicz, 1999), two longitudinal studies suggest that children's perceptions of caregiver availability and security actually increase in middle childhood (Kerns et al., 2006, Study 2; Verscheueren & Marcoen, 2005).

A second defining feature is that parents are the principal attachment figures for children in middle childhood. When asked about situations likely to invoke the need for an attachment figure (e.g., times when a child is afraid or sad, or specific situations such as separation from home), even 11- to 12-year-old children show a strong preference for parents over peers (Kerns et al., 2006; Kobak, Rosenthal, & Serwik, 2005; Seibert & Kerns, 2009). Interview studies reveal that children report going to parents in a range of situations, including when they are feeling ill or scared, coping with separation from or loss of an attachment figure or pet, and when they are distressed about a social conflict or have performed poorly

at school or in sports (Kerns & Seibert, in press; Vandevivere, Braet, & Bosmans, 2015). Children do spend substantial time with peers, and peers are clearly preferred over parents for companionship (Kerns et al., 2006; Seibert & Kerns, 2009). Children may report going to siblings, grandparents, teachers, and peers in situations in which contact with an attachment figure would be expected (e.g., when the child is sad or ill), but these nonparental figures typically play a secondary role and are more likely to be approached when parents are not immediately available (Seibert & Kerns, 2009). Mayseless (2005) has proposed that the use of peers as temporary attachment figures facilitates the transition to investment in peer relationships that is likely to occur in adolescence.

A third characteristic of attachment in middle childhood is a shift toward greater coregulation of secure base contact between the child and a parental figure. Bowlby (1973) proposed that a fourth phase of attachment, the goal-corrected partnership, emerges sometime after age 3, when a child is better able to understand a parent's desires, communications, and decisions, and is able to take these into consideration when developing plans and goals. Waters, Kondo-Ikemura, Posada, and Richters (1991) proposed that this shift in attachment may emerge later, during middle childhood, which they termed the *emergence of a supervisory partnership*. They suggested that parents may assume responsibility for maintaining contact with the child at younger ages, but in middle childhood, the child increasingly takes responsibility for communicating with the attachment figure (e.g., informing him or her of the child's whereabouts and changes in plans). Consistent with this suggestion is evidence that securely attached children are better about checking in and communicating with parents about their activities and whereabouts (Kerns, Aspelmeier, Gentzler, & Grabill, 2001). Another aspect of coregulation is that children and their parents may jointly work together to solve the child's problems, as a way to prepare a child to be able to cope better on his or her own (Cobb, 1996; Kerns, Brumariu, & Seibert, 2011). Thus, by the end of middle childhood, the attachment between child and parent can be viewed as a collaborative alliance, whereby the child is still relying on the stronger, wiser parental figure but is also beginning to use the parent as a resource rather than relying on the parent to solve the child's problems.

Finally, in middle childhood, attachment figures continue to function both as *safe havens* in

times of distress and as *secure bases* that support a child's exploration. This might seem like an obvious restatement of the secure base construct, but at older ages, attachment assessments tend to focus primarily on the safe haven function of attachments (e.g., asking a child what he or she does when upset). By middle childhood, as children's worlds expand, attachment figures also provide support for exploration (e.g., promoting confidence in tackling challenges, showing confidence in the child's abilities). Hence, a marker of secure attachment is the ability of parent-child dyads to coordinate and balance needs for care with needs for exploration (Cobb, 1996; Grossmann, Grossmann, & Kindler, 2005; Kerns, Mathews, Koehn, Williams, & Siener, 2015). Furthermore, consistent with studies of preschoolers (Bretherton, 2010), there is some evidence that mothers provide relatively more safe haven support and fathers provide relatively more secure base support to children in late middle childhood and early adolescence (Kerns et al., 2015).

Measuring Attachment in Middle Childhood

Due to space limitations, we do not present a thorough review of measurement issues and specific measures of attachment in middle childhood (for a comprehensive review, see Kerns & Seibert, in press; see also Bosmans & Kerns, 2015). Nevertheless, the topic deserves comment to aid readers in evaluating the literature discussed here. Unlike younger age periods, when observational assessments of specific attachments (e.g., to mothers) are universally used, there is currently no dominant conceptual or methodological approach for studies of middle childhood.

Although some studies have used observational assessments of attachment with children 6–8 years of age (e.g., Bureau & Moss, 2010), the vast majority of studies of middle childhood employ what can broadly be termed *representational measures of attachment*. Children develop cognitive (working) models of themselves in relation to their attachment figures, based on their experiences with their primary attachment figures (Bowlby (1969/1982)). Working models have often been conceptualized as schemas or scripts that capture relationship rules (see Bretherton & Munholland, Chapter 4, this volume). Given the decline in the frequency and intensity of attachment behaviors

in middle childhood, along with the child's enhanced coping abilities, most studies in middle childhood assess attachment representations rather than a child's secure base behavior toward a caregiver. Representational measures require obtaining reports from the child. There are three important distinctions among these measures. Some measures (e.g., script measures, story stems, autobiographical interviews) require scoring by an outsider who considers not only what the child says but how the information is presented (e.g., whether the narrative is coherent), whereas others (questionnaires) are based on the child's direct reporting about experiences with attachment figures. The former are thought to capture both conscious and unconscious representations, whereas the latter capture only conscious representations. As might be expected, the overlap between these two types of measures is modest (Granot & Mayseless, 2001; Kerns, Abraham, Schlegelmilch, & Morgan, 2007; Kerns, Brumariu, et al., 2011; Kerns, Tomich, Aspelmeier, & Contreras, 2000; Psouni & Apetroaia, 2014). A second important distinction concerns whether the measures are intended to assess the quality of a specific attachment relationship (e.g., to the mother) or more general representations. Relationship-specific measures include separation-reunion measures (Main, Kaplan, & Cassidy, 1985; Moss, Bureau, Béliveau, Zdebik, & Lépine, 2009), story stem interviews (Granot & Mayseless, 2001; Kerns, Brumariu, et al., 2011), ratings of parent safe haven and secure base support from autobiographical interviews (Kerns et al., 2015), and questionnaires (Brenning, Soenens, Braet, & Bosmans, 2011; Kerns et al., 2001). Measures of general attachment representations include script story assessments (Psouni & Apetroaia, 2014) and autobiographical interviews that focus on narrative coherence (e.g., Child Attachment Interview: Shmueli-Goetz, Target, Fonagy, & Datta, 2008; Friends and Family Interview: Kriss, Steele, & Steele, 2012). A third distinction is that some measures assess variations in security, whereas others are designed to assess both secure and specific insecure patterns of attachment.

The diversity of measures, and of the conceptualizations of attachment inherent in the measures, is both a strength and a weakness. On the positive side, multiple measures can be advantageous: With a single measure, there is always a concern that one is studying the measure rather than the underlying construct. The use of multiple measures allows for more thorough assessment of a

construct by more broadly sampling the relevant domain. In a new field, it can be helpful to have more than one approach because some measures may ultimately prove to have greater validity than others. By using different measures, the field avoids prematurely relying on a single approach. Unfortunately, several complications can arise when investigators adopt a wide range of approaches. Most measures are closely tied to the secure base and safe haven constructs, but in a few cases, assessments of “attachment” appear to tap other aspects of parent–child relationships (e.g., alienation or social support). Measures that assess global qualities such as social support may fail to be context-sensitive; the mother of a securely attached child would presumably be more sensitive to a child’s distress cues than a mother of an avoidantly attached child, but there is no theoretical reason to expect that a mother of an avoidantly attached child would be unsupportive of her child’s academic goals or shared interests (in fact, nonsocial activities might be a focus of interaction and could function to allow maintenance of the relationship without emotional engagement). Finally, a number of new measures have been published since the previous edition of this handbook, but most have generated only limited validity data, with the focus so far on testing how a new measure correlates with child adjustment rather than examining how it is related to observational assessments of parenting or even to other measures of attachment (Kerns & Seibert, *in press*).

What the field needs now is not new representational measures but studies that can shed light on which of the current approaches provide the best assessments. Needed are basic studies that examine the degree to which different measures of either specific relationships or general representations converge with each other; studies of the degree of overlap between relationship-specific and representational measures, which could shed light on how general representations are constructed; and careful consideration of both convergent and discriminant validity of measures. Evidence of convergent validity should include a demonstration that a measure of attachment is associated with the quality of care a child experiences, not just the child’s adjustment. As more studies are conducted, meta-analysis could be used to examine the relative magnitude of the correlates of different measures or measurement approaches. Finally, there are some observational procedures that assess attachment behavior in middle childhood. For example, separation–reunion procedures have been developed

for 6- to 8-year-olds to assess attachment patterns and forms of attachment disorganization (Bureau & Moss, 2010; Easterbrooks, Bureau, & Lyons-Ruth, 2012; see Solomon & George, Chapter 18, this volume, for a detailed discussion), and efforts are under way to develop assessments for 10- to 12-year-olds based on parent–child interactions during discussion tasks (e.g., Brumariu, Kerns, Bureau, & Lyons-Ruth, 2014; Cobb, 1996). In this chapter, we have included only studies in which attachment constructs were clearly measured, and we have excluded studies that employed questionnaire measures of perceived parenting (e.g., parental acceptance) or single-item questionnaires. We included studies based on questionnaire, interview, or observational measures, although due to space constraints, we do not separate findings by measurement approach.

Continuity and Change in Attachment in Middle Childhood

In the absence of disruptions in the quality of caregiving or the loss of attachment figures, one would expect at least moderate continuity in the quality of attachment over time (Fraley, 2002; Pinquart, Feussner, & Abnert, 2013). Several studies have evaluated whether attachment is stable within the middle childhood period (ages 7–12 years), examining intervals ranging from 1 month to 3 years. Most studies find evidence for stability, although there is substantial variability in the magnitude of the estimates (Granot & Mayseless, 2001; Kerns et al., 2000; Kerns, Schlegelmich, Morgan, & Abraham, 2005; Shmueli-Goetz et al., 2008; Verschueren & Marcoen, 2005). Ammaniti and colleagues (2000) found substantial stability in attachment from ages 10 to 14 years, and Grossmann and colleagues (2005) found evidence of continuity from middle childhood to early adulthood. By contrast, studies that examined whether behavioral measures of secure attachment in infancy or early childhood predict representational measures of secure attachment in middle childhood have been mixed (no association: Ammaniti, Speranza, & Fedele, 2005; Aviezier, Sagi, Resnick, & Gini, 2002; Bohlin, Hagekull, & Rydell, 2000; evidence for an association: Dubois-Comtois, Cyr, & Moss, 2011; Grossmann et al., 2002, 2005).

It should also be noted that some studies of stability have related early behavioral measures

of specific attachments (e.g., the Strange Situation) to later representational measures of general attachment representations. In addition to differences in methods, weak associations might be expected if the latter are based on experiences in multiple attachment relationships. Longitudinal, multimethod studies are needed to examine stability both within and across measurement approaches (i.e., observational and representational measures; relationship-specific and general measures). The substantial variation in stability estimates suggests that change is also occurring for many children during these years, and that the 8–10 age period may be a time of reorganization in children's models of relationships (e.g., advances in social comparison abilities may lead children to change their evaluations of their attachment figures). Thus, studies examining factors that may account for both continuity and change are warranted.

Associations with Parenting

One of the strong claims derived from attachment theory is that sensitive and responsive care provided by an attachment figure promotes the development of a secure relationship with that caregiver. Studies of young children have documented an association between maternal sensitivity and secure attachment (Thompson, Chapter 16, this volume). A few studies have examined how attachment is related to parenting for children ages 7–12 years. One set of studies examined secure attachment in relation to global parenting qualities and found that more securely attached children reported greater perceived acceptance by parents (Bosmans, Braet, Koster, & De Raedt, 2009; Kerns, Brumariu, et al., 2011). Such children also tend to have parents who report a greater willingness to serve as a secure base (Kerns, Klepac, & Cole, 1996, Study 2; Kerns et al., 2000). Secure attachment is also associated with observer ratings of maternal acceptance and positive affect (Dubois-Comtois et al., 2011; Kerns, Brumariu, et al., 2011; Scott, Riskman, Woolgar, Humayun, & O'Connor, 2011). In middle childhood, parents not only need to be responsive and available but also to act in ways that support the development of the child's autonomy (Cobb, 1996). Secure attachment is also associated with children's perceptions of parents as supporting autonomy and exerting low psychological control (Bosmans et al.,

2009; Kerns, Brumariu, et al., 2011), and with observer ratings of low levels of psychological control (Kerns, Brumariu, et al., 2011).

A second set of studies examined attachment and specific parenting practices. More securely attached children were more cooperative in monitoring situations and had parents who were more knowledgeable about (who more closely monitored) their children (Kerns et al., 2001; Scott et al., 2011). Attachment is also related to parental emotion socialization, in that parents of more securely attached children report less punitive reactions to child displays of distress (Cummings, George, Koss, & Davies, 2013), express less negative emotion when discussing their child (Scott et al., 2011), and endorse an emotion coaching (rather than a dismissing) meta-emotion philosophy (Chen, Lin, & Lu, 2012).

Some studies have examined associations between parenting and specific forms of insecurity. Children who reported more avoidant coping with mothers perceived their parents to exhibit lower levels of involvement, support, and monitoring of their activities (Karavasilis, Doyle, & Markiewicz, 2003; Yunger, Corby, & Perry, 2005). Children who scored higher on preoccupied coping also reported higher levels of psychological control from their mothers in one study (Yunger et al., 2005), but not another (Karavasilis et al., 2003). These researchers used child questionnaires to assess both parenting and attachment. In another study, avoidant coping was associated negatively with mothers' and fathers' reports of willingness to serve as a secure base (Kerns et al., 2000). Studies using observational assessments find that mothers of securely attached children show the most supportive parenting, whereas mothers of disorganized children show the most problematic parenting, with fewer distinctive associations for ambivalent and avoidant attachment (Kerns et al., 2000; Kerns, Brumariu, et al., 2011; Dubois-Comtois et al., 2011; Scott et al., 2011). In addition, Green, Stanley, and Peters (2007) found that mothers of disorganized children scored high on measures of "expressed emotion" (which generally involved negative or unpleasant emotion).

In summary, although the data are limited in comparison to that for younger age periods, secure attachment in middle childhood is related to sensitive, responsive, and accepting parenting, as well as to greater support for autonomy and low use of psychological control. Relatively few studies have included observational assessments of parenting or focused on parenting correlates of the

insecure attachment patterns. Parents of children in middle childhood face many important tasks other than fostering security (e.g., encouraging independence, mastery, politeness, and conformity to rules), but researchers are just beginning to examine how attachment is related to specific parenting practices. In addition, there has been little consideration of how attachment might moderate the influence of parenting practices, as has been examined at younger ages (e.g., Kochanska, Barry, Stellern, & O'Bleness, 2009), or whether attachment and parenting are uniquely related to child adjustment (Scott et al., 2011). Important tasks for future research include investigating these questions, as well as considering how the broader family system interfaces with child–parent attachments (see, e.g., work on attachment and marital conflict; Davies, Harold, Goeke-Morey, & Cummings, 2002).

Associations with Cognitive, Social, and Emotional Development

An important finding at younger ages is that the formation of a secure attachment to a parent is associated with greater cognitive, emotional, and social competence (see Thompson, Chapter 16, this volume), and researchers have also investigated these links in middle childhood (ages 7–12 years). In one kind of study, assessments of attachment in infancy or preschool have been used to predict children's competence in middle childhood. These studies, reviewed elsewhere (Fearon, Bakermans-Kranenburg, Van IJzendoorn, Lapsley, & Roisman, 2010; Groh, Roisman, Van IJzendoorn, Bakermans-Kranenburg, & Fearon, 2012; Groh et al., 2014; Madigan, Atkinson, Laurin, & Benoit, 2013; Pallini, Baiocco, Schneider, Madigan, & Atkinson, 2014; Schneider, Atkinson, & Tardif, 2001; West, Mathews, & Kerns, 2013; in this volume, see Thompson, Chapter 16, and DeKlyen & Greenberg, Chapter 28), indicate that attachment early in life is associated with greater social, emotional, and cognitive competence and fewer behavior problems in middle childhood. The typical strategy in these studies is to measure attachment in the first few years but not again, in middle childhood. Thus, the studies show the predictive significance of early attachment, although there is ambiguity in the interpretation of the findings. They might demonstrate that early attachment

per se is important for later development, or given that attachment is moderately stable (Fraley, 2002; Pinquart et al., 2013), they might imply that associations between early attachment and later outcomes are mediated by middle childhood attachment. Due to study designs used to date, these two possibilities cannot be distinguished, which indicates the importance of including assessments of attachment in middle childhood.

The following literature review focuses on studies in which both attachment and competence were assessed within middle childhood, and they show that in middle childhood attachment is related in theoretically meaningful ways to children's cognitive, social, and emotional adjustment. Measures of child functioning have included observations of child behavior, maternal reports, teacher reports, and child self-reports. A few studies relied solely on child questionnaires to measure both attachment and child functioning (mostly in the self-concept or behavior problem domains).

Associations with Cognitive Development and School Adaptation

Does the quality of attachment have implications for a child's cognitive competence and cognitive performance? The available data provide strong evidence for a link between secure attachment and a child's school attitudes and classroom behaviors. Studies show that more securely attached children report greater perceived academic competence and mastery motivation (Bacro, 2012; Diener, Isabella, Behunin, & Wong, 2008; Duchesne & Larose, 2007; Kerns et al., 1996, Study 1; Moss & St-Laurent, 2001); moreover, they are rated by teachers as showing better classroom adjustment in areas such as participation or academic skills (Aviezer et al., 2002; Diener et al., 2008; Easterbrooks & Abeles, 2000; Easterbrooks, Davidson, & Chazan, 1993; Granot & Mayseless, 2001; Jacobsen & Hofmann, 1997; Kerns et al., 2000). These links have been documented in both longitudinal and cross-sectional studies, using a variety of attachment measures. Other studies have examined how attachment is related to measures of cognitive performance such as achievement test scores and IQ tests. Here the data are more mixed (see West et al., 2013, for a review). Some researchers have found that secure attachment is not related to IQ scores, grade point averages, or

achievement test performance (Dubois-Comtois et al., 2011; Granot & Mayseless, 2001; Kerns et al., 1996, Study 1; Moss & St.-Laurent, 2001; Shmueli-Goetz et al., 2008; for mixed evidence, see Aviezer et al., 2002; Bacro, 2012), whereas other studies have found that secure attachment is associated with higher scores on IQ or logic tests (Easterbrooks et al., 1993; Jacobsen, Edelstein, & Hofmann, 1994; Jacobsen & Hofmann, 1997). In some samples, insecure-controlling or disorganized children have been found to have the lowest school grades or performance on tests of cognitive skills (Jacobsen et al., 1994; Moss & St.-Laurent, 2001), suggesting that this group may be especially at risk for problems in cognitive development.

A newer direction in this area involves exploring mechanisms that could explain *why* attachment is related to school attitudes, performance, or IQ. It is possible that the presence of a secure base directly fosters enthusiasm and exploration of the school environment, by providing children with the support and self-confidence needed to tackle challenges. It is also possible that associations between attachment and school outcomes are mediated (best explained) by parenting practices. For example, Moss, St.-Laurent, Dubois-Comtois, and Cyr (2005) found that the link between disorganized attachment and school performance could be explained by the quality of children's collaborative interactions with their caregivers. Other studies suggest that associations between early secure attachment and later school performance or IQ might be due to the quality of teaching assistance parents provide (O'Connor & McCartney, 2007; West et al., 2013; see Williford, Carter, & Pianta, Chapter 41, this volume). Child characteristics such as self-regulation and a cooperative orientation to school demands are other factors that help explain why early attachment is related to later grades or IQ (O'Connor & McCartney, 2007; West et al., 2013).

Associations with Self-Concept and Social Information Processing

Bowlby (1973) proposed that children who experience responsive and sensitive care are likely to view themselves as worthy of others' affection. In addition, children who form secure attachments are thought to possess a balanced self-view and are able to acknowledge personal limitations (Cassidy, 1988). This leads to the expectation that securely attached children will hold positive but realistic

self-views. In several studies of 8- to 12-year-olds, children who reported more secure attachments to parents also reported higher self-esteem (Cassidy, Ziv, Mehta, & Feeney, 2003; Doyle, Markiewicz, Brengden, Lieberman, & Voss, 2000; Kerns et al., 1996, Study 1; Sharpe et al., 1998; Verschueren & Marcoen, 2002, 2005; Yunger et al., 2005) or social self-efficacy (see Coleman, 2003, for child-father but not child-mother attachment). Secure attachment is also associated with fewer weight concerns, a more positive body image, and more adaptive beliefs and behaviors regarding eating (Goossens, Braet, Bosmans, & Decaluwé, 2011; Goossens, Braet, van Durme, Decaluwé, & Bosmans, 2012; Sharpe et al., 1998). These studies are limited in that both attachment and self-concept were measured with self-report questionnaires, which may overestimate the link between the two. In addition, these studies all tested the hypothesis that secure attachment would be related to higher self-esteem, yet children with an avoidant attachment may provide overly positive reports (Borelli, David, Corwley, Snaevelly, & Mayes, 2013; Cassidy, 1988). Thus, studies that assess self-worth on a positivity dimension may not be well suited to testing the hypothesis that securely attached children have a positive but *balanced* view of the self. These problems can be reduced by employing independent assessments of attachment and self-concept. More securely attached children were rated by teachers as having more self-confidence (Jacobsen & Hofmann, 1997), more positive self-views as assessed with a puppet interview (Clark & Symons, 2009), and greater access to self-evaluations (i.e., they discussed the self spontaneously and easily; Easterbrooks & Abeles, 2000), although in two studies, interview or observational measures of attachment were not related to child reports of self-esteem (Bohlin et al., 2000; Easterbrooks & Abeles, 2000).

One reason why more securely attached children are hypothesized to maintain positive self-views is that they are thought to process social information in a positively biased way. Research evaluating this hypothesis has accelerated in the last few years. One set of studies examined social information processing in the context of social problem solving. Securely attached children have shown a positive bias in their attributions about others in two studies (Bauminger & Kimhi-Kind, 2008; Clark & Symons, 2009), but not in a third (Granot & Mayseless, 2012). More securely attached children generated more prosocial solutions (Bauminger & Kimhi-Kind, 2008; Granot &

Mayseless, 2012). Another set of studies examined attention and memory biases in relation to attachment. Cassidy and colleagues (2003) found that more secure 11- to 14-year-olds were more likely to attend selectively to positive information about themselves. Two studies by Bosmans and colleagues (2007, 2009) examined how preferential attention to pictures of their mothers was related to children's attachment. The two studies showed that insecurely attached children focused their attention more narrowly on their mothers, which was interpreted as showing decreased exploration during the task. Another study showed that insecurely attached children were more likely to show biased (increased) recall of negative information about their mothers (Dujardin, Bosmans, Braet, & Goossens, 2014).

In summary, although there are some inconsistent findings, for the most part, the middle childhood literature shows that more securely attached children hold positive but balanced views of the self, show a positive bias in the way they interpret others' actions, and generate more pro-social solutions to peer problems. Most studies in this area have focused on the correlates of security, so it is not clear whether children with different insecure attachment patterns can be differentiated in terms of their self-esteem and social information-processing approaches.

Associations with Emotion Regulation and Personality

Emotion regulation is an integral aspect of attachment. By definition, emotional distress is addressed effectively in the secure parent-child dyad, with mitigation of distress (i.e., return of positive mood) and the child's return to exploration of the environment. Furthermore, it is hypothesized that securely attached children internalize effective ways to cope with stress and are consequently resilient when coping with problems, even in the absence of the caregiver (Kerns et al., 2007; Sroufe, 1983). By contrast, security of attachment is not hypothesized to be associated strongly with measures of temperament such as emotionality (Vaughn & Bost, Chapter 10, this volume).

In contrast to the situation at the time the previous edition of this handbook was published, there are now several studies that have investigated links between attachment and emotion in middle childhood (Parrigon, Kerns, Abtahi, & Koehn, 2015). Researchers who focus on mood

or the experience of specific emotion states have found that more securely attached children report more positive and less negative mood in daily interactions (Abraham & Kerns, 2013; Kerns et al., 2007) and higher positive emotion on a trait measure of affect (Borelli, Crowley, et al., 2010). The emotional experience of homesickness, by contrast, has not been consistently related to individual differences in attachment (Kerns, Brumariu, & Abraham, 2008; Thurber & Sigman, 1998; Thurber, Sigman, Weisz, & Schmidt, 1999). Securely attached children do report greater awareness of their emotional states (Brumariu, Kerns, & Seibert, 2012). More recently, researchers also tested whether securely attached children show more adaptive patterns of emotion regulation; they found that more securely attached children use more constructive coping strategies, such as seeking support from others or problem solving (Abraham & Kerns, 2013; Colle & Del Giudice, 2011; Contreras, Kerns, Weimer, Gentzler, & Tomich, 2000; Gaylord-Harden, Taylor, Campbell, Kesselring, & Grant, 2009; Kerns et al., 2007; Psouni & Apetroaia, 2014). One study found that avoidance was linked with emotion suppression, whereas ambivalence was linked with emotion dysregulation (Brenning, Soenens, Braet, & Bosmans, 2012). In the one study that assessed all four attachment patterns (secure, avoidant, ambivalent, disorganized), Brumariu and colleagues (2012) discovered that disorganization was related to coping; disorganized children were less likely to use active coping strategies and more often catastrophized when things went wrong. Finally, two studies examined attachment in relation to physiological indicators of emotion regulation. Borelli, David, and colleagues (2010) found that more securely attached children showed a stronger reaction followed by quicker recovery when presented with an aversive stimulus. Gillisen, Bakermans-Kranenburg, Van IJzendoorn, and van der Veer (2008) found that children who were securely attached showed lower electrodermal reactivity during a social stressor task, and this effect was accentuated for children who also had long alleles for a serotonin transporter gene (*5-HTT*).

Others have examined how attachment is related to personality or temperament. Surprisingly, one study found that secure attachment was not related to ego resilience (Easterbrooks & Abeles, 2000), although other studies suggest that securely attached children can better tolerate frustration and show better emotion control (Kerns et al., 2007; Shmueli-Goetz et al., 2008). Chen and

Chang (2012) found that insecurely attached children were more likely to use coercive strategies to control resources. Researchers have found no association between attachment and temperament in middle childhood when the latter was measured as extraversion (Jacobsen & Hofmann, 1997) or difficult temperament/negative emotionality (Chen, 2012; Contreras et al., 2000), with mixed evidence for behavioral inhibition/shyness (Borelli, David, et al., 2010; Brumariu & Kerns, 2010a).

Collectively, the emerging literature suggests that more securely attached children use more adaptive emotion regulation strategies and experience more positive and less negative mood states. One limitation is that most studies have examined attachment in relation to trait-like patterns of affect and emotion regulation; thus, we know relatively little about attachment and emotion as assessed in real time (for exceptions, see Borelli, David, et al., 2010; Gillisen et al., 2008), when it is possible to capture the dynamics of emotion (e.g., recovery following a stressor). There are also few studies that examined whether specific forms of insecure attachment (e.g., avoidance) are associated with distinct emotion profiles, as Cassidy (1994) and Sroufe (1983) have suggested (exceptions would be Brenning, Soenens, Braet, & Bosmans, 2012; Borelli, Crowley, et al., 2010; Brumariu et al., 2012). Finally, given the evidence that attachment is linked with emotional competence, it would be worth exploring whether emotion regulation mediates associations between attachment and other aspects of adjustment (for examples in the domain of internalizing symptoms, see Brenning et al., 2012; Brumariu et al., 2012; Brumariu & Kerns, 2013).

Associations with Peer Relationships and Peer Competence

One of the most extensively investigated questions in middle childhood research is whether attachment predicts the quality of children's peer relationships. There are several reasons for expecting an association between the two. The development of a secure attachment may foster greater exploration, including exploration of peer relationships (Kerns, 1996). In addition, children who form secure attachments to caregivers may show greater interest in and motivation for engaging with other social partners (Sroufe, Egeland, & Carlson, 1999), and may learn socially competent interaction styles from responsive

caregivers (Kerns et al., 1996). Also, more securely attached children may develop more adaptive emotion regulation capacities, which are especially important for peer relationships in middle childhood, when there is an emphasis on controlling one's emotions with peers (Contreras et al., 2000). Meta-analyses, based mostly on studies with younger children, showed that attachment is related to friendship and to social behavior or popularity with peers (Groh et al., 2014; Pallini et al., 2014; Schneider et al., 2001). The review below is more selective than the meta-analyses because it includes only studies of children in middle childhood, but it is more expansive than some meta-analyses that included only studies using behavioral measures of attachment.

In the friendship domain, investigators have examined whether attachment is related to the quantity and quality of children's friendships. Evidence for a link between attachment and the number of children's friendships is mixed (Kerns et al., 1996, Study 1; Lieberman et al., 1999). By contrast, studies consistently find that attachment is related to the quality of children's friendships, as indexed by measures of support, companionship, responsiveness, and conflict (Howes & Tonyan, 2000; Kerns et al., 1996, Study 2; Lieberman et al., 1999; see Abraham & Kerns, 2013, for a discussion of associations for positive friendship quality but not conflict). A second group of studies has examined whether children who form secure attachments to caregivers are more popular (more highly accepted) by their peers. Five studies found that children more securely attached to their mothers were better liked and less likely to be rejected by their peers (Barcons et al., 2012; Bohlin et al., 2000; Chen, 2012; Granot & Mayseless, 2001; Kerns et al., 1996, Study 1). However, two studies found an association between secure attachment and peer popularity for child–father, but not child–mother attachment (Verschuere & Marcoen, 2002, 2005), and another study found no association between peer popularity and attachment to mothers or to fathers (Lieberman et al., 1999). Thus, while the evidence is somewhat mixed, overall, it appears that secure attachment is associated with greater peer popularity.

A final group of studies examined secure child–mother attachment and global ratings of peer competence or observational measures of competent peer interactions. Securely attached children showed greater social engagement and participation with peers (Bohlin et al., 2000; Chen, 2012; Yunger et al., 2005); reported fewer

difficulties with peers (Cummings et al., 2013); and were rated higher by parents, teachers, or camp counselors on measures of peer competence (Abraham & Kerns, 2013; Barcons et al., 2014; Contreras et al., 2000; for contrary evidence, see Easterbrooks & Abeles, 2000).

In summary, there is substantial evidence for an association between secure attachment and peer relationships, especially when the *quality* of children's relationships and social behavior is the focus. These associations have been found in studies using a variety of measures of both attachment and peer relationships. In their review of the link between attachment and peer relationships, Schneider and colleagues (2001) concluded that there is not a strong need for additional studies documenting an association between the two. This conclusion also seems to apply to the study of attachment and peer relationships in middle childhood. Rather, we need more studies aimed at explaining why this link is found (e.g., Abraham & Kerns, 2013; Contreras et al., 2000; McElwain, Booth-LaForce, Lansford, Wu, & Dyer, 2008), as well as studies that consider how attachment and peer relationships jointly and uniquely influence children's social development (e.g., Sroufe et al., 1999).

We also note that most studies have focused on the peer correlates of secure attachment and have not examined whether specific insecure attachment patterns are associated with specific peer deficits in middle childhood. Some differences between preschoolers with secure, ambivalent, and avoidant attachments were hypothesized and found in the Minnesota longitudinal project (Sroufe, 1983). In one follow-up study of the Minnesota sample into middle childhood, ambivalent children were found to be least efficacious in their peer relations, whereas avoidant children were the most isolated from peers (Shulman, Elicker, & Sroufe, 1994). Three more recent studies have examined insecure attachment patterns and the specificity of peer difficulties. These studies, which, unlike the Minnesota studies, included disorganized children as a separate group, suggest that both avoidant and disorganized children show the most problems with peers in middle childhood, particularly in the areas of exclusion or aggression (Granot & Mayseless, 2001; Jacobvitz & Hazen, 1999; Seibert & Kerns, 2015). Ambivalent children showed few peer difficulties (Granot & Mayseless, 2001; Seibert & Kerns, 2015). Clearly, research in this area has only just begun to test the specificity hypothesis.

Associations with Behavior Problems and Clinical Symptoms

A secure attachment provides a healthy foundation for development, whereas an insecure attachment to one's primary attachment figures is likely to be associated with difficulties in personality development and, in some cases, clinical symptoms (see DeKlyen & Greenberg, Chapter 28, this volume). It is therefore not surprising that one of the most frequently investigated topics in middle childhood is whether attachment is related to signs of psychopathology. Almost all of the studies measure clinical symptoms (e.g., externalizing problems) rather than clinical diagnoses. In this section, we focus on studies published since the previous edition of this handbook.

As was found in the review in the previous edition of this handbook (Kerns, 2008), more recent studies show that attachment security is linked to lower levels of externalizing problems in middle childhood (Cummings et al., 2013; Scott et al., 2011). Lyons-Ruth (1996) proposed that disorganized attachment might be the insecure attachment pattern most clearly related to externalizing problems, but evidence for this idea is mixed (Granot & Mayseless, 2001; Jacobsen & Hofmann, 1997; Moss et al., 2009; Scholtens, Rydell, Bohlin, & Thorell, 2014). Interestingly, attention and thought difficulties have been linked to both secure attachment (Abrines et al., 2012) and disorganized attachment (Borelli, David, et al., 2010; Green et al., 2007; Scholtens et al., 2014; Thorell, Rydell, & Bohlin, 2012).

Studies published since the previous edition of the handbook also show that securely attached children experience lower levels of internalizing problems (Brumariu & Kerns, 2010a; Kerns, Brumariu, et al., 2011; Kerns, Siener, & Brumariu, 2011). Other researchers have examined whether specific forms of insecurity are differentially related to internalizing problems. Although there has been speculation that internalizing problems are most likely to be related to ambivalent or preoccupied attachment (Sroufe, Egeland, Carlson, & Collins, 2005; Yunger et al., 2005), studies indicate that measures of internalizing problems to correlate with self-report measures of both avoidance (Brenning et al., 2011, 2012) and ambivalent-preoccupied attachment (Brenning et al., 2011, 2012; Brumariu & Kerns, 2008). Conceptually, there has been little discussion of why disorganization would be related to internalizing problems. We suggest that the lack of a clear strategy to cope

with distress and the associated profound emotion dysregulation, combined with feelings of helplessness and vulnerability in the face of frightening situations, may lead disorganized children to experience anxiety and depression (Brumariu et al., 2012; Brumariu, Obsuth, & Lyons-Ruth, 2013). In studies that assessed disorganization, which utilize representational measures of attachment, disorganized attachment was related to internalizing symptoms (Borelli, David, Crowley, & Mayes, 2010; Brumariu & Kerns, 2010a; Brumariu et al., 2012; Moss et al., 2009).

In summary, children who form a secure attachment to their mothers are less likely to experience clinical symptoms in middle childhood, including conduct and attention problems, and internalizing symptoms. There are virtually no data on child–father attachment and children’s adjustment because studies have either assessed only child–mother attachment or have aggregated child–mother and child–father attachment measures (see Cummings et al., 2013, for an exception). It is difficult to draw conclusions regarding whether specific insecure patterns place children at risk for specific types of clinical symptom, partly because different studies included different insecure groups for both conceptual and methodological reasons. Some clinically focused studies examined only security and disorganization (e.g., Borelli, David, et al., 2010). Other studies used questionnaires, which can assess avoidance and ambivalence (preoccupation) but are unable to assess disorganization. Existing meta-analyses do not decisively answer questions about relations of attachment to clinical symptoms in middle childhood (Kerns & Brumariu, 2014). Some meta-analyses included only studies that used behavioral measures of attachment (Fearon et al., 2010; Groh et al., 2012; Madigan et al., 2013); as a consequence, the studies included mostly children under the age of 8. It is unclear whether those findings will generalize to older ages because some clinical symptoms (e.g., depression, social anxiety) do not typically emerge until late middle childhood or adolescence. A meta-analysis of attachment and anxiety did include a broad age range (Colnnesi et al., 2011), but a large number of the included studies had only questionnaire data for attachment, and disorganization was not examined. Furthermore, it is important to note that studies of attachment and clinical diagnosis are largely absent from the literature.

Finally, it is important to keep in mind that attachment is likely to be only one of many fac-

tors that influence the development of psychopathology; thus, it is not surprising that, when considered in isolation, attachment is only modestly related to signs of psychopathology. Even when attachment predicts psychopathology, it is almost a certainty that other factors (e.g., genes, poverty, abuse, and peer relationships) are also involved and, indeed, attachment is often not the strongest predictor of adjustment. One direction for future research is to study attachment along with other known risk factors to examine the relative importance of attachment for psychopathology. For example, recent studies indicate attachment is related to anxiety, even after researchers control for temperament. Emerging evidence with rodents and young children demonstrates epigenetic consequences of early social interaction, particularly with mothers, with implications for brain development, behavior, and mental health (e.g., Champagne, 2010). An exciting future direction is to investigate epigenetic modifications linked specifically with attachment in middle childhood. Similarly, another direction is to test models that include additional factors that may mediate or explain the links between attachment and clinical symptoms (e.g., Brumariu & Kerns, 2010b; Kerns & Brumariu, 2014).

Conclusions and Future Directions

This review reveals that there has been an acceleration of research on attachment in middle childhood (see also Bosmans & Kerns, 2015). Progress has been made in characterizing the nature of attachment in middle childhood. The variety of attachment measures that have been developed await further validation. Research on attachment and parenting highlights the need to expand beyond the earlier focus on sensitivity as the only or even the main aspect of parenting that may contribute to the development and maintenance of attachment at older ages, identifying other constructs such as psychological control and support for autonomy as important at this age. Finally, the substantial evidence that has accrued indicates that, similar to what has been found at younger ages, secure attachment in middle childhood is associated with greater social, emotional, and cognitive competence, and less clinical symptomatology.

While there has been substantial progress, a continuing limitation is that the literature often

seems to be driven mainly by a desire to retest old findings and questions in a new age period, rather than to take the developmental context of middle childhood into account. Some examples of how a developmental perspective could inform future work include answering the following questions:

- What are the important transformations in child–parent attachment in middle childhood, and what individual or contextual factors help parents and children negotiate these changes?

Although there has been attention to how the manifestation of avoidance, ambivalence, and disorganization may change in early childhood, we know very little about how these patterns may change in middle childhood.

- What are the most developmentally salient challenges in middle childhood, and is secure attachment most strongly linked to these?

There has been speculation regarding gender differences in attachment that may emerge during middle childhood, with girls tending toward ambivalence and boys tending toward avoidance, driven partly by biological changes (Del Giudice, 2009), but to our knowledge there have been few tests of these ideas (see Bakermans-Kranenburg & Van IJzendoorn, 2009, for mixed evidence).

- Children are beginning to spend more time away from parents. How do their experiences with peers or other adults affect a child's attachments to his or her parents?

- When are children able to integrate representations of different relationships into a general representation, and is the timetable for when this occurs affected by experiential factors?

Although at one time there was a lack of attachment measures for middle childhood, the current problem is that there are many measures, most of which have not been very extensively validated (Kerns & Seibert, in press). More attention needs to be paid to validation of measures, including studies examining overlap among measures and associations with parenting. Investigators need to consider their choice of measures carefully, making sure that the chosen measure captures the construct of interest. Self-report questionnaires have been used to assess children's perceptions of attachment, and although their use should not be ruled out a priori, it is important to recognize their limitations, especially when they are correlated only with other questionnaires completed by the children. The most common approach is to examine the correlates of secure attachment,

with some studies examining attachment disorganization. There is actually very little evidence for distinctive correlates of avoidant and ambivalent attachment in middle childhood. Is it that our measures are not adequately capturing these patterns at older ages? Is it that avoidant and ambivalent children are mostly coping adequately at this age, and only disorganized children are failing to show healthy adaptation? As of now, we simply do not know.

Our review shows that there is now substantial evidence that child–mother attachment is related to children's school adaptation, peer relationships, emotion regulation, social information processing, and internalizing and externalizing symptoms. There is not a strong need for additional studies designed solely to document these bivariate associations, but there are still a number of questions to address. Researchers are just beginning to examine specific mechanisms that might account for the documented associations. There could also be greater consideration of factors that might moderate the links between attachment and child adaptation. Another challenge for the field is to understand how attachment and other aspects of social experience operate together to influence children's social development. We need more studies that place attachment within a broader context, considering multiple influences (e.g., Sroufe et al., 2005).

Finally, the vast majority of studies have focused on mother–child attachment with American or European children growing up in traditional family structures (households headed by one or two parents). An important direction for future research to consider is the nature and role of attachment in a variety of circumstances. For example, there may be cultures in which children rely on several “principal” attachment figures that include extended relatives, as well as parents. We know of no studies in middle childhood that have examined attachments for children who have little contact with their parents.

Chapter 18

The Measurement of Attachment Security and Related Constructs in Infancy and Early Childhood

Judith Solomon
Carol George

In this chapter we examine the methods of assessing attachment security in infancy and early childhood, at both the level of behavior and the level of representation. Our first goal is to provide an overview and summary of available measures, along with information about their psychometric properties and the ways they have been used in research. Our second goal is to evaluate the current state of infant and early childhood measurement in the field of attachment. How well do the available instruments and protocols actually reflect the construct of attachment security? How useful are these measures for testing core predictions in attachment theory? Discussions of many of these measures have been updated to reflect work since 2008. Readers are referred to earlier editions of this handbook for more complete discussions.

This chapter can be used in several ways. Some readers, especially those new to research in this area, can use the chapter as a source of information to help select measures appropriate to their research. For readers who are familiar with childhood attachment assessment and well grounded in attachment theory, this is an opportunity to examine all of the measures together. This kind of overview is important for understanding the development of the field and providing a sense of new directions and opportunities for theory and research.

The Domain of Attachment Security

Attachment security was defined by Ainsworth, Blehar, Waters, and Wall (1978) as the state of being secure or untroubled about the availability of the attachment figure. As a construct, security can never be directly observed, but must be inferred from what is observable. Furthermore, a construct is “evidenced in a variety of forms of behavior and not perfectly so in any one of them” (Nunnally, 1978, p. 84). How, then, do we determine whether a particular measure of attachment security is a “good” or valid measure of the construct?¹

In practice, psychologists typically follow a three-step process in constructing a measure. First, they operationalize the construct of interest, either intuitively or with respect to theory or prior research. Second, they establish the reliability of the measure by looking at test–retest or short-term stability and, for measures that are tester-derived and require some judgment, determine whether there is interjudge agreement. Finally, they evaluate how well the measure predicts other theoretically important variables (convergent or construct validity) or is uncorrelated with theoretically unrelated variables (discriminant validity) (Campbell & Fiske, 1959).

Nunnally (1978) pointed out, however, that this approach is based on an inherent circularity in logic. We predict a relation between constructs, we “find” it using measures of the constructs at hand, and we thereby infer that our measures are valid. Optimally, Nunnally suggests three different steps: (1) The domain of relevant indices or variables (“observables”) must be specified, indicating which variables are indicative of security and which are not; (2) the intercorrelations among multiple concurrent measures of the construct must be ascertained; and (3) each measure must be cross-validated with respect to a network of other theoretically important constructs that have been similarly validated. Rather than being sequential, these three steps constitute a reflective process in which knowledge gained from one step transforms our understanding of the others.

For attachment researchers, the domain of “observables” for infancy and toddlerhood (12–20 months) is drawn from Bowlby’s (1969/1982, 1973, 1980) ethological attachment theory. *Attachment behaviors* are those that increase proximity to or maintain contact with a particular attachment figure. They are understood to be organized with respect to an internal control system (*the attachment system*) that has the adaptive function of protection and the set-goal of physical proximity or felt security. A critical feature of this model, with important implications for measurement, must be emphasized: The type of attachment behavior observed depends on the degree to which the attachment system is activated. When a young child is alarmed, he or she can be expected to signal clearly for proximity to and contact with the attachment figure (e.g., crying, approaching, reaching, clinging). Once these goals are achieved, and in the absence of further disturbance, the child can be expected to seek or accept some distance from the attachment figure and return to exploration. Attachment behavior under conditions of low activation, often referred to as *secure-base behavior*, can be difficult to distinguish from friendly, affiliative behavior and may be very much influenced by features of the external environment.

Ainsworth and colleagues (1978) argued that this pattern of shifting between exploration and attachment will appear disturbed or distorted to the extent that the infant perceives the attachment figure to be inaccessible or unresponsive. Thus, Ainsworth’s classic measure of attachment in infancy (the Strange Situation) and Waters and Deane’s Attachment Q-Sort measure (AQS; Waters, 1995; Waters & Deane, 1985) focus on

deviations from this basic pattern as a measure of insecurity in infant–parent attachment.

Attachment theory is less specific regarding appropriate measures of security in the third and fourth year of life and beyond. The attachment system is believed to function throughout this period, and indeed throughout the lifespan, but with diminishing sensitivity. Fewer situations are perceived as threatening, and knowledge of the parent’s accessibility (rather than actual proximity or contact) is increasingly effective in terminating attachment behavior. In addition, the broader and more flexible behavioral repertoire of the older child, and the child’s capacity to anticipate and coordinate with the parent’s behavior, can make it more difficult for scientific observers to perceive the underlying organization of attachment behavior. At the same time, language and symbolic achievements during this period make it feasible to begin assessing attachment security at the representational level.

Core Theoretical Predictions

Whether one follows Nunnally’s model of optimal construct validation or more approximate procedures, the validity (retrodictive, concurrent, predictive) of a measure is a fundamental concern. There are probably as many theoretically interesting relations among constructs in the field of attachment as there are researchers to propose them. Attachment theory, as articulated by Bowlby and Ainsworth, however, provides certain key predictions regarding the relation between security and other variables that are core to the theory itself. The validity of any particular measure of security should be assessed at a minimum with respect to these. Acknowledging that there may be some dispute in the boundary areas, we propose the following core predictions:

1. *Attachment security should be positively related to the caregiver’s accessibility and responsiveness to the child.* This prediction is implicit in the definition of security itself—that is, the state of being untroubled (confident) that the attachment figure will be available and will permit proximity and contact to the extent needed. An important corollary to this prediction is that attachment security with one caregiver should be independent of security with the other, insofar as the sensitivity of the two caregivers can be shown to differ. This fol-

flows from the definition of attachment security as a reflection of a particular relationship (Ainsworth et al., 1978) and not a property of the child (e.g., temperament).

Beginning with Ainsworth's pioneering work, maternal responsiveness and accessibility are typically assessed through variables reflecting the mother's prompt and appropriate response to the infant's attachment signals—that is, at the behavioral level. The field has shown increasing interest in the representational aspects of parental (especially maternal) sensitivity, and in the maternal qualities that permit or support sensitivity. By extension, such variables ought to be related to attachment security as assessed through behavior observations and, in turn, provide validity information for attachment measures.

2. *Attachment security in a particular caregiver-child relationship should tend to remain stable over time (continuity).* Although Bowlby (1973, 1980) was well aware of destabilizing influences on infant-caregiver attachment (e.g., repeated separation, life stress) and avoided the doctrine of critical periods, he proposed that the quality of attachment should become increasingly stable and resistant to change as a function of mutual adaptation in interaction patterns, and in each party's expectations about the other and the relationship, which become consolidated at the representational level. Sroufe and Waters (1977) emphasized the organizational quality of attachment; that is, although particular attachment behaviors may show little stability (due to the situation or the child's development), the underlying quality or organization of the relationship is expected to remain stable.

3. *Attachment security should predict other important aspects of development.* Related to but distinct from the notion of continuity is the general hypothesis proposed by Bowlby (1973) and elaborated both theoretically and empirically by Sroufe (1979; Sroufe & Waters, 1977) that attachment security should predict other key aspects of development. Bowlby emphasized the effects of insecurity arising from separation and loss on the development of psychopathology. In contrast, Sroufe articulated the more normative construct of "coherence" in development; that is, successes or failures in one developmental task (e.g., attachment in infancy) should predispose the child (and the caregiver-child dyad) to success or failure in subsequent developmental tasks

(e.g., autonomy, social competence). Sroufe's notion, though perhaps less central to attachment theory proper, parallels in many respects Erikson's (1950) classic formulation of developmental stages and has captured the attention of many researchers. It is important to note that it implies prediction relative to constructs other than attachment security, either concurrently or from one developmental period to another. In contrast, continuity implies prediction from an attachment security measure at one time relative to the same or a different measure of attachment security at another. Demonstration of *coherence* across time does not necessarily establish stability in the attachment relationship.

4. *Attachment security can be assessed by using similar or parallel measures cross-culturally and across attachment figures.* In the first two volumes of his *Attachment and Loss* trilogy, Bowlby (1969/1982, 1973, 1980) painstakingly built a case for the species-specific and therefore universal nature of attachment behavior in the young child. To the degree that a measure is based on ethological attachment theory, it should function similarly across cultures; that is, it should be as effective in describing the range of attachment relationships found in one culture (society, ethnic group, socioeconomic status [SES]) as in any other. In addition, it should be correlated in similar ways with measures of other theoretically important constructs, particularly caregiver behavior. By virtue of the same reasoning, the effectiveness of security measures and the pattern of correlations with caregiver behavior should be similar for all attachment figures (e.g., mother, father, other caregivers).

Organization of This Chapter

For the period of infancy through early childhood (ages 12 months to approximately 72 months), measures of attachment security are based on observation of behavior. They vary according to whether they focus on attachment behavior directed toward the caregiver or on representational assessment based on the child's linguistic or play behavior. The foundation of attachment assessment is the classification approach to attachment relationships pioneered by Ainsworth and colleagues (1978). This system of multidimensional categories of relationship based

on the infant's behavior in a laboratory separation-and-reunion context is both intuitively and theoretically compelling. The majority of measures for the period beyond early toddlerhood have been designed deliberately to capture these same or similar qualitative differences in child-caregiver attachment at both the behavioral and representational levels. An alternative approach is Waters's (1995) AQS method, which permits observers to capture the *dimension* of security in naturalistic circumstances.

We begin by describing Ainsworth's classification system and the subsequent addition of the disorganized/disoriented category. For this "gold standard" measure we review findings for all the validation criteria describe above. This is followed by a description of classification systems for reunion behavior and mental representation of preschool and kindergarten-age children, then by information on the AQS approach. Due to space limitations, our survey of validation studies for these measures is more compressed. Each section includes a brief discussion of unresolved issues in the construct validation of the measure(s) in question. We conclude with some general comments on the state of measurement in the field.²

Attachment Classification in Infancy: The Strange Situation

Attachment classification is based on the behavior of the young toddler (12–20 months of age) in the Strange Situation. (Following Ainsworth's usage, this age child is referred to as an *infant*.) This laboratory procedure was designed to capture the balance of attachment and exploratory

behavior under conditions of increasing, though moderate, stress. Full directions for running the session and for classification are presented in Ainsworth and colleagues (1978). Contrary to those instructions, however, experienced users typically do not provide a distraction to the mother (e.g., reading material), and they curtail separations if the infant becomes extremely distressed. An outline of the episodes that make up the Strange Situation is shown in Table 18.1. Infant attachment relationships are classified into one of three main groups: a "secure" group (B) and two "insecure" groups, "avoidant" (A) and "resistant" or "ambivalent" (C). Table 18.2 provides a brief description of classification criteria. Instructions are also available for designating eight subgroups, but the subgroups are rarely examined separately (due to limited sample sizes) and are not considered further here. Classification is based on the infant's behavior toward the caregiver during the two reunion episodes, viewed in the context of behavior in the preceding and intervening episodes and in response to the caregiver's current behavior. The infant's behavior during reunions is also rated on four scales of infant-caregiver interactive behavior that are used in the process of classification: Proximity and Contact Seeking, Contact Maintaining, Avoidance, and Resistance to Contact and Interaction.

About 15% of attachments in normative samples, and much higher percentages in high-risk samples, are difficult to classify with the original ABC criteria (Main & Solomon, 1986, 1990; Van IJzendoorn, Schuengel, & Bakermans-Kranenburg, 1999). Main and Solomon (1986) described the range of behaviors found in such unclassifiable infants and developed guidelines for assignment of most of these insecure infants to a

TABLE 18.1. Episodes of the Strange Situation

Episode	Duration	Description
1	1 minute	<i>Parent, infant:</i> Dyad introduced to room.
2	3 minutes	<i>Parent, infant:</i> Infant settles in, explores. Parent assists only if necessary.
3	3 minutes	<i>Parent, infant, stranger:</i> Introduction of a stranger. Stranger plays with infant during the final minute.
4	3 minutes	<i>Infant, stranger:</i> Parent leaves infant with stranger. <i>First separation.</i>
5	3 minutes	<i>Parent, infant:</i> Parent returns. Stranger leaves quietly. <i>First reunion.</i>
6	3 minutes	<i>Infant:</i> Parent leaves infant alone in room. <i>Second separation.</i>
7	3 minutes	<i>Infant, stranger:</i> Stranger enters room and stays with infant, interacting as necessary.
8	3 minutes	<i>Parent, infant:</i> Parent returns. Stranger leaves quietly. <i>Second reunion.</i>

TABLE 18.2. Strange Situation Classification Groups

Group	Brief description
Secure (B) (Ainsworth et al., 1978)	Uses mother as secure base for exploration. Separation: Signs of missing parent, especially during the second separation. Reunion: Actively greets parent with smile, vocalization, or gesture. If upset, signals or seeks contact with parent. Once comforted, returns to exploration.
Avoidant (A) (Ainsworth et al., 1978)	Explores readily, little display of affect or secure-base behavior. Separation: Responds minimally, little visible distress when left alone. Reunion: Looks away from, actively avoids parent; often focuses on toys. If picked up, may stiffen, lean away.
Ambivalent or resistant (C) (Ainsworth et al., 1978)	Visibly distressed upon entering room, often fretful or passive; fails to engage in exploration. Separation: Unsettled, distressed. Reunion: May alternate bids for contact with signs of angry rejection, tantrums; or may appear passive or too upset to signal, make contact. Fails to find comfort in parent.
Disorganized/disoriented (D) (Main & Solomon, 1990)	Behavior appears to lack observable goal, intention, or explanation—for example, contradictory sequences or simultaneous behavioral displays; incomplete, interrupted movement; stereotypes; freezing/stilling; direct indications of fear/apprehension of parent; confusion, disorientation. Most characteristic is lack of a coherent attachment strategy, despite the fact that the baby may reveal the underlying patterns of organized attachment (A, B, C).

Note. Descriptions in Groups A, B, and C are based on Ainsworth et al. (1978). Descriptions in Group D are based on Main and Solomon (1990).

fourth classification group termed “disorganized/disoriented” (D). Infants classified as Group D show a diverse set of behaviors characterized by a sometimes momentary disruption or contradiction in the smooth flow of behavior, a lack of observable explanation in the immediate situation, a breakdown or violation of the well-recognized sequences of behavior that are characteristic of the attachment groups, or direct signs of fear and confusion. The underlying ABC classification often remains detectable and, in the majority of cases, this underlying pattern matches the mothers’ attachment classification (Van IJzendoorn, 1995). Main and Solomon suggested, therefore, that this underlying pattern be noted as part of the classification process.

Validation of the Measure

Beginning with Ainsworth’s seminal work, validation of the infant classification system has been an ongoing priority. Many chapters in this volume reflect this progress and should be consulted accordingly. We begin with a lengthy discussion of reliability issues because the methodology departs substantially from what researchers in other areas of psychology may be familiar with, but we set this issue aside when discussing other measures later in the chapter.

Reliability

INTERCODER AGREEMENT

The Ainsworth system and other classification measures that we describe elsewhere in this chapter require extensive training. *Certification*, that is, proof that the researcher can meet a minimum reliability standard (usually 80% or higher) is desirable and typically is a requirement in peer-reviewed publications. Unlike *event coding*, which involves tallies of precisely defined acts, the *classification process* requires matching a particular case to a multidimensional, categorical template or prototype. Manuals for classification are composed mainly of written descriptions of these templates but cannot capture the range and nuance of behavior that is necessary for accurate categorization, which is why training by experts is common practice.

Within-laboratory agreement for trained coders tends to be very high, ranging from 100% to 85% (Ainsworth et al., 1978; Main & Weston, 1981; Waters, 1978). Five expert coders and Ainsworth independently classified all or a subset of 37 cases (videotapes), several of which were chosen because of the classification difficulties they presented (Carlson & Sroufe, 1993). Agreement percentages ranged from 50 to 100%, with the highest agreement (86%) found between Ain-

sworth and others. The fact that not all coders were trained to identify the disorganized/disoriented group may have lowered average reliability. Studies that made use of coders trained to identify the disorganized/disoriented group report across- and within-laboratory agreement ranging from 80 to 88% (Carlson, 1998; Lyons-Ruth, Repacholi, McLeod, & Silva, 1991).

When classification groups are disproportionately represented in a sample, high overall agreement (between judges or between classifications in stability assessments) may mask poor concordance for one or several of the (less common) groups. This is a particular problem in attachment research because secure classifications usually account for at least 50% of cases in nonclinical samples. Indeed, several investigators have noted that reports of high stability in classification are actually disproportionately due to stability (continuity) in the secure group but not in the insecure groups (e.g., Belsky, Campbell, Cohn, & Moore, 1996; Solomon & George, 1996; Waters, Merrick, Treboux, Crowell, & Albersheim, 2000). It is recommended that researchers report kappa or equivalent statistics that are adjusted for the relative frequencies of categories, along with raw reliability/stability figures. A large discrepancy between the raw (unweighted) concordance statistic and kappa indicates that agreement, stability, and so on, are unevenly distributed in the sample.

TEST–RETEST (SHORT-TERM) STABILITY

Ainsworth repeated Strange Situation assessments over a 2-week period and found low stability, presumably reflecting sensitization of infants to the separation procedure (Ainsworth et al., 1978). The collapse of avoidant strategies in the second assessment was especially noteworthy: A number of previously avoidant infants on retest showed behavior patterns that we might now classify as disorganized. Separation of assessments by a month or more is recommended, and this practice appears to be the rule for observation-based attachment measures.

Relation to Other Measures of Security

One of the most compelling aspects of the original work was Ainsworth and colleagues' exceptional effort to validate the classification groups with respect to infant behavior toward the mother in the home. Home observation data for the original

sample of 23 babies was based on detailed narrative records of monthly visits over the course of the first year of life. Drawing on this work, Ainsworth was able to develop a rich and complex portrait of each relationship. Well-known findings from the study link classification in the Strange Situation to a set of variables reflecting the frequency and quality of infant attachment behavior in the home. Attachment classifications have also been assessed against home-based measures of attachment security—both a category system developed by Ainsworth and the AQS, which yields a summary security score reflecting the quality of an infant's secure-base behavior in the home. Both approaches show that secure versus insecure laboratory attachment classifications are related to different patterns of infant behavior in the home in ways predicted by theory. The two main insecure groups (A and C), however, were generally less well discriminated from each other in the home (Ainsworth et al., 1978; Vaughn & Waters, 1990).

Prediction to Core Variables

MOTHER–CHILD INTERACTION

Ainsworth's original home observations established key differences among mothers of secure, avoidant, and ambivalent infants on four highly intercorrelated variables: *sensitivity* (defined as prompt and appropriate responsiveness to the infant's signals), *acceptance* (vs. rejection), *cooperation*, and *psychological accessibility*. Mothers of secure infants were high on all four dimensions; mothers of avoidant infants provided the infants little positive experience with physical proximity and were rejecting; and mothers of ambivalent infants were inconsistently responsive to infant distress and other signals. These findings were replicated in several studies in both naturalistic and structured situations, although the associations have been weaker in the replications. An often cited meta-analysis concluded that parental sensitivity, although clearly important, does not appear to be the exclusive factor in the development of secure attachment (De Wolff & Van IJzendoorn, 1997). Given the centrality of the sensitivity construct in contemporary attachment theory, this is a radical notion. Failure to replicate Ainsworth's original findings may be due to reliance on limited samples of interaction, or shifts in the operational definition of sensitivity toward an emphasis on theoretically distinct constructs such as warmth, acceptance, and emotional availability. In support

of this suggestion, more recent studies demonstrate that maternal sensitivity to distress signals in the early months, rather than sensitivity in general, is the key predictor of attachment security (Leerkes, 2011; McElwain & Booth-LaForce, 2006).

The identification of the disorganized/dis-oriented category exerts another influence on the strength of the association found between sensitivity and attachment security. Recent studies indicate that two dimensions of maternal behavior are linked to this classification—frightening or frightened/dissociative behavior, and some kinds of atypical, disrupted communication (Lyons-Ruth et al., 2013; Madigan et al., 2006). A growing body of literature also suggests that attachment disorganization may reflect neurological vulnerability (Padrón, Carlson, & Sroufe, 2014; Tharner et al., 2011). The variation reflected in the standard Ainsworth ABC categories, however, is better explained by the history of mother–child interaction than by the direct effect of biological variables (Fearon et al., 2006).

CONTINUITY

Estimates of continuity depend on the age of the child at time of first and follow-up assessments, and the measures involved. The empirical findings have been mixed. Findings of very high stability of classification (over 70%) have been reported across both short and long time periods (e.g., Hamilton, 2000; Main & Cassidy, 1988; Waters, 1978). Nevertheless, studies showing substantial instability of classification between infancy and early childhood, and between these periods and young adulthood, are accumulating. In their review of longitudinal findings for 1,000 children in the National Institute of Child Health and Human Development Study of Early Child Care and Youth Development (NICHD SECCYD), Groh and colleagues (2014) reported low but significant concordance in secure versus insecure classifications between infants ages 15 and 36 months, and no significant concordance between the 15-month and 18-year assessments. Similarly, Pinquart, Feussner, and Ahnert (2013) in the most comprehensive meta-analysis of stability studies to date, reported lower stability for those originating in the second year of life compared to studies initiated later. Lack of stability of the D group attachment classification within the second year of life may be due to an increase in numbers of disorganized/disoriented infants between ages 12 and 18 months (Lyons-

Ruth, Yellin, Melnick, & Atwood, 2003; Vondra, Shaw, Swearingen, Cohen, & Owens, 2001). Possibly, at infant age 15 months, the Strange Situation captures mother–child dyads at a time when this transition is not yet complete. However, in the NICHD Early Child Care Research Network (2001) study, the greatest instability was in the avoidant, not the disorganized dyads. A critical finding is that in most stability studies, change in classification is systematically related to major shifts in maternal sensitivity or to family events such as loss, divorce, major illness, and poverty (on the negative side) and marriage or new relationships (on the positive side). Thus, findings of low stability do not challenge the bedrock assumption that Strange Situation classifications provide a reasonable reflection of the parent–child relationship and perhaps should be given less weight overall in the evaluation of the validity of measures.

COHERENCE

Inspired by Sroufe's (1979) early articulation of the coherence of development across developmental tasks, the field has continued to generate a large body of research on the links between early attachment security and later functioning, including those in relationships with parents, peers, and romantic partners (in this volume, see Thompson, Chapter 16; Ehrlich, Miller, Jones, & Cassidy, Chapter 9; Williford, Carter, & Pianta, Chapter 41). Bowlby's seminal predictions about the connections between early parent–child attachment and later psychopathology have borne fruit in the study of the sequelae to disorganized attachment, which predicts both dissociative and externalizing behavior in longitudinal studies and meta-analyses (Carlson, 1998; Fearon & Belsky, 2011; Rutter, Kreppner, & Sonuga-Barke, 2009). In contrast, avoidance appears to be linked to general internalizing symptoms (Carlson, 1998; Groh, Roisman, Van Ijzendoorn, Bakermans-Kranenburg, & Fearon, 2012; Madigan, Atkinson, Laurin, & Benoit, 2013; in this volume, see DeKlyen & Greenberg, Chapter 28; Lyons-Ruth & Jacobvitz, Chapter 29).

CROSS-CULTURAL PREDICTIONS AND PREDICTIONS RELATIVE TO OTHER CAREGIVERS

Studies of infants from cultures beyond North America in the Strange Situation have mainly

been limited to Western Europe, but researchers have also examined infants and their mothers in Israel, Japan, Shanghai in China, Indonesia, Puerto Rico, Mexico, and two sites in Africa. Although secure classifications appear to be normative (modal) cross-culturally, cultural differences have emerged in the proportions of attachment groups. Corresponding observations of maternal behavior in the home suggest that such differences reflect systematic cultural patterns of maternal sensitivity to infant signals and cross-cultural differences in the frequency of separation from their mothers (for a review, see Mesman, Van IJzendoorn, & Sagi-Schwartz, Chapter 37, this volume).

Investigators report no difficulty in classifying infant–father attachment relationships from the Strange Situation. In several, but not all, studies, the modal classification category is secure (e.g., Cox, Owen, Henderson, & Margand, 1992). A recent meta-analysis of attachment to father shows a clear link between attachment to father and paternal sensitivity to the infant’s attachment signals (Lucassen et al., 2011). Studies do suggest that in comparison to mothers, fathers’ behavior is more closely linked to marital conditions, and to infant temperament and gender (Lickenbrock et al., 2013; Schoppe-Sullivan et al., 2006). The mechanisms by which infants arrive at qualitatively similar attachment strategies given large culture- and parent-related differences in patterns of interaction continues to need further investigation.

Discussion

There can be little doubt that attachment classification by highly trained judges captures fundamental and far-reaching qualities of the infant–mother relationship. The reliability and predictive validity of Ainsworth’s classification measure are well established in U.S. and Western European populations. However, important questions remain about the psychometric properties and meaning of the measure for infant–father relationships, relationships with other caregivers, and attachment relationships in non-Western societies. One of the most significant contributions of the method stems from its recognition of attachment relationship patterns or types, which has permitted researchers to describe and explicate individual differences in early relationships in a simple way that predicts significant developmental outcomes years later.

The ABC groups were based on the study of a middle-class sample of only 23 mothers and infants, observed four decades ago. As described previously, studies using much larger samples have revealed lower levels of stability of attachment between 12 and 18 months than were suggested by earlier, smaller studies (e.g., Waters, 1978). Mothers’ work patterns, the degree of fathers’ involvement in the lives of very young children, and economic conditions also have changed considerably since the era when early work was undertaken.

The most consequential addition to the original Ainsworth system, the disorganized/disoriented group, would not have been identified had researchers not attempted to replicate early findings in larger and atypical populations, and had they not been open to unexpected variations in behavior (Main & Solomon, 1990). Systematic research following on that original work has revealed the importance of this category for understanding variation at the more insecure and clinical end of the spectrum. The explanatory power of Ainsworth’s methodology is increased substantially when this category is included in the study.

Ainsworth’s reliance on a categorical approach to qualitative differences in attachment reflected her background in clinical assessment and her conviction that patterns of behavioral constellations, rather than individual differences in particular behaviors, distinguish types of attachment (Ainsworth & Marvin, 1995). Statistically less sensitive than dimensional measures, categorical systems require larger samples to establish reliable group differences. Many researchers who make use of Ainsworth’s classification system (or other systems derived from it) are forced to reduce variability to a simple secure–insecure dimension because of inadequate sample size, usually in the insecure groups.

Fraley and Spieker (2003) tested the taxonomic structure of the standard Ainsworth categories. They argued that a very large portion of the variance associated with the ABC classifications can be summarized by two dimensions broadly representing “approach–avoidance” and “resistance–emotional confidence.” Researchers interested in avoiding some of the well-known methodological pitfalls of categorical analysis could make use of this approach to dimensional scaling or the early one devised by Richters, Waters, and Vaughn (1988) from Ainsworth’s interactive scales. Neither approach taps aspects of behavior relevant to

attachment disorganization, but the disorganization scale, usually used as a part of the classification process (Main & Solomon, 1990) can serve this same purpose. (For an example of how these scales intercorrelate, see Groh et al., 2014.) Infant classification procedures have become so closely identified with the construct of security that it is difficult for researchers to conceive that different or additional measures may be necessary or feasible. In part, this reflects the simple brilliance of the Strange Situation procedure: It is hard to imagine another situation that can as reliably and ethically activate attachment behavior in the second year of life. The procedure makes use of a “natural cue to danger” (Bowlby, 1973)—separation from the attachment figure—to activate the attachment system. The use of distinct episodes allows the coder to observe the infant’s immediate response to particular events and the coherence of behavior across episodes. Furthermore, the situation appears to provide the “right” amount of stress. Too little stress does not activate the attachment system adequately, judging by the results of home observations (e.g., Ainsworth et al., 1978; Vaughn & Waters, 1990) and therefore may not allow critical distinctions among insecure groups to be revealed. Very high stress, such as that provided by repeating the procedure twice in 2 weeks, appears to result in a breakdown of attachment strategies, again obscuring important differences among groups. Last, given that the primary threat to the child in the Strange Situation is a (transitory) threat to the relationship, the inferential leap from an observed pattern of attachment behavior to the infant’s confidence regarding the psychological responsiveness of the caregiver seems to be a relatively modest one.

The validity of the security construct as measured by the Strange Situation requires its cross-validation with one or more other measures of infant security. Researchers often treat adult attachment measures as sources of cross-validation, but this presumes the very theoretical association that Bowlby’s theory was designed to test. As we discuss later, the alternative measure of security in early toddlerhood, the AQS, does not reveal distinctions among the insecure groups, although, as we discuss later, some researchers attempt to use it in this way. Strictly speaking, the construct validation for infant attachment classifications technically is incomplete. We hope that this rather unsettling realization inspires researchers to devise alternative measurement approaches.

Classification of Attachment in the Preschool Period

Investigators have followed two approaches to developing classification systems for children’s attachment behavior beyond infancy. The dominant approach is based on an assumption of continuity between infancy and older ages, with allowances for developmental changes in the actual behaviors indicative of one or another type of relationship. In order to develop guidelines for 2-year-olds, Marvin (1977) and Schneider-Rosen (1990) modified Ainsworth’s assessment criteria developmentally; for example, the timing and quality of distance interaction (including talking) were used as indices of security instead of the proximity seeking and contact maintenance of very young children. Marvin also considered the quality of parent–child negotiations around departures and reunions as an index of the quality of the goal-corrected partnership that according to attachment theory begins to emerge in an older toddler (Bowlby, 1969/1982, 1973, 1980). Main and Cassidy (1988) developed classification criteria for 6-year-olds by finding lawful continuities in reunion behavior for children whose infant attachment classifications were known. This effort was followed by Cassidy and Marvin, with the MacArthur Attachment Working Group (1992), who adjusted the Main and Cassidy kindergarten system downward for preschool-age children (from 2½ to 4½ years old) based on careful and extensive observations of their reunion behavior.

The second approach, called by Crittenden (1992a, 1992b) the “dynamic-maturational model,” focuses on dynamic changes in the quality of attachment arising from the interaction between maturation and current experience. Based on the concept of developmental pathways, this approach emphasizes the possibilities for changes in quality of attachment over time. The classification process places greater emphasis on inferences regarding the function of the child’s behavior toward the parent, framed in terms of seeking psychological safety. There are strong similarities between the Preschool Assessment of Attachment (PAA; Crittenden, 1992a) system and the Preschool Attachment Classification System (PACS; Cassidy et al., 1992), as well as a number of subtle but significant differences. In both systems, attachment groups are distinguished by the communicative or defensive goals that underlie attachment patterns. In both, for example, the avoidant pat-

tern is viewed as a defensive behavioral strategy organized around the goal of decreasing the probability of emotional involvement or confrontation. In Crittenden's PAA, however, this defensive strategy includes not only cool or neutral avoidance of the parent (as in the Main–Cassidy and Cassidy, Marvin, and MacArthur systems) but also behavior that might be seen as caregiving or hypercompliance. These are linked to neutral avoidance by the fact that in both strategies, the child takes the major initiative in regulating proximity and communication with the parent.

Both approaches use the Strange Situation procedure, especially the two separations and reunions of the original. Some investigators have introduced variations to accommodate the older age of the children, such as slightly longer separations, changes in the role and/or gender of the stranger, changes in the instructions to the caregiver, and blending with other laboratory tasks and procedures. A common approach in recent studies, recommended in the manual (Cassidy et al., 1992), is to omit the stranger episodes entirely, thus leaving the child alone in the room during both separations. We refer to this procedure as a “modified Strange Situation procedure.” (The manual also accepts the use of the stranger as it is done for infants. Unfortunately, there has been no systematic determination of whether these variations materially affect the reunion behavior of the children.)

A description of the categories used in systems for the 5- to 6-year-olds and 2- to 3-year-olds is provided in Table 18.3. Although the Main and Cassidy system for 6-year-olds was developed earlier, we present information about the Cassidy, Marvin, and MacArthur system (1992) first because it applies to chronologically younger children. We next consider the Main–Cassidy system. Crittenden's PAA system has seen some increased use in recent years, especially with high-risk samples. It has been adapted to capture precursors in toddlerhood of the more extreme A- and C-type relationships and for school-age children, using representational materials (Crittenden, Kozłowska, & Landini, 2010; Farnfield, Hautamäki, Nørbech, & Sahhar, 2010). The dynamic maturational model also has been elaborated to follow attachment development through adulthood. Due to space limitations, we do not further describe the limited validation information available for the PAA below, but note that despite some overlap in category labels, the two systems do not result in comparable classifications in low risk samples

(Hautamäki, Hautamäki, Neuvonen, & Malinemi-Piispanen, 2010; Rauh, Ziegenahin, Muller, & Wijnroks, 2000; Spieker & Crittenden, 2010).

The Cassidy, Marvin, and MacArthur Group Preschool Attachment Classification System for Preschoolers

The PACS provides guidelines for a “secure” group (B) and four “insecure” groups as follows: “avoidant” (A), “ambivalent” (C), “controlling/disorganized” (D), and “insecure/other” (IO). (Main and Cassidy [1988] noted in their kindergarten age sample that the majority of formerly disorganized/disoriented infants showed a pattern of controlling the mother in a negative (D1) or positive (D2) manner, and this is reflected in the combination of these types into a single “D” group in the preschool system.) Classifications are based primarily on the child's behavior toward the mother during both reunions. Researchers report adequate interjudge agreement on these measures.

Relation to Other Measures of Attachment Security

Classification in the PACS has been shown to be related both to the AQS Security subscale (Waters & Deane, 1985) and to representational measures of attachment. Considering the AQS findings first, a meta-analysis of studies through 2004 showed that secure PACS classification is significantly related to preschoolers' attachment security in the home, but at a more modest level than for infants (combined $r = .26$; range = $.10$ to $-.40$ for children 30 months or older and $r = .31$; range = $.25$ to $-.57$ for children ages 12–18 months; Van IJzendoorn et al., 2004). Subsequently, Moss, Bureau, Cyr, and Dubois-Comtois (2006), found significant differences in AQS security overall among children classified according to the Cassidy and colleagues (1992) system. AQS security was higher for children classified as secure than for those classified as ambivalent or disorganized (but not controlling), but there were no reliable differences between the secure and avoidant or controlling groups. Posada (2006) reported no significant difference among attachment classification groups in the overall AQS security.

Early on, three studies showed links between PACS classifications and the Attachment Story

TABLE 18.3. Early Childhood Laboratory Separation–Reunion Classification Systems: Major Classification Groups

Group	Cassidy, Marvin, & MacArthur (PACS)	Crittenden (PAA)	Main–Cassidy
B	<i>Secure</i> : Uses parent as secure base for exploration. Reunion behavior is smooth, open, warm, positive.	<i>Secure/balanced</i> : Relaxed, intimate, direct expression of feelings, desires. Able to negotiate conflict or disagreement.	<i>Secure</i> : Reunion behavior is confident, relaxed, open. Positive, reciprocal interaction or conversation.
A	<i>Avoidant</i> : Detached, neutral nonchalance, but does not avoid interaction altogether. Avoids physical or psychological intimacy.	<i>Defended</i> : Acts to reduce emotional involvement or confrontation. Focuses on play and exploration at expense of interaction.	<i>Avoidant</i> : Maintains affective neutrality; subtly minimizes and limits opportunities for interaction.
C	<i>Ambivalent</i> : Protests separation strongly. Reunion characterized by strong proximity-seeking, babyish, coy behavior.	<i>Coercive</i> : Maximizes psychological involvement with parent; exaggerates problems and conflict. Is coercive, for example, threatening (resistant, punitive) and/or disarming (innocent, coy).	<i>Ambivalent</i> : Heightened intimacy and dependency on parent. Reunion characterized by ambivalence, subtle hostility, exaggerated cute or babyish behavior.
D	<i>Controlling/disorganized</i> : Characterized by controlling behavior (punitive, caregiving) or behaviors associated with infant disorganization.		<i>Controlling</i> : Signs of role reversal: punitive (rejecting, humiliating) or caregiving (cheering, reassuring, falsely positive).
A/C		<i>Defended/coercive</i> : Child shows both defended and coercive behaviors, appearing together or in alternation.	
A/D		<i>Anxious/depressed</i> : Sad/depressed; stares, extreme distress/panic.	
IO or U	<i>Insecure/other</i> : Mixtures of insecure indices that do not fit into any of the other groups.	<i>Insecure/other</i> : Acts incoherently in relation to parent.	<i>Unclassifiable</i> : Mixture of insecure indices that do not fit into any of the other groups including behaviors associated with infant disorganization.

Note. Cassidy–Marvin, Main–Cassidy: Organized groups = A, B, C. PAA: Organized groups = A, B, C, A/C.

Completion Task (ASCT), a representational measure of attachment security (Bretherton, Openheim, Buchsbaum, Emde, & the MacArthur Narrative Group, 1990; Bretherton, Ridgeway, & Cassidy, 1990; Shouldice & Stevenson-Hinde, 1992). Preschoolers classified as secure, compared to those classified as insecure, received higher scores for representational security (i.e., they were judged more open to negative feelings and better able to tolerate attachment fears). Finally, Groh and colleagues (2014) report significant negative

correlations between security in the PACS and dismissive and preoccupied profile scores generated from the Adult Attachment Interview.

Prediction to Core Variables

MOTHER–CHILD INTERACTION

Clear differences between the secure and insecure groups' quality of interaction have been demonstrated in several studies. Mothers of secure chil-

dren are rated higher than mothers of insecure children in qualities such as sensitivity, socialization, positive involvement, and scaffolding in cognitively challenging tasks or cleanup in normative families across the full spectrum of incomes (e.g., NICHD Early Childcare Research Network, 1991). Recently, Dexter, Wong, Stacks, Beeghly, and Barnett (2013) investigated low-income African American and European American mothers, and found no effect of ethnicity but a clear link between maternal warmth and responsiveness in secure versus insecure dyads. In contrast, differences between the secure and the various insecure groups, or among the insecure groups, have not uniformly been found. In the previously discussed NICHD study, significant differences between attachment groups were mainly found between the controlling/disorganized and secure classifications. Moss and her colleagues (Humber & Moss, 2005; Moss, Bureau, Cyr, Mongeau, & St.-Laurent, 2004; Moss, Cyr, & Dubois-Comtois, 2004) found overall smoother and more positive interaction during a brief “snack time” in a comparison between secure and insecure dyads with children ages 3 to 7 (note that the Main–Cassidy system was adapted for classifications for children age 6 years and older). The clearest differences in both age periods were between dyads with secure versus disorganized/controlling children. O’Connor, Bureau, McCartney, and Lyons-Ruth (2011) looked in detail at the mother–child interaction variables that best differentiated the disorganized/controlling groups from organized insecure (A, C) and secure groups in the NICHD sample. Maternal hostility was significantly higher for the disorganized groups, whereas maternal support and respect for autonomy was lower for the D group as opposed to the secure and insecure groups. Within the subtypes of the controlling/D-group children, quality of interaction was worst for the controlling/punitive and behaviorally disorganized groups and comparable to secure dyads for the controlling/caregiving group. The dimensional scales used in the study likely were insensitive to the unique qualities of the caregiving group, where positive interaction is supported by the child’s rather than the mother’s behavior (Main & Cassidy, 1988; Solomon & George, 1999d). Finally, between-group differences in maternal behavior emerged in a study by Britner, Marvin, and Pianta (2005). They developed a classification system and rating scales for maternal behavior in the modified Strange Situation reflecting qualities captured from Ainsworth’s original studies and studies of adult attachment representation. Agreement be-

tween mother and child classifications was high, though not exact ($\kappa = .57$). Though this system seems to provide strong evidence for distinctions in maternal behavior corresponding to all of the child classifications, the fact that mother and child categories are based on the same sample of behavior is problematic.

Studies in non-normative samples provide indirect evidence that classification reflects differences in maternal behavior. Just to cite relatively recent studies involving, variously, maltreated children, children whose mothers experience domestic violence, and mothers who are adolescent, impoverished, depressed, or anxiety-disordered, fewer relationships are classified as secure and more as “atypical” (e.g., disorganized, controlling, or insecure/other) than comparison children (Barnett et al., 2006; Campbell et al., 2004; Fish, 2004; Levendosky, Bogat, Huth-Bocks, Rosenblum, & von Eye, 2011; Lounds, Borkowski, Whitman, Maxwell, & Weed, 2005; Toth, Rogosch, Manly, & Cicchetti, 2006). Several researchers who studied attachment involving adopted or institutionalized young Romanian or Chinese children found disorganized and atypical behavior to be highly characteristic (Zeanah, Smyke, Koga, & Carlson, 2005). Lower levels of disorganization or atypical behavior and increased security become evident after placement in foster or adoptive homes (McLaughlin, Zeanah, Fox, & Nelson, 2012).

CONTINUITY

A number of studies provide data on continuity (stability) of classification from toddlerhood. Three studies found significant but very low stability in classifications over time (Levendosky et al., 2011; NICHD Early Child Care Research Network, 2001; Seifer et al., 2004), and two studies with somewhat smaller samples reported no significant stability over the early childhood period (Bar-Haim, Sutton, Fox, & Marvin, 2000; Fish, 2004). Significant but moderate continuity of classification ($\kappa =$ approximately .40) is reported in yet other studies (Cassidy, Berlin, & Belsky, 1990; Cicchetti & Barnett, 1991; Lounds et al., 2005; Shouldice & Stevenson-Hinde, 1992). The secure pattern showed the highest consistency over time, but the studies differed on which of the insecure patterns was most likely to shift. Shifts into the secure category were the most common for the unstable insecure infants.

In the only study to date of stability *within* the preschool period of the Cassidy and colleagues

(1992) classifications in a normative population, Moss, Cyr, Bureau, Tarabulsy, and Dubois-Combois (2005) found moderate stability between 3½- and 5½-year-olds in a sample that was heterogeneous with respect to SES. Stability of group assignment was over 60% for all groups except the avoidant group, which shifted considerably. Seventy percent of disorganized 3½-year-olds shifted into the controlling category within this time period, suggesting that this is the point at which disorganized children consolidate their secondary controlling strategies. The level of instability in classification might in itself raise questions about the validity of the Cassidy and colleagues' system, based on the premise that stability will be the norm. Investigators in each of these studies established, however, that shifts between the secure and insecure classification(s) typically were related to corresponding changes in mother-child interaction and/or other key factors (e.g., domestic violence, marital distress, and separation).

COHERENCE

Differences between secure and insecure children are found in other, theoretically related developmental domains. Several studies show, as would be expected, that secure children are more cooperative with their mothers than insecure ones in brief laboratory tasks (e.g., Cassidy et al., 1992; Moss, Bureau, et al., 2004). A key matter from the point of view of coherence of development, however, is whether group differences can be detected in other relationships and in underlying social or cognitive strengths. Questions along these lines have been addressed in secondary analyses of the findings from the NICHD SECCYD. For example, Raikes and Thompson (2008) found that at 24 months, AQS security and secure versus insecure attachment in the PACS system at 36 months predicted children's social problem-solving skills and lower self-reported loneliness at 54 months of age. Similarly, Drake, Belsky, and Fearon (2014) used latent growth curve analysis to demonstrate effects of secure attachment at 36 months on social self-control and flexibility and task persistence in grade 1. Social self-control, in turn, mediated links between earlier attachment and school engagement in grades 3 and 5 (see also Fish, 2004; Moss & St-Laurent, 2001; Stacks & Oshio, 2009). The NICHD studies did not find similar effects of attachment security measured earlier, at 15 months. Researchers have also found that children classi-

fied as secure in the PACS were less likely than insecure, especially avoidant and/or controlling/disorganized children, to show externalizing behavioral problems (Moss, Cyr, et al., 2004). In a clinical population, children classified as controlling/disorganized were more likely to be diagnosed with conduct disorder (for further information, see Lyons-Ruth & Jacobvitz, Chapter 29, this volume).

CROSS-CULTURAL STUDIES AND OTHER RELATIONSHIPS

The PACS has been used to study attachment in the United States, England, Canada, and Romania. There is no published information on preschool attachment in countries or cultures other than these.

The Main-Cassidy Attachment Classification for Kindergarten-Age Children

The Main and Cassidy (1988) attachment classification system for kindergarten-age children was developed on a sample of 33 children whose infant attachment classifications in the Strange Situation (A, B, and D) were known and who had experienced no major change in caretaking relationships. The system was further tested and extended on a new sample of 50 children that afforded enough C children to establish classification guidelines for this group. Classification is based on a child's behavior during the first 3 or 5 minutes of reunion with the parent following a 1-hour separation, rather than on the episodes and timing of the Strange Situation. Guidelines are provided for five major classification groups: "secure" (B), "avoidant" (A), "ambivalent" (C), "controlling" (D), and "unclassifiable" (U). Criteria for subgroup classifications are also provided. Rating scales for security and avoidance have been developed as well. The major criteria for classification are shown in Table 18.3.

Short-Term Stability

Stability of classification over a 1-month period in Main and Cassidy's (1988) sample of 50 was 62%. Instability was largely due to change involving the controlling group. The authors suggest that instability in part reflects sensitization to the test situa-

tion (i.e., the relaxation of defenses under conditions of safety).

Relation to Other Measures of Security

Main–Cassidy classifications have been shown to be related to secure versus insecure classifications using five different procedures for classifying children's representations of attachments, including picture-based and doll play protocols and family drawings (Barone & Lionetti, 2012; Behrens & Kaplan, 2011; Bureau, Béliveau, Moss, & Lépine, 2006; Gloger-Tippelt, Gomille, Koenig, & Vetter, 2002; Jacobsen & Hofmann, 1997; Solomon, George, & De Jong, 1995). Most systems captured secure versus insecure attachment status or show concordance for some of the A, B, C, and D groups. Only Solomon and George's ADPA differentiated reliably among all of the groups A–D in both a U.S. and a Japanese sample (Kayoko, 2006).

Prediction to Core Variables

MOTHER–CHILD INTERACTION

Based on their studies of a French Canadian sample, Moss and colleagues reported that mother–child interaction in secure dyads was more harmonious than that within insecure dyads, with the lowest scores received by mothers of controlling, disorganized, or unclassifiable children of all subtypes (Humber & Moss, 2005; Moss, Gosselin, Parent, Rousseau, & Dumont, 1997; Moss, Rousseau, Parent, St.-Laurent, & Saintonge, 1998). George and Solomon (1990, 1996, 2000) replicated this finding in their U.S. sample. Finally, in a study of Japanese kindergarteners, classification with the Main and Cassidy system was significantly associated with mothers' Adult Attachment Interview classifications (Behrens & Kaplan, 2011).

CONTINUITY

Main and Cassidy (1988) and Wartner, Grossmann, Fremmer-Bombik, and Suess (1994) reported very high stability ($\kappa > .76$) between 12-month and 6-year A, B, C, and D classifications with mothers. As described previously, Moss and colleagues (2005) recently demonstrated moderate continuity over a 2-year period between Cassidy and Marvin (1992) preschool classifications and adapted Main–Cassidy classifications at age 6.

COHERENCE

Cohn (1990) and Wartner and colleagues (1994) found that securely attached children were judged to be more socially competent and accepted than the insecurely attached children, although the studies differed as to which insecure group showed the greatest deficit (C or A). Insecure classification, especially in the D group, was linked to externalizing behavioral problems in high- and low-risk samples (Easterbrooks, Biesecker, & Lyons-Ruth, 2000; Lecompte & Moss, 2014; Solomon et al., 1995). Paralleling these findings, Cassidy, Kirsh, Scolton, and Parke (1996, Study 2) found that secure children had more positive representations of peers' intentions and feelings, as assessed from social problem-solving vignettes, than did insecure children. Secure versus insecure Main–Cassidy classifications were also found to be related to representational measures of self-esteem and attachment, with secure children judged to be more open about themselves and about feelings of vulnerability than insecure children (Cassidy, 1988; Slough & Greenberg, 1990). Controlling children were found to depict more themes of conflict on a representational storytelling measure (Moss, Bureau, Béliveau, Zdebik, & Lépine, 2009). Seven years later, children classified controlling–punitive in kindergarten described themselves as higher in externalizing behavior at age 13, and their mothers were more likely to describe themselves as helpless to control the child (Lecompte & Moss, 2014).

CROSS-CULTURAL STUDIES

The Main–Cassidy system has been used in the United States, Canada, Iceland, Germany, Italy, Australia, and Japan. Fathers' self-reported responsiveness to their child's distress, but not warmth, were associated with child classification group and lower avoidance (George, Cummings, & Davies, 2010).

Discussion

Based on widespread use and the corresponding state of validation overall, the Cassidy and Marvin (1992) system must now be considered the preferred measure for assessment of attachment of 3- and 4-year-olds, especially for researchers who are interested in differences among the four classification groups. The measure has been investigated with respect to all of the validation criteria

described earlier and appears to be related both to other relationship measures and to the core variables in ways that broadly parallel research on infant classifications.

In the 2008 edition of this volume, reports of low or inconsistent continuity between toddler and preschool classifications led us to question the validity of the PAC. Since then, accumulating evidence of limited stability of classifications in the 12- to 15-month range have caused us to rethink this issue. Furthermore, recent analyses of longitudinal data showing that PAC classifications correspond more closely than early classifications to 24 month AQS scores and to later socioemotional development indicate its value (Drake et al., 2014; Raikes & Thompson, 2008). Instability in classification may be a poor marker of the validity of the measure in this age range. Attachments are likely to undergo major change between the third and fifth years of life, reflecting expectable shifts in parent–child relationships and development in the child’s capacity for language, representation, goal-corrected behavior, and self-control. Appropriately, studies of parent–child interaction in this period tend to focus on cooperation in cleanup tasks or joint cognitive problem solving rather than parental guidance of play. This may be one reason why researchers have found that preschool classifications show clearer relations to social problem solving and school readiness than do toddler classifications.

Finally, we would like to point out a methodological issue that may not have emerged clearly in earlier discussion. The Main–Cassidy classification system that served as a model for the PACs seems not to have seen much use in recent years. Possibly this is because it covers a transitional age between preschool and elementary school; possibly this is due to a scarcity of formal training opportunities for the Main–Cassidy system. Moss, and researchers trained by her, typically refer to adapting the Main–Cassidy procedure when their participants are 5–6 years of age. It is not always clear what is meant. In some reports, the 1-hour separation is shortened; in others, these investigators report basing classifications on two separations and reunions rather than one. From our own research with the Main–Cassidy system, we know that there can be surprising inconsistencies between first and second reunion behavior, with some children apparently changing from avoidant to ambivalent or the reverse, to provide one example. These adaptations may lead to classification differences between

those trained by Moss and others who strictly follow the Main–Cassidy guidelines. There may be sound reasons for adaptations. Nevertheless, it has become something of a tradition for us, as authors of this chapter, to emphasize the need for better standardization and cross-validation of adapted measures, and we do so here again.

Attachment Measures Based on Symbolic Representation

Bowlby (1969/1982) posited the construct of an internal representational model of attachment that arises from actual experiences and is used to evaluate present circumstances and guide future action. Such models are now conceptualized variously as comprising specific content or scripts, including affect, and information-processing rules that integrate and determine perception and memory (Bretherton, Grossmann, Grossmann, & Waters, 2005; Waters & Waters, 2006). Recent studies suggest that infants as young as 12 months may encode knowledge about their relationships in both representational and sensorimotor forms (Johnson et al., 2010). By the preschool years, symbolic forms of mental representation are readily accessed and therefore have been the subject of considerable research.

Research on children’s internal representations of attachment was inspired by work in Main’s laboratory in the mid-1980s, which led to the development of the Adult Attachment Interview (AAI; George, Kaplan, & Main, 1984, 1985, 1996). Beginning with Kaplan’s (1987) attempts to capture representational processes in family drawings and the Separation Anxiety Test (see below), and Cassidy’s (1988) self-esteem and family stories, investigators have gone on to create a wide variety of measures, some original, others adapted from previous efforts. No single measure has been systematically validated according to our criteria. Due to space limitations, we restrict our discussion to a few measures that are currently in use or have accumulated the most validity information. We briefly describe the general procedures for the different types of measures, along with key validation information. We further compare and contrast validation findings as part of a general discussion. We refer readers to the original reports and to previous editions of this book for additional information.

Picture Response Measures

Two closely related measures (Kaplan, 1987; Slough & Greenberg, 1990) incorporate the procedures of the Separation Anxiety Test (SAT), a picture-response protocol that was first developed for adolescents by Shouldice and Stevenson-Hinde (1992) and modified from Hansburg (1972) for children ages 4–7 by Klagsbrun and Bowlby (1976). The procedure consists of a set of six photographs depicting attachment-related scenes ranging from mild (a parent says goodnight to a child in bed) to stressful (a child watches a parent leave). Each picture is introduced by an adult, and the child is asked to describe how the child in the picture feels and what that child will do. Kaplan (1987) developed a classification system for children's verbal responses to the pictures that differentiates attachment groups on the basis of emotional openness and ability to envision constructive solutions to feelings engendered by separation; this system was significantly related to 6-year-olds' infant attachment classifications. Using Kaplan's procedure or adaptations of it, other researchers find that SAT responses differentiate secure from insecure children's reunion and AQS security scores, self-acceptance, behavioral adjustment, and school and cognitive performance, and foster mothers' emotional investment in the child (Ackerman & Dozier, 2005; Clark & Symons, 2000; Easterbrooks et al., 2000; Jacobsen & Hoffmann, 1997).

Doll Play

Several different doll-play protocols have been developed, along with major variants in approaches to classification and rating. Bretherton's original approach to studying symbolic representation in the preschool period, the ASCT (Bretherton et al., 1990) is the foundation for most of the work in this area. Here we describe Bretherton's system in some detail along with three commonly used variations: the ASCT Q-Sort Classification System (Miljkovitch, Pierrehumbert, Bretherton, & Halfon, 2004; Miljkovitch, Pierrehumbert, Karmaniola, & Halfon, 2003); the Attachment Doll Play Assessment (ADPA; George & Solomon, 1990, 1996, 2000), and the Manchester Child Attachment Story Task (MCAST; Goldwyn, Stanley, Smith, & Green, 2000). Other similar protocols appearing in the literature include those by Gloger-Tippelt and colleagues (2002), Op-

penheim (1997), and Verschueren, Marcoen, and Schoefs (1996).

The ASCT doll-play procedure was originally designed to assess attachment security in 4-year-olds. The procedure makes use of four stories: child spills juice, child hurts her knee, child "discovers" a monster in the bedroom, and parental separation–reunion. (Three of these four stories can also be found in the MacArthur Story Stem Battery (MSSB), a group of 10 stories reflecting a variety of parent–child interactions, which were developed in collaboration between Bretherton and other members of the MacArthur team (Bretherton et al., 1990). In the ASCT, an adult introduces each story with a story stem that describes what has happened, and the child is asked to enact what happens next using a standardized, four-member family (mother, father, and two siblings of the same gender as the child). Bretherton developed a classification system to identify the four main attachment groups (A, B, C, and D). Detailed transcripts are made of children's verbal behavior and enactment of each story, and classifications are based on summary scores of the children's predominant responses to the stories. Separate criteria for each story were established on a priori grounds based on characteristic reunion behavior for each group and Kaplan's early descriptions of SAT responses. Bretherton reported significant concordance with secure versus insecure classifications on the Cassidy and colleagues (1992) PACS. There was no match, however, for type of insecurity (A, C, D) across the two measures. Doll-play classifications were converted to security scores and were found to be highly correlated with prior AQS security scores at 25 months and marginally correlated with concurrent AQS security scores at 47 months. Variations on Bretherton's security scale in Portuguese samples replicated the finding of significant correspondence with prior AQS security scores of preschoolers (Wong et al., 2011) and demonstrated that security ratings of institutionalized four to eight year olds were lower than those of children in comparison samples and related to teacher and caretaker ratings of aggression (Torres, Maia, Verissimo, & Silva, 2012). Page and Bretherton (2001) developed an expanded assessment that also includes additional stories from the MSSB and an extensive set of categories representing attachment-related themes, scored simply present–absent. This approach does not permit ratings or classification of attachment but has been employed to describe children's representations of

family relationships postdivorce (Bretherton et al., 2013; Page & Bretherton, 2001), and in studies of maltreatment and maternal depression (Macfie et al., 1999; Toth, Rogosch, Sturge-Apple, & Cicchetti, 2009; Trapolini, Ungerer, & McMahan, 2007).

Miljkovitch, Pierrehumbert, and colleagues (Miljkovitch et al., 2003, 2004; Pierrehumbert, Ramstein, Karmaniola, & Halfon, 1996) developed a *Q*-sort rating and classification procedure for children's ASCT narratives that is the basis for several studies by that group. It includes 65 items tapping content and narrative structure in a manner that is meant to parallel ratings for the AAI ratings. Along with the *Q*-sort, they developed a priori criterion sorts (i.e., profiles) for security, avoidance, ambivalence (hyperactivation), and disorganization (i.e., chaotic, violent events). They report high intercoder reliability for the *Q*-sort profiles, and researchers have posed interesting questions about non-normative groups; yet results of studies using this system are uneven. For example, with regard to the core variable of parental sensitivity, Miljkovitch and colleagues (2013) reported that maternal unresponsiveness during play at 6 months and low sensitivity at 12 months predicted ASCT disorganization at 42 months, but the positive end of those continua were unrelated to security. When maternal AAIs were used to establish predictive validity, concordance was found only for the ASCT secure and avoidant groups, but not the hypervigilant (ambivalent) or disorganized groups (Miljkovitch et al., 2004). In a similar study with a French sample of single and married parents, predicted concordance between the AAI and ASCT group was found for married but not for single mothers (Miljkovitch, Danet, & Bernier, 2012). Recent studies by Stievenart, Roskam, Meunier, and Van de Moortele (2012) with a Belgian sample show a lack of correspondence between AQS and the ASCT *Q*-sorts, and an overall increase in security and decrease in disorganization *Q*-scores between the ages of 3 and 8 among children with externalizing symptoms.

George and Solomon (1990, 1996, 2000; Solomon & George, 2002; Solomon et al., 1995) developed the ADPA using an alternative pattern-based approach to deriving classifications from doll-play responses to the ASCT (Bretherton) story stems. The system originally identified four attachment groups descriptively termed "confident" (B), "casual" (A), "busy" (C), and "frightened" (D). A later revision of this scheme integrated those classification criteria with Bowlby's

(1973, 1980) description of defensive processes related to separation and loss. These patterns can also be detected in mothers' internal caregiving representations and in adult responses to projective attachment stimuli (George & West, 2012; Solomon & George, 1999a, 1999c, 1999d). Security is expected to reflect a flexible integration of attachment-related thoughts and feelings, whereas strategies of defensive exclusion of information can be systematically brought into play as responses to anxiety regarding attachment figures. These processes include *deactivation* (prevention of attachment-related thoughts and feelings) associated with avoidant classifications and *cognitive disconnection* (disconnection from awareness of the links between affect and thought), associated with ambivalent classification. When attachment-related distress cannot be contained (assuaged), "dysregulation" of the attachment system (or in Bowlby's [1980] terms, a "segregated system") is likely to be the result. Depiction of uncontained frightening and catastrophic events, as well as persistent constriction (refusal to play), is seen as evidence of dysregulation. Both the original and the revised systems were tested on a sample middle-class kindergartners (ages 5–7). Concordance between the revised representation classifications and attachment classifications based on reunion behavior is 79% ($\kappa = .70$) (Kayoko, 2006; Solomon & George, 2002). Mother-child synchrony in a cooperative task significantly differentiated the secure from each of the insecure groups, with the largest differences occurring between the secure and disorganized groups (George & Solomon, unpublished data). The ADPA has been used successfully with a range of normative and high-risk samples (e.g., Goodman, Bartlett, & Stroh, 2013; Stacks & Oshio, 2009).

The MCAST (Goldwyn et al., 2000) constitutes a third, slightly different approach to classifying doll-play enactments. The procedures and stories differ slightly from the ASCT; most notably, in the MCAST a story about a child getting lost in the mall is substituted for the overnight separation and reunion story stem. The 33 scales devised for the procedure cover attachment behavior, coherence of the narrative, disorganized phenomena (both depicted and displayed by the subject), and mentalization. Protocols are classified into A, B, C, and D groups by comparing scale profiles to a priori profiles. In the original validation study with 4- to 7-year-olds, there was substantial stability of classification over a 5-month period. Children classified secure on the MCAST were also classi-

fied as secure on the SAT, but there was no discrimination regarding the insecure classifications. There was low to moderate concordance between secure and insecure child classifications and maternal AAI classifications, with the best match between disorganized child representation and maternal unresolved status. The MCAST has been administered to low-SES primary grade children (Berlin et al., 2011), children with reactive attachment disorder (Minnis et al., 2009), and those with conduct disorder (Pasalich, Dadds, Hawes, & Brennan, 2012). The disorganized classification was overrepresented in both clinical groups. The MCAST protocol has been computerized for ease of group administration (Minnis et al., 2009) and has been used to capture the movement toward security in a study of late adopted children (Pace, Zavattini, & D'Alessio, 2012).

Family Drawing

Kaplan and Main (Main, Kaplan, & Cassidy, 1985) developed a preliminary classification system for the drawings of children of kindergarten age or older, based on features such as the individuality of family members, groundedness of the drawing, and frightening or overbright content. Some investigators report concordance between this system or adaptations of it and Strange Situation classifications, especially for the secure or disorganized groups (Benoit, Parker, & Zeanah 1997; Fury, Carlson, & Sroufe, 1997; Madigan, Goldberg, Moran, & Pederson, 2004; Madigan, Ladd, & Goldberg, 2003; Main, Kaplan, & Cassidy, 1985; Pianta, Longmaid, & Ferguson, 1999; but see Behrens & Kaplan, 2011). Clarke, Ungerer, Chahoud, Johnson, and Stiefel (2002) reported links among picture drawing classifications, SAT classifications, and Cassidy Puppet Interview classifications (designed to tap self-esteem) for a sample of boys with attention-deficit/hyperactivity disorder (ADHD).

Discussion

A review of the available literature on measures of young children's representations of attachment reveals a wealth of efforts to capture variation related to security. Investigators find the representational measures to be a rich source of information and a fruitful basis for hypothesis generation. At their best, representational data reveal both the content and the structure of young

children's "state of mind" (Main, 2000) regarding attachment, permitting researchers to explore psychologically important regulatory processes in young children, such as fantasy and defense, and to trace the links between children's and adults' construction of representational models. Given the similarity between these procedures and traditional clinical tools such as doll play and family drawing, it is understandable that they have been readily adopted by researchers with clinical interests. Construct validation for any one measure is incomplete, yet, collectively, it seems that more researchers are attempting to assess their measures with respect to the four core hypotheses we have outlined. We urge investigators to establish the congruence of new measures with reunion or other interaction-based measures of child attachment security. This continues to be necessary because a high level of abstraction is inherent in the construct of an attachment representation, and children's cognitive and language development can influence the quality of their responses to representational stimuli.

Research to date demonstrates direct analogues to well-established qualitative differences in parent-child interaction and to representational processes identified in secure adults. For example, the behavior of the secure infant and kindergartner is characterized by open and direct communication of affect and by active, persistent, and unambivalent expression of attachment behavior. Criteria for representational security in several systems also include direct acknowledgment of affect (sadness, longing, anger) and a clear sense that reassurance or relief is forthcoming. In the ADPA classification system, secure children symbolically depict separation anxiety, as well as confidence, in the favorable resolution of these fears and concerns. Furthermore, the cognitive complexity and narrative structure of their play clearly parallel the coherence and integration of thought characteristic of the attachment representations of secure adults (Main, 2000). Studies focusing on representational processes in high-risk populations show that several of the available measures detect the disorganized end of the continuum in the form of highly aggressive, chaotic, or catastrophic representations of family life typically associated with disorganized attachment. To our knowledge, only the ADPA system places "frozen" or constricted doll play at that end of the continuum as well. The former are associated with controlling-punitive reunion behavior in the Main and Cassidy system, whereas the latter

are associated with controlling–caregiving classification (Solomon et al., 1995).

Most of the representational measures show correspondences with either concurrent or prior attachment measures, but none, except the ADPA and, in some studies, the Kaplan SAT classification, differentiates completely or reliably among insecure reunion classifications. This means that most of the systems we described earlier ought not to be used as attachment classification proxies. We speculate that the relative success of the ADPA and Kaplan's SAT stems from a development process that focused on cases with known classification, allowing the developer to home in on the features of greatest importance (see also Main & Cassidy, 1988). The more common approach is to move from theory to a priori categories based on what might appear to be qualitative parallels between behavior and representation.

We briefly note two areas that need special attention as measures continue to be refined. First, we encourage investigators to develop measures directly from the representational material produced by a particular procedure, instead of relying on a priori considerations alone or “borrowing” criteria from one measure and applying them to another. For example, it appears that in response to SAT stimuli, avoidant children often say, “I don't know.” In the ADPA, this response is not characteristic of avoidant children when they are responding to doll-play scenarios; when it is repeated or mixed with other “response-avoidant” tactics, it is instead characteristic of some controlling/disorganized children. Transfer of Kaplan's picture-based system to doll-play materials may be one reason why several doll-play-based systems have failed to distinguish among insecure classification groups. Verbal responses to pictures and doll play may well draw on different memory processes (e.g., explicit vs. implicit memory).

Second, we continue to be uneasy with how freely investigators adjust or reinvent coding and rating scales from the originals, borrow scales and operational definitions from other systems, and extend rating and classification systems to older or younger children without clear rationale or revalidation of the new approach. Space limitations have precluded detailed description of all of the methodological variations flying under the same banner, so to speak, but there are certainly many available. Diversity in approach is essential to the joint project of construct validation. Yet standardization of procedures and definitions of variables (e.g., security) is required to replicate findings,

understand replication failures, and make punitive progress in general.

On a hopeful note, we are pleased to call attention to a promising new paradigm for assessing mental representations of attachment in infants as young as age 12 months (Johnson & Chen, 2011). Johnson and colleagues (2010) used a visual habituation paradigm and animated video stimuli to test the implicit expectations of 12-month-olds about the responsiveness of mothers. In the simplest protocol, infants were habituated to a video depicting a large, nonrepresentational shape (the mother) moving away from a small one, which then cried. Infants were next shown a test video depicting either the return of the large figure to the small one (responsive mother portrayal) or the further removal of that figure (unresponsive mother portrayal). Results showed that secure infants looked longer at the mother in the unresponsive scenario, implying a violation of their expectations, whereas insecure infants looked longer at the responsive mother video, suggesting that maternal responsiveness violated their expectations. The investigators have focused on contributory hormonal and genetic factors to this phenomenon. Clearly, however, this general paradigm will allow exploration of a host of questions about individual differences in very early representational processes.

The AQS: Infancy through 5 Years

In contrast to systems of classifying child behavior and representation, the AQS assesses the quality of a child's secure-base behavior in the home. The system was developed by Waters (1995) to provide a practical alternative to the Ainsworth home observation narratives. Within the AQS system, *secure-base behavior* is defined as the smooth organization of and appropriate balance between proximity seeking and exploration (Posada, Waters, Crowell, & Lay, 1995). The Q-set for the AQS consists of 90 items designed to tap a range of phenomena believed to reflect either the secure-base phenomenon itself or behavior associated with it in children ages 1–5. Items are sorted into one of nine piles, according to whether they are considered characteristic or uncharacteristic of a child's behavior. Sorts can be completed by trained observers or by parents. Waters (1995) recommends that sorts by observers be based on two to three visits, for a total of 2–6 hours of observation in the home, with additional observations if observers disagree.

The AQS permits the salience of a behavior in a child's repertoire to be distinguished from the frequency with which the behavior occurs. In addition, it helps to prevent observer biases and lends itself to an array of qualitative and quantitative analyses. AQS data can be analyzed in terms of individual items or summary scales, or a child's Q-sort profile can be compared to a criterion sort. Waters developed criterion sorts for the construct of attachment security and for several other constructs (social desirability, dependence, sociability) by collecting and averaging the item sorts of experts in the attachment research field. The child's security score is the correlation coefficient between the observer's sort and the criterion sort; it represents the child's placement on a linear continuum with respect to the security construct. Validated sorts for the A, C, or D insecure attachment groups defined by the Strange Situation are not available, although some researchers have developed classifications on a priori grounds for particular purposes (Howes & Wishard Guerra, 2009; Smeekens, Riksen-Walraven, & Van Bakel, 2009). We return to the issue of demarcating classification groups with AQS criterion scores later in this section.

Van IJzendoorn and colleagues (2004) undertook a meta-analysis of 139 AQS studies ($N = 13,835$ children, ages 12–70 months) for the purpose of establishing the validity of this measure. Below we rely on their findings for parsimony but refer to specific studies in which updated information is available or when specific points require a more fine-grained approach.

Intercoder Agreement

In comparison to classification systems, reliability on the AQS does not require extensive training or certification of reliability. Studies report interobserver reliability (correlations between sorts) ranging from .72 to .95. The correlation between mothers' and trained observers' sorts tends to be moderate (approximately .40 to .55) in small to medium-size samples but improves considerably as a function of training and supervision of mothers, as well as the degree to which observers have opportunity to see a sufficient range of child behavior (Teti & McGourty, 1996). Tarabulsy and colleagues (2008) found that residual maternal and observer scores result in different patterns of correlation with extraneous factors such as temperament and psychosocial risk, indicating that

multiple observers are preferable for generating reliable data.

Short-Term Stability

Short-term stability data, representing repeated sorts in close succession, are not reported in the literature.

Relation to Other Measures of Attachment

AQS security scores differentiate infants classified as secure and insecure in the Strange Situation in several but not all published studies. Average AQS scores for the secure group in the Strange Situation tend to range from about .30 to .50; average scores for the insecure groups tend to be about .25 (Waters & Deane, 1985). Paralleling Ainsworth's original finding that insecure groups are difficult to distinguish on the basis of their behavior in the home, distinctive differences between infants classified as A or C in the Strange Situation typically do not emerge clearly; however, infants classified as disorganized in the Strange Situation are characterized by very low or negative AQS scores.

Van IJzendoorn and colleagues' (2004) meta-analysis reveals significantly lower correlations between the AQS and reunion-based attachment measures for preschoolers than for younger children. Moss and colleagues (2006) found the two measures to be significantly associated overall, with significant differences between the secure and the disorganized and ambivalent classifications, but not between the secure, avoidant or controlling ones. Results from Posada (2006), however, are consistent with the meta-analysis. Links between AQS security and representational measures are also somewhat mixed; there are positive correlations at 25 months and 37 months using the Bretherton ASCT measure, but failure to find a relation in others using different doll-play measures (Oppenheim, 1997; Smeekens et al., 2009; Stievenart et al., 2012).

Prediction to Core Variables

Parent–Child Interaction

Across both the infancy and preschool periods, maternal sensitivity scores based on brief home visits are significantly related to AQS security, especially using observer-generated sorts. In contrast

to Strange Situation classifications, assessments of temperament, especially negative reactivity, show moderate correlations with AQS security, but, again, less so for observer-generated sorts than for caregiver-generated ones. Some researchers reported moderate concordance between mothers' and fathers' AQS security scores, which might also reflect the effect of temperament, among other factors (Bakermans-Kranenburg, Van IJzendoorn, Bokhorst, & Schuengel, 2004; Caldera & Lindsey, 2006). Van IJzendoorn's meta-analysis revealed no relation between security with father and AQS scores, or between paternal sensitivity and AQS security. However, a recent, carefully conducted study by Brown, Mangelsdorf, and Neff (2012) revealed significant associations between paternal sensitivity and AQS scores at 36 months.

Continuity

Using caregiver sorts, Belsky and Rovine (1990) and Teti and McGourty (1996) reported low to moderate long-term stability between ages 1 and 3. Steele and colleagues (2014) demonstrated significant but low continuity between 24-month-olds' AQS scores and secure base script knowledge at age 18.

Coherence

In Van IJzendoorn and colleagues' (2004) meta-analysis and in more recent studies, AQS security is significantly related to measures of social competence with peers and siblings, to fewer child problem behaviors, and to greater child empathy (Murphy & Laible, 2013). A variety of parental and couple/family variables (e.g., marital/couple relationship quality, social support, parenting stress, SES) also appear to be related to AQS security (Howes & Wishard Guerra, 2009; Moss et al., 2006). Raikes and Thompson (2008) found that AQS security was superior to Strange Situation measures at 15 and 36 months in predicting declines in peer conflict from preschool to first grade.

Cross-Cultural Studies

In a major study on the cross-cultural validity of the AQS, researchers determined that mothers and experts in a range of countries (China, Japan, Israel, Columbia, Germany, Norway, and the United States) discriminated attachment se-

curity from the constructs of dependency and social desirability (Posada et al., 1995). Although the structure of the data was broadly similar cross-culturally, the correlations among maternal sorts across cultures tends to be low. Posada and colleagues (2013) extended this approach by showing broad cross-cultural agreement among experts about the manifestations of secure-base behavior in the home in nine different countries. Mothers' sorts demonstrated both the normative nature of secure-base behavior as assessed with the AQS and unique cultural profiles.

Discussion

The great promise of the AQS lies in its emphasis on naturalistic observation in ecologically valid contexts. The procedure can be used reliably across a variety of national, cultural, and risk groups. From a practical perspective, it permits researchers to estimate attachment security without the need for laboratory space and equipment or extensive training of observers. For the infancy period (ages 12–18 months), there is a substantial literature demonstrating a reliable though modest correspondence with judgments of security in the Strange Situation and with maternal sensitivity; a more inconsistent picture of the relationships among these variables emerges for the preschool period. The AQS procedure also does not allow reliable distinctions to be made among the insecure groups, although, as would be predicted theoretically, infants and children classified as disorganized are characterized by the lowest security scores (Atkinson et al., 1999; Roskam, Meunier, & Stievenart, 2011).

In versions of this chapter in earlier editions, we commented extensively on possible reasons for this divergence. Given limited space, we refer readers to those earlier discussions and turn instead to recent developments. Somewhat ironically, the first of these is an upsurge in the number of investigators describing their AQS findings in terms of secure versus insecure classifications or even disorganized classifications (Altenhofen, Clyman, Little, Baker, & Biringen, 2013; Bergin & McCollough, 2009; Howes & Wishard Guerra, 2009; Niemann & Weiss, 2011; Smeekens et al., 2009; Stievenart et al., 2012; Steele et al., 2014). For this purpose, the investigators cite previous studies (e.g., Park & Waters, 1989) that used AQS scores in the neighborhood of .33 as a security cutoff score. Most of the previously described studies

focus on atypical populations, such as foster care and adopted children, cocaine exposed infants, and immigrant families. It is understandable that authors want to make use of comparisons to the well-established Strange Situation categories, especially when communicating clinical data; the AQS is certainly more portable and “user-friendly” than Strange Situation procedures. We see this practice as an unfortunate expedient, however. There is as yet relatively little empirical information about how high-risk and clinical samples differ from normative ones in the distribution of AQS security scores or how these scores map onto actual Strange Situation classifications. Such data are costly and time-consuming to gather. Until more suitable methodological tools are available, however, we remind researchers that the AQS security criterion represents only one of the many dimensions relevant to classification; the data cannot be “reverse-engineered” to approximate Strange Situation classifications.

In this context, we note with interest some initial attempts to create “user-friendly,” brief attachment assessment tools. For example, John, Morris, and Halliburton (2012) asked mothers of intellectually disabled children in India to rate 62 of the AQS items on a scale from 1 (characteristic of her child) to 3 (uncharacteristic of her child). Cronbach’s alpha was .77. These Q ratings were modestly but significantly correlated with scores for the mother’s Emotional Availability. This technique was adapted from work by Roggman (Coyl, Newland, & Freeman, 2010; Newland, Coyl, & Freeman, 2008), who found that mothers’ ratings were highly correlated with their subsequent sorts, following 2 weeks of observation of their child ($r = .62$). Although one could wish for considerably more validation of the “Q-list,” this technique has the merit of simplicity, and further development of this measure and others like it may be promising in future. A different approach is illustrated by Andreassen and West (2007), who described painstaking efforts to create a 45-item Toddler Attachment Q-Sort (TAQS-45) for over 10,000 preschoolers who were part of the Early Childhood Longitudinal Study–Birth Cohort. Preliminary validation on a small sample of preschoolers showed a positive relation between security and dyadic mutuality (Spieker, Nelson, & Condon, 2011). Readers may also be interested in work by Tarabulsy and colleagues (2009) as an example of this kind of adaptation, applied to the validation of shortened version of the Maternal Behavior Q-Sort.

Conclusions

Our survey of the research in attachment measurement for infants and young children has given us a reasonably good overview of the area and a sense of where the field as a whole seems to be heading. The period since the last edition of this handbook has not seen major development of new measures. Despite unresolved methodological questions, investigators have made use of the available “good-enough” instruments and protocols to press on, focusing in particular on more diverse and high-risk populations, intervention studies, biological mechanisms, and long-term developmental trajectories.

This is a good time to consider whether the available attachment measures and their adaptations (validated or intuitively crafted) are adequate for the questions investigators wish to study, or whether new tools are now required. In our view, there is a need for two kinds of methodological tools. The first may be described as “efficient” measures, that is, observer- or parent-generated, that are suitable for large-scale, multivariate research and intervention studies. Conventional questionnaires have proven difficult to design in this field (but see George and Solomon, 2011). In part, this is because of the difficulty of getting past parents’ defensive exclusion of the very information we would like them to report (George & West, 2012). The AQS seems to be the most promising instrument to adapt for this purpose. The full process, however, can take one to several hours to complete. Earlier we described attempts to create short-form AQSs that might be suitable for large samples or subjects with limited time available. To our knowledge, these adaptations have not been validated against Strange Situation classifications, but this should be feasible. These efforts are promising, but we refer researchers to our previous cautions about using Q-sort data as a substitute for attachment classification.

Though less efficient, there is also a need for new or revised measures based on direct observation, the tradition that was so fruitful in the early years of building and testing attachment theory. There is a particular need for improved measurement for the D classification, which is evidently characteristic of a very broad group of infants in high-risk samples but is also in normative samples. The developmental and mental health risks associated with disorganization appear to go beyond the early findings of a link between maltreatment and disorganization, and may include the full

range of externalizing disorders (from classroom disruption to callous–unemotional traits), borderline and dissociative disorders, and, possibly, a range of internalizing disorders (see Lyons-Ruth & Jacobvitz, Chapter 29, this volume). As a first step in this process, it might be worthwhile to reexamine the extensive list of D indices that are used for classification, originally delineated by Main and Solomon (1990). The indices are grouped according to classes of conflict behavior, dissociative processes, states of fear and confusion, or heterogeneous varieties of anomalous behavior patterns. The underlying logic of this categorization, naturally enough, presumes a particular causal explanation structure—Main’s hypothesis that disorganization reflects irresolvable conflict aroused by a frightening or frightened parent (Hesse & Main, 2000). But there may be other ways to organize the indices to reveal the existence of additional mechanisms or processes. For examples of preliminary approaches to understanding individual differences among the indices, see Forbes, Cox, Moran, and Pederson (2006) and Padrón and colleagues (2014).

In this context, we reprise a concern that we expressed in the second edition of the *Handbook of Attachment*: the assessment of attachment for children who have or are continuing to experience deprivation of attachment figures, disrupted attachments, and major or frequent separations. These children were originally of great interest to Bowlby and other researchers who contributed to our basic knowledge in this area. They are also a population of growing interest to attachment researchers and increasingly fill the caseloads of infant mental health and other clinical practitioners—many of whom use (or would like to use) conventional attachment measures as part of their assessments. It is not clear, however, that our current attachment methodology is sensitive enough for clinical uses or whether there are modifications that might make it so.

We propose that questions such as these require a new look at standard measures and the development of new, ecologically valid ones. Attachment researchers are aware that the interpretation of separation–reunion procedures is questionable when it is uncertain whether a child has developed an attachment to a particular caregiver, or when the child has recently undergone a major separation. Disorganized attachment is very commonly observed in adopted and foster children and in young institutionalized children. The meaning of this “disorganized” attachment behavior cannot be assumed to be the same as it is for typical, home-

reared children. Many of these children show, in addition, what have been termed “anomalous” patterns that are not well described in the literature (see Jacobsen & Haight, 2011; Zeanah et al., 2005). There is clearly a need for further behavioral differentiation among all of these groups of children, including those who merit the “atypical” or “unclassifiable” label (Kreppner, Rutter, Marvin, O’Connor, & Sonuga-Barke, 2011). Careful observation may reveal behavioral variants that discriminate among various etiological conditions. In short, we need a reexamination of the separation–reunion behavior of these children—akin to what was involved originally in detecting disorganization of attachment (Main & Solomon, 1986, 1990). Additional research is equally necessary to explore the nature of attachment under other very adverse conditions (e.g., when parents are severely mentally ill) and to determine whether disorganized attachment behavior in benign circumstances carries much risk at all. The present methodological challenge is to expand our ability to make finer distinctions within the disorganized group, which currently is undifferentiated. We end this chapter, confident that we will see progress in this fertile area.

Notes

1. It must be emphasized that the construct of security is meaningful only for a relationship in which a child has already developed an attachment to a particular caregiver. In situations where this is in doubt (e.g., in studies involving transitions to foster care), the interpretation of any measure of security is problematic.
2. For this review, we rely mainly on the published, English-language journal literature. This may have the unintended consequence of exaggerating the appearance of a relation between any two variables, but it ensures that studies have undergone peer review and that we ourselves have seen the article.

PART IV

ATTACHMENT IN ADOLESCENCE AND ADULTHOOD

Chapter 19

The Multiple Facets of Attachment in Adolescence

Joseph P. Allen
Joseph S. Tan

The psychosocial development that takes place across adolescence brings profound changes in the meaning and expression of attachment-related cognition, behavior, and affect. Our understanding of the changing and multifaceted nature of the adolescent attachment system has advanced greatly since the previous edition of this handbook was published. Previously, we had argued that research should begin to focus not simply on adolescents' internal states of mind regarding attachment but also on their attachment *relationships*. Several prescriptions followed, including the need to assess caregiver relationships *both* historically and currently, to begin to take into account peer relationships, and to recognize the role of broader physical and cognitive factors influencing attachment processes. The field has recently made remarkable strides in addressing each of these needs: We have developed promising measures of qualities of adolescent attachment relationships with parents, including assessments of the ways these change over time. We have documented the gradual emergence of attachment-like qualities in peer and romantic relationships. And we have learned about the ways in which attachment states of mind intersect both with physiological states and perceptual biases to

help explain qualities of both current and future relationships.

The study of adolescent attachment has now moved productively back toward its origins—as a means to understand *relationship* qualities and behaviors. This movement inevitably shifts our conceptualization of attachment in adolescence away from a unitary focus on internal states of mind and toward a multifaceted view recognizing the constellation of relational, behavioral, and affective elements at play. This shift in turn has profound implications for our understanding of both the meaning of attachment in adolescence and the continuities with attachment at other points in the lifespan. Below we consider our advances in understanding of these multiple facets of attachment in adolescence, first in terms of normative development, then in terms of individual differences in attachment processes and their relation to adolescent psychosocial functioning. We then conclude with a discussion of the implications of this multifaceted perspective on adolescent attachment for the study of continuities with attachment in other phases of the lifespan, and for our understanding of the broader nature of the attachment system during this period.

Normative Development of the Attachment System in Adolescence

Transformations in Attachment Relationships with Caregivers

One of the defining social challenges of adolescence is that in seeking to establish emotional self-sufficiency, adolescents must often work *not* to need to turn to their primary caregivers to meet attachment needs. During adolescence, rapidly developing competencies decrease the need for dependence on parental attachment figures, and the strong need to explore and master new environments promotes healthy growth in the exploratory system. These changes necessitate a new balance between attachment behaviors and exploratory needs, with exploration taking an increasingly central role.

In principle, this process is analogous to the competing influences of the exploratory and attachment systems in infancy, although the press for autonomy in adolescence may be more relentless and more directly in competition with the press of the attachment system (Allen, Moore, & Kuperminc, 1997). These changes, however, may change the *threshold* at which the attachment system activates and drives behavior, although, by themselves, they are not likely to fundamentally alter the dynamics at play. Parents continue to be used as attachment figures even into young adulthood (Rosenthal & Kobak, 2010), and the attachment system is still likely to activate and be readily observable under conditions of danger or separation distress (Rosenthal & Kobak, 2010). Adolescents may be on the verge of tears far less often than infants, but when they are highly distressed, their likelihood of turning to parents for help is still likely to increase dramatically. In this respect, the attachment system operates much as it always has, albeit with a different and rapidly changing balance between attachment and exploratory behaviors.

Yet this balancing act is more challenging than it first appears because at the same time that adolescents are seeking to develop greater emotional self-sufficiency vis-à-vis their attachment figures, they are also negotiating often contentious issues of behavioral autonomy (i.e., who controls the teens' behavior) with these same figures. Whereas the goal-corrected partnership in infancy might be described as reflecting a coordinated effort between parent and child, in adolescence it

seems more appropriate to consider this as a *negotiated* effort, and the negotiations will almost inevitably be challenging. To a degree unparalleled elsewhere in development (with the possible exception of early toddlerhood), the adolescent struggle for behavioral autonomy becomes an omnipresent background against which attachment processes must play out. The many years of prior operation of the attachment system—and the habitual patterns of responding that have become established—are likely at times to be perceived by the adolescent as a potential threat to efforts to establish behavioral autonomy. Put simply, it can be difficult at times for a teen to fiercely oppose his or her parents' control efforts while feeling pulled by both habit and the attachment system to retain their shoulders to cry on.

Kobak and Duemmler (1994) suggested that a potential saving grace in this process is a subtle but important shift in the goal of goal-corrected partnership: The partnership with caregivers ideally becomes less about the caregiver meeting most or all of the adolescents' attachment needs, and more about helping the adolescent develop a capacity to meet attachment needs autonomously, in ways that do not solely depend on interactions with a caregiver. As an adolescent gains communication and perspective-taking skills, it becomes possible for both teen and parent to modify (or correct) their attachment-related behavior when necessary, to meet the teen's evolving attachment needs appropriately, while balancing other needs as well. Even the shared goal of seeing the adolescent gradually achieve autonomy from and even occasional opposition to parental desires can become something onto which both parties can hold. This shared goal can then become an extension of the adolescent's internal representation of the parent as a secure base supporting the adolescent's exploration of evolving independence (Sroufe, Egeland, Carlson, & Collins, 2005). In this way, the attachment bond can remain strong, at least for secure teens, even if at times teens say they do not necessarily want to feel attached.

A further critical change as adolescence progresses is that the attachment hierarchy—implied by teens giving consistent preference to certain individuals over others when the attachment system is activated (Bowlby, 1969/1982)—becomes more flexible and even multidimensional. First peers, then romantic partners, begin to enter into this hierarchy. Although the stress of severe illness likely would still cause an adolescent to turn to parents, as in the original attachment hierarchy, peer-relat-

ed stressors, which can also be severe and distressing, might well result in a close peer or romantic partner moving temporarily into the primary position in the attachment hierarchy (Markiewicz, Lawford, Doyle, & Haggart, 2006). Parent gender also matters, with mothers being more likely than fathers to remain at the top of the attachment hierarchy through the transition from adolescence to young adulthood (Rosenthal & Kobak, 2010).

One might question whether this constellation of changes might lead teens to become more dismissing of attachment. A comparison of the distribution of teen AAI classifications with adult AAI classifications finds that teens' states of mind regarding attachment are more likely to be classified as insecure-dismissing of attachment than adults' states of mind (Bakermans-Kranenburg & Van IJzendoorn, 2009). This finding may be somewhat misleading as a marker of teens' overall status, however, stemming in part from the primary focus of the Adult Attachment Interview (AAI) on early childhood memories of attachment to *parents*. The most healthy and adaptive approach appears to be a gradual, somewhat intentional shift in the focus of the adolescent's attachment system from parents to peers and/or to romantic partners. Even for secure adolescents, this shift may require directing attention away from childhood memories of dependency on parents and toward both emotional independence and stronger peer bonds. Assessing attachment states of mind primarily with regard to the one type of relationship that adolescents are most likely to be trying to deemphasize is likely to yield a portrait of adolescent attachment that overidentifies dismissing states of mind. Indeed, the intense adolescent preoccupation with establishing deep, emotionally engaging peer relationships—in part around attachment and dependency needs—suggests that even if the adolescent is deemphasizing the attachment relationship *with parents*, this is not at all the same as being dismissive of attachment more generally.

Transformations in Intrapsychic Processes

As an individual moves into adolescence, the intrapsychic roots of the attachment system (in representations of early experience with caregivers) begin to grow, enriched by the rapidly developing functional independence and cognitive capacity of the adolescent. These developing capacities allow an adolescent to begin to construct, from

experiences with multiple caregivers, a more integrated and generalized state of mind regarding attachment experiences (Hesse, 2008; Main, Kaplan, & Cassidy, 1985). Moreover, by adolescence the attachment system can be assessed in terms of a single overarching attachment state of mind that displays stability over time (Allen, McElhaney, Kuperminc, & Jodl, 2004; Hesse, 2008; Zimmermann & Becker-Stoll, 2002). In adolescence, the domains in which attachment-relevant experiences occur, and the ways in which these can be evaluated, have grown and broadened, with significant implications for the development of an internalized attachment state of mind. The adolescent continues to have attachment relationships with caregivers, although these are changing as described earlier. In addition, the adolescent is able to integrate diverse attachment-relevant experiences (e.g., past and present, with multiple caregivers, and in new relationships) and to begin to reevaluate cognitions, memories, and affective reactions related to attachment. The resulting adolescent state of mind is not so much a mirror of past experiences as an *outgrowth* of those experiences that is also influenced by current relationship qualities, as well as growing cognitive and emotional capacities.

The factors that drive the development of adolescent internal states of mind regarding attachment are both emotional and cognitive. Emotionally, the adolescent is not simply moving away from reliance on parents; rather, he or she is continuing the lifelong process of learning to self-soothe and regulate emotional reactions. An important secondary effect of this growing self-soothing capacity in adolescence is an increase in the adolescent's capacity to reevaluate the nature of his or her attachment relationship with parents. As the adolescent comes to need caregivers less to maintain a sense of emotional equilibrium and felt security, he or she is freed up to evaluate more critically the caregiver relationships. Main, Goldwyn, and Hesse (2002) refer to this cognitive and emotional freedom as "epistemic space," and suggest that it allows individuals to evaluate their parents as attachment figures more objectively.

Similarly, the adolescent's developing cognitive capacity aids in integrating a history of diverse experiences with individual caregivers into a single overall state of mind regarding attachment. The development of formal operational reasoning ability and dramatic increases in cognitive differentiation of self and other that characterize this period (Keating, 1990) also allow the teen to begin

to establish a more consistent view of the self as existing apart from interactions with specific caregivers. The advent of formal operational thinking also allows an adolescent to contemplate abstract and counterfactual possibilities. This in turn allows him or her to compare relationships with different attachment figures both to one another and to hypothetical ideals. Adolescents therefore not only demonstrate a capacity to think about attachment in a general way, which extends beyond any single relationship, but they also have the capacity to operate metacognitively on this thinking. As a result, they can begin to reconstruct (or at least tinker with) their own states of mind regarding attachment. The adolescent therefore gains the capacity to “deidealize” parents—to see them in both positive and negative ways (Steinberg, 2005). This capacity to evaluate past attachment experiences coherently is one of the hallmarks of a state of mind regarding attachment, labeled “autonomous, yet valuing of attachment.” Indeed, adolescent deidealization in the context of an overall positive relationship with parents has been strongly associated with greater security (Allen et al., 2003). This potential for reevaluation is one of the prime reasons why adolescents’ states of mind are neither bound nor even likely to mirror exactly the qualities of their past attachment experiences.

Transformations in Peer Relationships

In the midst of changing parental relationships and growing cognitive and emotional capacities, adolescents are beginning a major lifelong task: learning to establish supportive peer bonds. By midadolescence, interactions with peers have begun to take on many of the functions they will serve for the remainder of the lifespan—providing important sources of intimacy; feedback about social behavior, social influence, and information; and ultimately attachment, sexual relationships, and lifelong partnerships (Collins & Laursen, 2004; Collins, Welsh, & Furman, 2009). These developments create important challenges for our efforts to understand the operation of the attachment system during this period.

One key question is: When do peer relationships become attachment relationships? Alternatively, this question can be more fruitfully, though less conventionally, phrased: How do peer relationships *gradually* take on attachment functions? A continuum perspective seems necessary to understand this process and, indeed, such an

approach is increasingly being adopted within the research literature. We now know that there is a broad array of neural, physiological, and psychological systems underlying attachment behavior (see Coan, Chapter 12, this volume). These include systems that manage physiological arousal, establish a sense of emotional security, and deactivate primitive centers of the brain that support “flight” under conditions of stress (Coan, 2010; Hofer, 2006; Sbarra & Hazan, 2008).

We also know that by late adolescence, long-term relationships can be formed in which peers (either romantic partners or close friends) potentially serve as attachment figures in all senses of the term (Hazan & Shaver, 1987). Main (1999) has posited that the attachment system evolved partly because of the value for humans, as vulnerable members of a ground-living species, of associating with others as a source of safety. Indeed, the absence of positive social connections in adulthood creates as great a risk for illness and even early death as widely recognized risk factors such as obesity and cigarette smoking (Holt-Lunstad, Smith, & Layton, 2010). The implication of these findings is that the task of learning to form supportive attachment relationships may be nearly as much a survival skill in adolescence as it is in infancy.

But is this about attachment, or are these new relationships something different? If we are interested in identifying a relationship process identical to what is seen in infancy, the answer is clearly that what is seen in adolescence is something different. Attachment relationships, as they exist in infancy, appear in many ways unique to that phase of life. Given the infant’s extreme vulnerability, limited capacities for self-help, and intense, completely dependent relationships with caregivers, an array of attachment-related emotions, cognitions, physiological reactions, and behaviors all come together simultaneously and powerfully under conditions of stress, creating a fully functioning attachment system. In adolescence, in contrast, it is not clear whether the more primitive neural circuits in the brain (e.g., the amygdala and the caudate/nucleus accumbens) responsible for detecting and physically responding to threat are activated in quite the same way by the psychosocial stressors that adolescents typically experience. In addition, the change that is occurring is not just a gradual transition from one class of attachment figures (parents) to another (peers). A relationship among equals, in which each person may serve at different times in both the care-seeking and caregiving roles, may be a context that fundamentally

alters the meaning and expression of attachment behaviors that were previously directed toward a caregiver.

With these differences comes the likelihood that the multiple functions and features of the attachment system—which often operate powerfully and in unison during infancy—may begin to operate less synchronously in adolescence, particularly in interactions with peers. In addition, with the adolescent's increased cognitive capacity comes increased flexibility in directing attachment behavior. Adolescents gradually gain the capacity to be “opportunistic” in seeking out a potential attachment figure, whether it be a fellow camper at a 6-week summer camp or a close-in-age sibling to whom a teen turns as his or her parents go through a divorce. Rather than wading into the semantic quagmire of delineating the precise conditions under which a given relationship beyond infancy becomes an “attachment relationship,” it may make more sense to recognize that adolescent relationships increasingly take on critical attachment functions, even if such functions are neither as synchronous nor as intense as they were in earlier relationships with caregivers.

Recent research has produced significant gains in our understanding of how this process grows and unfolds. Zeifman and Hazan (2008) conducted pioneering work in developing the WHOTO interview, which assesses the extent to which adolescents learn to turn to peers to meet the various attachment functions outlined by Ainsworth. Similarly, Rosenthal and Kobak (2010) brought these conceptualizations together in developing the Important People Interview. These two lines of work have established that adolescents do indeed establish hierarchies of attachment that include persons other than primary caregivers. They also show that the relative positioning of peers, romantic partners, and caregivers in these hierarchies depends not only on the developmental stage of the adolescent but also the particular stressor facing the adolescent. In non-emergency situations of stress, peers are often preferred over parents for support (Zeifman & Hazan, 2008). Peers are also increasingly sought out in adolescence when parents are not available (Kobak, Rosenthal, Zajac, & Madsen, 2007). General peer support-seeking is not the same as full-blown attachment behavior, however (Waters & Cummings, 2000). Finding that peers are increasingly preferred for support seeking does not mean that peer relationships have become full attachment relationships (Rosenthal & Kobak, 2010). Furman (2001) has suggested, for example, that friendships

serve proximity-seeking and safe-haven functions but lack other qualities of attachment relationships, such as separation distress and enduring commitment. Although peers are often sources of support, parents overwhelmingly are found at the top of the attachment hierarchy under conditions in which adolescents are likely to need to draw strongly on the attachment system (i.e., situations involving danger or separation distress; Rosenthal & Kobak, 2010). Understanding which stressors and responses can be clearly labeled as attachment processes, which are “merely” support seeking, and which are in the hazy middle as peer relationships gradually develop in intensity, is a work in progress.

Yet, there is a clear developmental progression in whom adolescents turn to in stressful situations. Peers, for example, steadily increase in primacy from early into mid- to late-adolescence. This evolution then continues, with friends gradually receding somewhat in primacy as romantic partners take increasingly primary roles, eventually even in comparison with primary caregivers (Markiewicz et al., 2006; Rosenthal & Kobak, 2010). The length of a romantic partner relationship is one of the primary determinants of whether this relationship becomes a clearly identified full attachment bond because such bonds take time to develop (Rosenthal & Kobak, 2010). These romantic relationships do not, of course, result solely from developing interests in forming attachments with peers. They also reflect the operation of a sexual/reproductive system that is at least as biologically rooted and critical to species survival as the attachment system (Collins et al., 2009; Hazan & Shaver, 1987). The sexual and attachment systems both push toward the establishment of romantic relationships, characterized by sufficient intensity, shared interests, and strong affect, to begin to take over some of the functions of prior parent-child relationships.

Individual Differences in the Attachment System in Adolescence

Individual Differences in Relationships with Primary Caregivers

The potential tension between adolescents' developmental push to gain autonomy and the operation of the attachment system is central to understanding individual differences in adolescents'

attachment relationships with primary caregivers. The negotiation of attachment and autonomy issues is normatively challenging for virtually all families at some point, but it may be especially difficult for the family of an adolescent with an insecure state of mind or an insecure ongoing attachment relationship with one or both parents. The combined stress of new peer and academic challenges, changing relationships, and growing emotional and behavioral independence from parents tend to activate the attachment system repeatedly and increase the impact of insecurity on an adolescent's behavior. In addition, insecure adolescents (and parents) may be overwhelmed by the affect brought on by disagreements that are part of the autonomy-development process (Kobak, Cole, Ferenz-Gillies, Fleming, & Gamble, 1993), and may perceive these disagreements as threats to already shaky relationships. An insecure adolescent may have a history of less than positive experiences with attachment figures in times of need, which is likely to further color attachment-related interactions during adolescence.

Just as the balance of exploration from a secure base has been highly informative with respect to individual differences in infant attachments, the balance of autonomy and attachment processes in adolescence is a robust indicator of the quality of an adolescent's state of mind regarding attachment (Allen et al., 2003). A secure, goal-corrected partnership potentially allows both parent and teen to recognize the teen's autonomy strivings and to support these while maintaining the relationship. Prematurely disengaging from this partnership and transferring attachment behavior to peers, in contrast, has been associated with risk for difficulties ranging from susceptibility to peer influence, to aggressive and delinquent behavior (Markiewicz et al., 2006; Rosenthal & Kobak, 2010). For a secure partnership to be maintained, two key ingredients are required: a strong capacity to communicate across the increasingly divergent perspectives and needs of the parent and teen, and a willingness on both sides to manage conflict in a way that allows the adolescent to seek autonomy while maintaining the parent-teen relationship.

Communication

Qualities of parent-teen communication and concordance between key parent and teen perceptions in interactions now appear to be among the most consistent and strongest correlates of both the adolescent's state of mind regarding attachment and

the current quality of the parent-teen attachment relationship. If a parent knows his or her teen well, and perceives the teen's current state similarly to the way the teen perceives it, communication processes are clearly functioning well. This concordance in perceptions turns out to be one of the best predictors both of an autonomous/valuing adolescent state of mind and of a secure, ongoing parent-teen relationship. For example, a mother's accuracy in predicting her teen's responses on a self-perception inventory has been robustly linked to adolescent security in the AAI (Allen et al., 2003). The correlation of security with this marker of sensitivity is even somewhat higher ($r = .35$) than is typically found in studies of parental sensitivity toward infants (De Wolff & Van IJzendoorn, 1997). Similarly, coherence in the AAI is linked to the degree of parent-teen synchrony regarding the teens' internalizing symptoms, externalizing behaviors, and perceptions of family conflict (Berger, Jodl, Allen, McElhaney, & Kuperminc, 2005; Ehrlich, Cassidy, & Dykas, 2011). Beyond the AAI, adolescent reports of lower avoidance in current relationships with parents using the Experiences in Close Relationships (ECR) scale have been linked to fewer discrepancies in parent and teen reports regarding parenting behavior (Ehrlich, Cassidy, Lejuez, & Daughters, 2014).

Two possible mechanisms can account for the relation between security and parent-teen concordance in perceptions: First, more secure adolescents may *allow* parents to be more sensitive because the teens communicate their emotional states to their parents more accurately. Becker-Stoll, Fremmer-Bombik, Wartner, Zimmermann, and Grossmann (2001) reported a reliable association between adolescents' security and the degree to which they were affectively communicative in a discussion task. Other evidence links teen attachment insecurity to broader perceptual biases and asynchronies between teens and their *peers* (Berger et al., 2005; Dykas, Woodhouse, Ehrlich, & Cassidy, 2012; Ehrlich et al., 2013). These findings, discussed in greater detail below, suggest that the security-concordance link in teen-parent relationships at least partly reflects a stable property that resides in the teen—perhaps accuracy of communication in reporting internal states.

A second mechanism accounting for the relation between insecurity and parent-teen concordance in perceptions is a relative lack of difficulty among secure (compared to insecure) individuals in accurately recalling past emotional experiences (Allen & Manning, 2007; Hesse, 2008). In

laboratory tasks, parents and teens with insecure-dismissing states of mind display reduced memory for childhood emotional stimuli (Dykas, Woodhouse, Jones, & Cassidy, 2014), a pattern that has also been observed at other points in the lifespan (Dykas & Cassidy, 2011). This is at best only a partial explanation of the discordance–insecurity link, however, as a preoccupied state of mind was related to heightened recall of childhood experiences in this paradigm. Lack of parent–teen concordance may also be a result of *biases* in memories that are recalled. Six weeks after an observed mother–teen interaction, teens with autonomous/valuing states of mind in the AAI recalled less negativity in interactions with their mothers than they had initially perceived, although no such changes for insecure teens were observed (Dykas, Woodhouse, Ehrlich, & Cassidy, 2010). With fathers, conversely, it was insecure teens who changed in taking on less positive memories of interactions over time; no change was observed for secure teens. Although somewhat inconsistent, these findings provide evidence of memory biases operating in ways that would bolster positive feelings about relationships for secure teens, while undermining them for insecure teens. Notably, teen insecurity was also linked to increased *maternal* negativity in recall over time in this paradigm, suggesting just how tightly interwoven family systems processes and attachment systems are during this period.

Some evidence suggests that particular types of miscommunication and dyadic asynchrony are associated with particular types of insecure states of mind regarding attachment. For teens with a dismissing attachment state of mind, parent–teen concordance regarding adolescents’ internalizing symptoms was generally poor and discrepancies were not directional in nature (i.e., there was not a consistent pattern of over- or underreporting symptoms by either party relative to the other; Berger et al., 2005). The tendency for individuals with dismissing states of mind to avoid or resist discussing emotionally distressing events that activate the attachment system may account for their generally poor communication regarding their internal states. This notion is consistent with longstanding evidence that avoidance restricts communication (Mikulincer & Nachshon, 1991).

For teens with a preoccupied attachment state of mind, a specific form of bias in communication was found: Adolescents with preoccupied states of mind consistently reported the presence of symptoms at levels that were significantly high-

er than those recognized and reported in the adolescents by either their parents or peers. For preoccupied individuals, symptom reports may be seen as cries of distress (e.g., as attachment behaviors) (Allen, Moore, Kuperminc, & Bell, 1998). From this perspective, we see that insecure-preoccupied adolescents are behaving in a way that might reflect hyperactivation of their attachment system. They are reporting their distress to a high degree, although they do not find that these reports are heard (or fully believed) by the people closest to them.

Conflict Resolution

One of the more consistent findings in the adolescent attachment literature is that teens with secure attachment states of mind tend to handle conflicts with parents by engaging in productive, problem-solving discussions that balance autonomy strivings with efforts to preserve relationships (Allen et al., 2003, 2004; Allen, Porter, McFarland, McElhaney, & Marsh, 2007; Zimmermann, Mohr, & Spangler, 2009). Similar findings have been observed with regard to self-reported security, as well as with interview-based assessments of the security of current family relationships (Steinberg, Davila, & Fincham, 2006). In particular, relationship-maintaining behaviors in the midst of conflict are most consistently linked to adolescent security and, typically, the behavior of the adolescent (rather than the parents) is most predictive. In some sense, these relationship-supporting behaviors may be viewed as “secure-base” behaviors, in which the secure adolescent revisits and refreshes the attachment bond even in the midst of exploring verbal autonomy from parents. This process can be observed even very early in adolescence. Attachment security in current relationships with parents, assessed via the Late Childhood Attachment Interview (Zimmermann & Scheuerer-Englisch, 2000) is related to more agreeable and less hostile autonomy displays among 12-year-olds (Zimmermann et al., 2009). Although much of the research in this area has been done with mothers, research with fathers is consistent with the operation of a similar process in which paternal use of harsh, relationship-undermining conflict tactics is linked to adolescent insecurity (Allen et al., 2007).

Security within the current relationship with parents also appears to moderate effects of preexisting genetic dispositions on the autonomy pro-

cess. The short allele of the serotonin transporter gene, *5-HTTLPR*, for example, has been associated with greater emotionality and sensitivity to emotional stimuli in the environment. Secure adolescents with this short allele have been found to have greater agreeability in handling autonomy issues with parents, whereas insecure adolescents with this same short allele displayed more hostile autonomy in interactions with parents (Zimmermann et al., 2009). The results suggest that security may aid the adolescent in handling preexisting temperamental emotionality and sensitivity. Notably, no main effects of this short allele on attachment security were found.

In terms of specific types of insecure states of mind, dismissing adolescents show the least autonomy and relatedness of all attachment groups observed in interactions with parents (Becker-Stoll et al., 2008). This suggests that a dismissing individual's characteristic withdrawal from engagement with attachment experiences may particularly hinder the task of renegotiating parent-adolescent relationships. Families of dismissing adolescents also tend, in turn, to be less responsive to their adolescents, at least as compared to families of preoccupied adolescents (Reimer, Overton, Steidl, Rosenstein, & Horowitz, 1996).

For adolescents with dismissing states of mind, research on a physiological marker of stress—heart rate interbeat interval reactivity—suggests that difficulty in managing the stress of autonomy-based conflicts with parents may partially explain the link between attachment insecurity and adolescent autonomy and relatedness struggles. Dismissing adolescents displayed less interbeat interval reactivity (i.e., appeared *less* stressed) during the AAI than secure adolescents, perhaps reflecting their general success in minimizing attention paid to stressful aspects of attachment memories. However, during a conflict interaction task with their mothers, dismissing adolescents displayed significantly greater interbeat interval reactivity, thus appearing significantly more stressed than adolescents with secure states of mind (Beijersbergen, Bakermans-Kranenburg, Van IJzendoorn, & Juffer, 2008). These results are consistent with the idea that dismissing adolescents avoid emotionally charged discussions but then struggle when such discussions cannot be avoided. This finding in many ways is consistent with the earlier suggestion that insecure adolescents with the short allele of the *5-HTTLPR* gene may struggle more with emotionality in handling autonomy discussions (Zimmermann et al., 2009).

Insecure preoccupation, in contrast, appears to be most strongly associated with heightened and unproductive overengagement with parents in arguments that ultimately undermine an adolescent's autonomy (Allen & Hauser, 1996). This overengagement appears to extend well into late adolescence because adolescents with insecure-preoccupied states of mind appear more likely to have difficulty leaving home successfully for college, displaying higher levels of both conflict and contact with parents during the transition (Bernier, Larose, & Whipple, 2005). These effects were not observed for adolescents who were not leaving for college, suggesting that these attachment dynamics are activated mainly in the presence of the significant stress of leaving home on the attachment system.

Individual Differences in Peer Relationships

A large, rapidly growing body of research suggests a fairly tight link between a secure adolescent attachment organization and competence in close friendships. Secure adolescents are more comfortable with the intimate emotional interactions common in close friendships (Allen et al., 2007; Sroufe et al., 2005; Weimer, Kerns, & Oldenberg, 2004; Zimmermann, 2004). Security has also been consistently associated with higher quality friendships and lower stress in peer relationships in general (Seiffge-Krenke, 2006; Shomaker & Furman, 2009). Observational data suggest that this competence is a result of generalized comfort in handling emotional reactions in challenging situations (Zimmermann, Maier, Winter, & Grossmann, 2001). Conversely, using Hazan and Shaver's (1987) three-category prototype measure of attachment style, anxious-ambivalent adolescents are found to be more prone to interpersonal hostility (Cooper, Shaver, & Collins, 1998). Preoccupied states of mind similarly are associated with greater stress in peer relationships (Seiffge-Krenke, 2006). Although some research suggests that security is more relevant to functioning in close relationships than in broader peer relationships, and that representations of different types of relationships at times display only modest concordance with one another (Furman, Stephenson, & Rhoades, 2014; Lieberman, Doyle, & Markiewicz, 1999), adolescent security has been linked to broader measures of social competence, such as popularity and social acceptance, as well as to generally more prosocial

behavior and less shy or aggressive behavior with peers (Allen et al., 1998, 2007; Dykas, Ziv, & Cassidy, 2008). Conversely, more dismissing (vs. secure) states of mind have been associated more generally with poorer focus on problem discussions and weaker communication skills with friends, even after accounting for gender differences and current parent–adolescent relationship qualities (Shomaker & Furman, 2009).

Similar to the previously discussed findings with parents, significant communication and perceptual difficulties appear as one potential explanation for the problematic peer relationships of insecure adolescents. Using the ECR scale, for example, avoidant attachment styles in adolescence have been associated with absolute discrepancies between adolescent and peer perceptions of the adolescent's peer relationships (Ehrlich et al., 2014). In addition, teens with avoidant styles report more negative self-perceptions of peer relationships (even compared to their peers' reports), suggesting a specific negative attentional bias on the part of the avoidant adolescent. At least in part, this bias appears to be linked to difficulties in trying to recall and evaluate past relationship experiences. For example, although adolescents classified as secure and insecure on the AAI did not differ in how they perceived unfamiliar peers initially, attachment-related differences emerged over time. Two weeks after the interaction, insecure adolescents remembered the interactions as less positive and more negative and also recalled being treated with greater hostility than they had initially reported. In contrast, secure adolescents' memories of the negative aspects of the interaction and of hostile treatment remained stable, although, like insecure adolescents, they recalled the conflicts as being less positive than initially reported (Dykas et al., 2012).

These findings are important as a potential explanation of the origin of hostile attributional biases in adolescents. These attributional biases, in which individuals interpret ambiguous behaviors of others as likely to be hostile in nature, have proven to be one of the best explanatory mechanisms identified to date to account for adolescent aggression toward peers (Dodge, 1993). The perceptual and recall bias findings cited earlier—tying together insecurity, perceptual biases, and hostility—suggest that the origin of hostile attributional biases may lie within qualities of attachment relationships and attachment memories. These findings are also consistent with the long-standing finding that hostility, as observed by close friends, is linked to late

adolescents' insecure attachment states of mind (Kobak & Sceery, 1988).

A second mechanism to explain the peer-relational difficulties of insecure adolescents relates to their potential difficulty in handling the intensity of close relationships. Discomfort with attachment-related affect and experiences may lead adolescents with dismissing attachment strategies to push away peers, particularly those who could become close friends (Larose & Bernier, 2001; Spangler & Zimmermann, 1999). Anxious attachment styles assessed via the Measure of Attachment Quality have similarly been related to stronger physiological reactions, in the form of higher blood pressure, to peer interactions and to conflict situations (Gallo & Matthews, 2006). This suggests that one reason insecure adolescents may push away peers who could become close friends is to prevent being overwhelmed by the emotionality engendered by close relationships.

Strong connections have also been found between security and the ability to seek emotional support from a peer (Allen et al., 2007). Linkages between AAI security and adaptive support seeking have even been found when adolescents are asked to interact with unfamiliar peers (Feehey, Cassidy, & Ramos-Marcuse, 2008). The use of unfamiliar peers makes clear that the observed linkages are unlikely to be solely a result either of qualities of current peer interactions influencing attachment or of peer selection effects. In some cases, adaptive support-seeking behavior with peers is more strongly linked with adolescent attachment states of mind than are some of the best markers of maternal and paternal relationship qualities (Allen et al., 2007). This is not necessarily surprising given that mastering the realm of peer relationships may be the single greatest social-developmental challenge faced by most adolescents, and that the nexus of energy in developing attachment behaviors is gradually shifting from parent to peer relations during adolescence.

Individual differences in attachment are also consistently linked to behavior in romantic and sexual relationships in adolescence. Qualities of adolescents' representations of relationships with romantic partners display substantial similarities to representations of relationships with parents and friends (Furman, 2001). Similarly, positive adolescent secure-base scripts from interactions with parents have been linked to romantic attachment styles characterized by less avoidance and anxiety (Dykas, Woodhouse, Cassidy, & Waters, 2006). Notably, both attachment states of mind from the

AAI and attachment representations from the Current Relationship Interview have been found to predict qualities of current romantic relationships, with each of these indices accounting for unique variance in current relationship qualities (Haydon, Collins, Salvatore, Simpson, & Roisman, 2012; Roisman, Madsen, Hennighausen, Sroufe, & Collins, 2001): These constructs are clearly not redundant, but rather are each capturing important aspects of adolescent attachment processes linked to future behavior.

In terms of attachment within romantic relationships, assessments of self-reported insecurity in these relationships has been linked both to greater anxiety among relationship partners and to greater incidence of (but less enjoyment derived from) sexual intercourse (Tracy, Shaver, Albino, & Cooper, 2003). Current social-environmental factors appear to moderate these effects. Adolescents with preoccupied states of mind whose mothers appeared overbearing in interactions were more likely to engage in early sexual activity, whereas preoccupied adolescents whose mothers were less overbearing had strikingly lower rates of early sexual activity (Marsh, McFarland, Allen, McElhaney, & Land, 2003). Similarly, preoccupied females who also had problematic interactions with teachers were at heightened risk of precocious sexual involvement (Kobak, Herres, Gaskins, & Laurenceau, 2012). Of course, in thinking about qualities of romantic relationships, *partners'* attachment organization will also be important to consider because even later in adulthood, only modest evidence of assortative mating with respect to attachment exists (Treboux, Crowell, & Waters, 2004).

Attachment and Adolescent Mental Health

A number of recent studies suggest substantial links between adolescent states of mind and mental health. As described below, both preoccupied and dismissing strategies have been implicated in problems of psychosocial functioning, although the two are associated with somewhat different patterns of problematic functioning. Recently, insecurity in measures of both current attachment styles and qualities of current attachment relationships have also been linked to mental health difficulties.

Adolescents' use of preoccupied strategies has been most closely linked to internalizing prob-

lems, including self-reports of depression, anxiety disorders, internalizing symptoms, and stress during transitions (Bakermans-Kranenburg & Van IJzendoorn, 2009; Bernier et al., 2005; Cole-Detke & Kobak, 1996; Larose & Bernier, 2001). In addition, preoccupied attachment states of mind may interact with a wide array of psychosocial and environmental factors to predict critical outcomes. When preoccupied teens are confronted with intrapsychic states or environments that are confusing or enmeshing, higher levels of internalizing symptoms are found. For example, Adam, Sheldon-Keller, and West (1996) reported that suicidality in adolescence was associated with a combination of preoccupied and unresolved attachment status. Similarly, preoccupied adolescents who had mothers who could not exercise their own autonomy in discussions (i.e., were passive and enmeshed) displayed higher levels of depression (Marsh et al., 2003).

Preoccupied teens also display risk for at least some externalizing behaviors, tending to increase over time in levels of sexual risk-taking and aggressive behavior (Dawson, Allen, Marston, Hafen, & Schad, 2014; Kobak, Zajac, & Smith, 2009). This risk for externalizing behavior also appears to be moderated by social-environmental factors. For example, when preoccupied teens are exposed to positive friendships, they appear at lower risk for delinquent behavior (McElhaney, Immele, Smith, & Allen, 2006). When exposed to effective maternal behavioral control strategies, both preoccupied and secure teens have lower levels of delinquent behavior than do dismissing teens exposed to the same maternal behavior (Allen et al., 1998). In contrast, in unresponsive environments, such as when mothers who display extremely high levels of their own (maternal) autonomy in discussions, perhaps asserting themselves to the point of ignoring their adolescents, preoccupied teens have higher levels of drug use and delinquent behavior over the following year (Marsh et al., 2003).

One potential explanation for this effect in female adolescents may be that an insecure-anxious attachment style is linked to the presence of higher cortisol levels upon awakening and a diminished cortisol awakening response indicative of a degree of dysregulation in physiological stress mediation processes (Oskis, Loveday, Hucklebridge, Thorn, & Clow, 2011). This potential dysregulation, and the need to manage it, may in turn lead preoccupied and anxiously attached adolescents to be particularly sensitive to their social environments. It should be noted, however, that

a hyperactivated attachment system, although clearly problematic, is nonetheless a system that continues to function; in cases where it brings the adolescent into contact with positive social interactions, it appears to at least potentially leave the teen responsive to these as well (Allen et al., 1998).
